Proximity and Coresidence of Adult Children and their Parents: Description and Correlates

Abstract

The ability of family members to engage in intergenerational transfers of hands-on care requires close proximity or coresidence. In this paper we describe and analyze the patterns of proximity and coresidence involving adult children and their mothers using data from the National Survey of Families and Households (NSFH) and the U.S. Census. Although intergenerational coresidence has been declining in the United States, most Americans live within 25 miles of their mothers.

In both the raw data and in regression analyses, the most robust predictor of proximity of adult children to their mothers is education. Individuals are less likely to live near their mothers if they have a college degree. Virtually all previous studies have considered coresidence alone, or else treat coresidence as a limiting case of close proximity. We show that this treatment is misleading. We find substantial differences in the correlates of proximity by gender and marital status, indicating the need to model these categories separately. Other demographic variables such as age, race and ethnicity also affect the probability of coresidence and close proximity, but characteristics indicating a current need for transfers (e.g., disability) are not correlated with close proximity.

1.   Introduction

The need for non-parental childcare has increased with increases in non-marital fertility, divorce, and the labor force participation of mothers; the ability of grandparents to provide such care depends on close proximity or coresidence. The need for long-term care of the disabled elderly may have increased with their increasing life expectancy; the ability of adult children to provide hands-on assistance to their disabled elderly parents depends on close proximity or coresidence. In this paper we describe the patterns of proximity and coresidence involving adult children and their mothers. We then consider the relationship between the current need for intergenerational transfers of care and the distance between adult children and their mothers.

If both parents are alive and living together, the distinction between proximity to mothers and proximity to fathers disappears. If both parents are alive and living apart, we focus on proximity to mothers rather than fathers because mothers are more likely than fathers to provide and to receive hands-on care: grandmothers are more likely than grandfathers to provide care for grandchildren, and elderly mothers are more likely than elderly fathers to receive long-term care from adult children.[1]

Demographers, sociologists, and economists generally focus on migration rather than proximity. Although proximity patterns are the result of migration behavior of adult children and their parents, these behaviors are usually studied separately. Konrad et al. (2002) and, following their lead, Rainer and Siedler (2009), focus on the migration of

---

[1] Because mothers are far more likely than fathers to be the custodial parent (e.g., following divorce), focusing on mothers is better than focusing on fathers. Although we could look at fathers who do not live with mothers, such a project immediately raises the issue of stepfathers and stepmothers. Pezzin, Pollak, and Schone (2008) discuss stepparents, stepchildren and long-term care.

siblings and the resulting patterns of proximity. Konrad et al. develop a model in which older siblings are more likely to move away from their parents to avoid the burden of caring for the parents when they become elderly and disabled. Both of these papers focus on the costs of close proximity, but the adult children may also benefit from child care provision. If adult children benefit from childcare at early stages and elderly parents from long-term care at later stages, the balance of benefits and burdens for adult children who live continuously with or in close proximity to their parents will vary predictably over the life cycle.

If proximity is influenced by the current need for care, we might expect closer proximity when young grandchildren are present and when mothers are older and in poor health. We focus on the need for hands-on care, rather than monetary transfers because intergenerational exchanges involving money require neither close proximity nor coresidence, but exchanges involving hands-on care (e.g., of grandchildren or the disabled elderly) do require close proximity or coresidence.[2] Glaser and Tomassini (2000) attempt to assess the relative importance of long-term care and childcare as motives for proximity in Italy and Britain. They find that in Italy the adult children's characteristics were a more important correlate of intergenerational proximity than parents' characteristics, but in Britain parents' characteristics were more important than those of the adult children.

Most previous studies of proximity have used the elderly parent as the unit of observation and considered the distances between adult children and their parents, using

---

[2] Supervision and monitoring of hands-on care also requires close proximity or coresidence if the individual receiving care is unable to supervise and monitor it (e.g., because of age or cognitive impairment).

the adult child's marital status as a control variable; examples include Glaser and Tomassini (2000), Shelton and Grundy (2000), Rogerson, Burr and Lin (1997), Silverstein (1995), Lin and Rogerson (1995), Clark and Wolf (1992). The appropriate unit of observation depends on the question addressed. When the question involves care of the disabled elderly, the proximity of parents to their closest adult child is of primary importance. Unlike these studies, we focus on the life-cycle pattern of proximity for adult children and, therefore, we use the adult child as the unit of observation.[3] Rogerson, Weng and Lin (1993) also use adult children as the unit of observation. Unlike Rogerson, Weng and Lin, however, we distinguish sharply between coresidence and proximity, between unmarried and married adult children, and for married adult children, between his mother and her mother.

Hands-on care requires close proximity, but not necessarily coresidence. Michael, Fuchs and Scott (1980), Costa (1999), and Ruggles (2007) document the decline in intergenerational coresidence in the United States, although they offer different explanations for its decline. The two earlier studies argue that the decline is primarily the result of the increased affluence of elderly parents who, following the introduction of social security, were able to exercise their preference for independent living. Ruggles disagrees, arguing that the decline in coresidence is the result of the increased affluence of adult children, a consequence of increased wage labor, mass education, and the declining importance of household production. Regardless of the reasons for the decline in coresidence, intergenerational exchanges, to the extent that they take place, are increasingly likely to take place across households rather than within households. A substantial literature has analyzed coresidence, but proximity has not yet received the

---

[3] Choi (2009) uses PSID data to investigate life-cycle patterns of proximity.

attention it deserves.

We say that an adult child lives in "close proximity" to his or her mother if they live within 30 miles of each other *but do not live in the same household.* Thus, in our terminology, coresidence is *not* a special case of "close proximity." This sharp terminological distinction between proximity and coresidence is crucial because proximity and coresidence differ discontinuously in their implications for cost and privacy. Coresidence with one's mother or mother-in-law and living one mile away differ in dimensions that living one mile away and two miles away do not. Using data from the National Survey of Families and Households (NSFH), we find that coresidence of adult children and their parents is associated with different variables than proximity, so neither the theory nor the data support treating coresidence as a limiting case of close proximity.

We treat separately married and unmarried adult children for both theoretical and empirical reasons. Theory suggests that migration and location decisions of married adult children are taken jointly with spouses whose preferred locations may differ from theirs because of career or family considerations. Furthermore, with increasing age at marriage and increasing geographical mobility before marriage (e.g., going away to college), mothers and mothers-in-law are less likely to live near each other.[4] When mothers and mothers-in-law live far apart, a couple's decision to live close to his mother, close to her mother, or close to neither will depend on how each spouse perceives the costs and benefits of proximity. The need to distinguish between married and unmarried

---

[4] According to the National Center for Education Statistics, in 2006, 25 percent of four-year college freshman who had graduated from high school in the past 12 months attended college out-of-state. (http://nces.ed.gov/programs/coe/2008/section1/indicator10.asp#info)

adult children is underscored by our findings about the proximity of women and their mothers. Pooling all adult children and controlling for marital status, we find no impact of gender on proximity or coresidence. When we separate the sample by marital status, however, we find that gender is a strong correlate of coresidence: married women are more likely than married men to live with their mothers, but unmarried women are less likely than unmarried men to live with their mothers.

To investigate the extent to which patterns of intergenerational proximity and coresidence are gendered, we treat separately the distances between a couple and her mother and between a couple and his mother. We see higher levels of time transfers between mothers and daughters than between mothers and sons, suggesting that the relationship between transfers and proximity may differ by gender.

Following a brief description of the data, we discuss the relationship between proximity, coresidence and time transfers. Unsurprisingly, intergenerational time transfers are strongly related to close proximity, and there is a positive relationship between and the disability of parents and coresidence. We next describe proximity patterns in the U.S. focusing on differences in education. Then, using regression analysis, we examine the correlates of coresidence and close proximity between adult children and their mothers. We find that coresidence is more likely when mothers are most likely to need care – when they are older, in poor health and unmarried. But we find the probability of close proximity depends primarily on age and education of the adult child, not the presence of young children or characteristics that might indicate the mothers' need for care. We end with a brief conclusion.

2. Data

We use data from the second wave of the National Survey of Families and Households (NSFH) (Sweet and Bumpass, 1996). The original survey (1987-1988) includes a sample of 13007 households, with an oversampling of blacks, Puerto Ricans, Mexican Americans, single-parent families, families with stepchildren, cohabiting couples, and recently married couples. Wave 2 is a five-year follow-up of the original survey with interviews conducted in 1992-1994.[5] The primary respondent was randomly selected from the adults in the household. Both the primary respondents and their spouses or partners were asked to complete the entire survey. We include cohabiting heterosexual couples in the "married" category.[6] Wave 2 collected information about the parents of both the respondent and the respondent's spouse or partner. Mothers' information includes distance from the respondent, marital status, health status and contact with the respondent. We analyze two sub-samples: all unmarried individuals aged 25 and older whose mothers are **A**live and **L**iving in the **U**nited **S**tates (ALUS) and all couples in which both spouses are aged 25 and older and the mother of at least one spouse is ALUS. Thus, our analysis excludes Americans whose mothers are deceased or live outside the U.S.

---

[5] We use wave 2 rather than wave 1 because it is more recent data. We did not use the data from wave 3 (2002-2004) because the sample for wave 3 was cut drastically and nonrandomly. Sample inclusion required that the respondents had a child over the age of 3 in wave 1 or were 45 years of age and older. Also, spouses were only interviewed for wave 3 if they were present in wave 1 (i.e., if someone married between wave 1 and wave 3, the new spouse was not interviewed.)

[6] Although the NSFH does not include cohabitors in their marital status indicator, they are identifiable and the questionnaire given to cohabiting partners is the same as that given to legally married partners. In our sample, there are 441 cohabiting couples, approximately 10 percent of couples. We ignore same-sex couples because there are only 11 such observations in the data.

3.　　　　**Proximity, Coresidence and Intergenerational Time Transfers**

Before analyzing the correlates of coresidence and proximity, we consider the relationship between intergenerational time transfers and distance. The NSFH provides information on transfers of time between adult children and their parents.[7] For couples, NSFH reports transfers to and from both his parents and her parents. More specifically, NSFH reports time transfers given to or received from "mother," "mother and father," and "father." We refer to the sum of "mother" and "mother and father" as transfers between adult children and their mothers; this sum is the time transfer variable we analyze. For time transfers, the NSFH indicates whether the unmarried child or couple report providing the following categories of help to his mother or her mother in the past month: (1) shopping, errands, transportation; (2) housework, yard work, car repairs, other help around the house; (3) advice, encouragement, moral or emotional support. The NSFH also indicates whether the adult children report receiving help in these three categories from their mothers or mothers-in-law, as well as two additional categories of help received: (4) childcare while working and (5) childcare not while working.

Three patterns of intergenerational transfers are evident from table 4 which shows

---

[7] NSFH asks about transfers between the respondent and individuals not living in the same household. Therefore the sample includes all adult children not currently living with their mothers. The NSFH also includes information about monetary transfers between respondents and their parents. We included these transfers in the analyses but obtained weak and non-robust results. This may in part be due to the survey design. Rrespondents are asked whether they received (or gave) a gift over the amount of $200 at any one time in the past 12 months. Smaller amounts given over the course of the year would not be captured. Also, for monetary transfers we cannot distinguish between gifts coming from mother and those coming from father, because the coding only lists "parents." This is a potential problem for the 10 percent of cases where parents are not living together. We have focused on time transfers, because monetary transfers require neither coresidence nor close proximity.

the percentage of the sample who report giving or receiving help from their mothers.[8] First, and unsurprisingly, time transfers are more likely when mothers and children live in close proximity. Second, the positive correlation between time transfers and close proximity holds not only for transfers that require a physical presence, but also for emotional help. Third, the pattern of transfers is gendered: the incidence of time transfers from and to her mother exceeds that from and to his mother in all categories.[9]

Regression analyses (not shown) indicate that the patterns described above continue to hold when controls are added – time transfers between adult children and their mothers are strongly associated with proximity and with the gender of the adult child.[10] Additionally, adult children benefit from transfers of time when they are younger and have children of their own, and when their mothers are not in poor health. Adult children are more likely to provide time transfers when they are older and when their mothers are in poor health and unmarried.

While the NSFH does not provide comparable information about transfers between those living in the same household, coresidence of an elderly parent with an adult child is often associated with disability. Table 5 presents data from 2000 U.S.

---

[8] In this section we combine married children with both mothers ALUS and married children with one mother ALUS.
[9] This is consistent with the findings of Duflo (2000), who investigated the effect of the South African Old Age Pension that was extended to black South Africans in the early 1990s after the end of apartheid. Duflo found that the well-being of grandchildren, especially granddaughters, was more strongly related to pension payments received by their maternal grandmothers than those received by their paternal grandmothers. Duflo finds that pension payments received by grandfathers had little or no effect on grandchildren.
[10] The regressions are available from the Compton, compton@cc.umanitoba.ca.

Census on the disability characteristics of those aged 65 and over by their living arrangements (Ruggles et al., 2009). The categories are ordered from left to right from the highest average proportion of disability to the lowest. This ordering shows the strong relationship between household organization and disability status. The groups with the highest proportion of disabilities are individuals who do not own or rent their current residence.[11] The individuals in columns (A) and (B) live in institutions; those in columns (C) and (D) live with their adult children in the children's households. Those in columns (E) to (H) have lower levels of disability and are the owners or renters in their own households. Although coresidence is often studied in conjunction with long-term care, with the exception of the unpartnered (e.g., widowed; divorced) disabled elderly, the incidence of coresidence is low. Adult children who live with their parents are also more likely to be disabled than those who do not live with their parents. In 2000, 18.3 percent of women and 20.2 percent of men aged 30-60 whose mothers were not in the same household reported a disability, while 27.7 percent of women and 30.7 percent of men in the same age group whose mothers were in the same household reported a disability.[12],[13]

To summarize: there is a strong relationship between the transfer of general and emotional help and close proximity between adult children and their mothers. Additionally, coresidence is strongly related to the need for intergenerational transfers. In the

---

[11] In prior language, these are individuals who are neither "head" nor "spouse of head" in the household. Beginning in 1980 the census questionnaire no longer referred to a "head of household," specifying instead the designation of "person one"--the first person listed on the census form. This reference person could be any household member in whose name the property was owned or rented.

[12] This includes all U.S. Census respondents who indicated any of the following disabilities: disability that causes difficulty working, difficulty with mobility, personal care limitation, physical difficulty, memory difficulty, and hearing or seeing difficulty

[13] Many adult children who coreside with their elderly mothers have never left home. Using the PSID, Hotz, McGarry, and Wiemers (2008) find that "Even by age 85, 7 percent of widows are living with children who are not observed to have left their parents' household after 1968, and this arrangement constitutes one-fifth of those children living with their parents (p. 17)."

regression analyses that follow, we consider whether the characteristics that indicate a need for time transfers are also correlated with close proximity.

4.   Proximity of Adult Children and their Mothers

Most adult Americans live very close to their mothers. Table 1 provides information on the full distribution of distances from the NSFH. For married couples, the median distance from his mother is 25 miles and the median distance from her mother is 20 miles. Thus, there is a gender effect, with married couples living somewhat closer to her mother than to his. These distances are relatively insensitive to whether we include or exclude coresidence from the sample because few married couples live with her mother or his mother. For unmarried individuals, however, especially for unmarried men, the median distances are quite sensitive to the treatment of coresidence: if we include coresidence (as distance = 0) in the sample, the median distance between unmarried men and their mothers is 5 miles, while if we exclude coresidence, the median distance is 15 miles. For unmarried women, the corresponding medians are 8 miles and 15 miles. Thus, for unmarried individuals, we find a gender difference only when coresidents are included, because coresidents are more likely to be unmarried men.

The probability that individuals live close to their mothers is strongly related to education. Census data provides a first look at this issue. The U.S. Census does not report distance from mother, but it does report the state in which individuals were born. Figure 1 shows the percentage of U.S. born adults living in their birth state in 2000.[14] At age 30, 63 percent of native-born adults reside in their birth state. The proportion living

---

[14] Calculations by authors.

in their birth state ranges from only 52 percent for those with a college degree to 71 percent for those with a high school diploma or less. This 19 percentage point difference between those with a college degree and those with a high school education or less also holds for the elderly. At age 75, 56 percent of U.S. born adults reside in their birth state, 45 percent of those with a college degree and 64 percent of those with a high school education or less. Because interstate migration peaks when individuals are in their mid-20s, this education gap does not close.[15]

The observed relationship between education and proximity is due in part to the fact that couples with more education are less likely to have mothers who live close to each other. Spouses whose mothers live far apart cannot locate near both his mother and her mother. Spouses' resolution of this marital co-location problem has implications for childcare, for long-term care of the disabled elderly, and for married women's labor force participation.

In 2000, 59 percent of all married couples aged 25 and older consisted of spouses born in the same state (table 2, top panel). This proportion differs with education. For "power couples" -- couples in which both spouses hold a college degree -- only 46 percent were born in the same state. (We borrow the "power couples" terminology from Costa and Kahn (2000).) For low-power couples – couples in which neither spouse holds a college degree – 64 percent were born in the same state.[16] These figures have remained

---

[15] Boyd et al. (2005) analyse the location decisions of teachers in New York State. They conclude: "In seeking their first teaching jobs, prospective teachers appear to search very close to their hometowns and in regions that are similar to those where they grew up. Location of college plays an independent, although less important, role in teachers' employment location decisions. These conclusions are supported by descriptive statistics and our estimated behavioral model. Moreover, these results are robust to several alternative specifications (p. 127)."

[16] For part-power couples in which only the husband has a college degree, 54 percent were born in the same state; for part-power couples in which only the wife has a college degree 57 percent were born in the same state.

fairly constant from 1980 through 2000, while the proportion of power couples in the census population has increased from 9 percent in 1980 to almost 17 percent in 2000. If these trends in education and marriage continue, the percentage of couples in which both spouses were born in the same state will continue to decline.

Census data also show that the probability that a couple lives in the birth state of one or both spouses declines with education (table 3, top panel). In 2000, 53 percent of low-power couples lived in the birth state of both spouses, compared with only 33 percent of power couples. These numbers are almost unchanged from the previous decade.[17]

Throughout this paper, we say that adult children live "in close proximity to" or "close to" their mothers if they live within 30 miles of their mothers but do not coreside with them. We say that adult children who live more than 30 miles from their mothers live "far from" her.[18] Although the variables in NSFH and the census are not identical, the two datasets tell similar stories. The bottom panel of table 3 shows the proximity of married couples with various levels of education to his mother and to her mother. In NSFH we find that only 18 percent of power couples live close to both mothers, while 50 percent of low-power couples live close to both mothers. At the opposite extreme, almost half of power couples live far from both mothers, while only one-fifth of low-power

---

[17] The census data show some evidence of a gender effect: while an equal percentage of couples live in her and in his birth state, for part-power couples the proportions living in the birth state of both or neither depends on which spouse has the college degree. Among couples in which only the husband has a college degree, 39 percent live in the birth state of both spouses while 36 percent live in the birth state of neither spouse. Among couples in which only the wife has a college degree, 47 percent live in the birth state of both spouses while only 26 percent live in the birth state of neither spouse.

[18] Other studies use similar cut-offs for distance. Robustness tests around this cut-off yielded similar results. A number of studies use temporal rather than distance measures; in the appendix we describe the variables used in other studies. We include county level measures of density, size of place, and commuting time to control for differences in travel time.

couples live far from both mothers.[19]

The regression results in the following sections confirm the robust negative association between education, on the one hand, and close proximity and coresidence, on the other.

5.   Proximity and Coresidence

Proximity and coresidence differ qualitatively.   If distance were the only relevant metric, then coresidence (distance = 0) would be the limiting case of proximity. But distance is not the only relevant metric. For both adult children and elderly parents, living in the same household and living next door differ qualitatively because of their implications for cost and for privacy. Hence, we should expect to find that the correlates of coresidence differ from the correlates of close proximity. Recent empirical work, however, has often imposed on the data statistical models that require the correlates of close proximity to be the same as the correlates of coresidence. We summarize the recent literature on the proximity between adult children and their parents in appendix 1. A number of papers, for example, Konrad et al. (2002), Rainer and Siedler (2009), employ ordinal limited dependent variables models. Other papers, for example, Rainer and Siedler (2009), and Silverstein (1995), use Tobit models with coresidence as the limiting case. Still others, such as Clark and Wolf (1992), Rainer and Siedler (2009), Shelton and Grundy (2000), combine the categories of coresidence and close proximity when using grouped data. Lin and Rogerson (1995) and Rogerson, Weng and Lin (1993) exclude

---

[19] There is little evidence of any gender effect for high-power couples and part-power couples in which the husband has a college degree, but low-power couples and part-power couples in which the wife has a college degree are much more likely to live near her mother than near his.

coresidents from their sample, creating a sample selection issue that compromises the interpretation of their results. Rogerson, Burr and Lin (1997) use multinomial logit models to assess the correlates of convergence and divergence in proximity. Only Glaser and Tomassini (2000) use the multinomial logit to model the correlates of proximity and coresidence, and they do not test the multinomial logit against alternative specifications.

Our descriptive regressions confirm the need to treat separately coresidence and close proximity rather than treat coresidence as a limiting case of proximity. Tobit and logit treat coresidence as a limiting case of proximity, while the multinomial logit does not. Table 6 presents the results of regressions on proximity and coresidence for the full sample, including both married and unmarried adult children. Column (A) shows the coefficients from a Tobit regression in which the dependent variable is distance from mother, treating coresidence as the limiting case of proximity. Column (B) presents the results from a logit regression in which the dependent variable equals one if the individual coresides with, or lives in close proximity (i.e., within thirty miles) to, his or her mother. We present the logit coefficients as odds ratios. Column (C) presents the results from a multinomial logit regression, our preferred specification, in which the dependent variable includes three alternatives: to coreside, to live close to, or to live far from.

The coefficients on education, age, gender and siblings tell a consistent story. Adult children with college degrees are much less likely to live with or near their mothers. Younger adult children are more likely, and older adult children are less likely, to live with or near their mothers. Gender has no impact on proximity or coresidence. Finally, compared to second-born or higher order children, only children are more likely

to live with their mothers or close to them. There are, however, a number of differences across columns.

Consider ethnicity and race. For Hispanics, different regressions suggest different patterns. From the Tobit results alone, we would conclude that Hispanics live farther from their mothers. From the logit results alone, we would conclude that the Hispanic ethnicity has no significant effect (i.e., is the same as white, the omitted category). The multinomial logit, which imposes fewer *a priori* restrictions, shows that, compared with whites, Hispanics are no more likely to live in close proximity to their mothers, but twice as likely to live with their mothers. Unlike Hispanics, for blacks the three regressions tell very similar stories. Blacks are more likely to live near their mothers and more likely to live with their mothers.

The multinomial logit also provides a more nuanced view of the effect of marital status. From the Tobit results alone, we would conclude that, compared with never married adult children, both married and previously married children live farther from their mothers. The multinomial logit shows that this conclusion rests solely on the lower incidence of coresidence among married and previously married adult children and not on proximity. Finally, unlike Konrad et al. (2002) who find that first born children are less likely than second born children to live close to their parents, our multinomial logit results suggest that first born children are slightly more likely than later born children to live close to their mothers. This conclusion is not evident from the Tobit or the logit results.[20]

For mothers' characteristics, the multinomial logit again paints a more nuanced

---

[20] Our findings are consistent with those of Rainer and Siedler (2009) who find a sibling effect (only children live closer to their mothers, on average) but no birth order effect.

picture. The Tobit results would lead us to conclude that only the marital status of mothers predicts distance. The multinomial logit shows that adult children are less likely to live close to mothers with college degrees, less likely to live with mothers in poor health, and more likely to live with mothers 75 years of age and over.

The empirical results of this section confirm the superiority of the multinomial logit specification. The Tobit and logit specifications constrain regressors (e.g., Hispanic ethnicity; marital status of the mother) to affect moving out and moving away in the same direction, but the data are not consistent with this *a priori* restriction. Because the multinomial logit does not impose this restriction, it provides a better description the patterns in the data.

6.   Proximity of Adult Children to their Mothers

Tables 7a and 7b presents the results of multinomial logit regressions that model whether adult children live with, close to, or far from their mothers. These regressions are similar to column (C) in table 6, but here we run them separately by gender and marital status. To facilitate comparisons with previous studies, we omit spousal characteristics in section 6.1 and introduce them in section 6.2.

6.1   Individual regressions

Educational attainment is the most consistent correlate of close proximity of the adult children to their mothers. Adult children with college degrees are much less likely to live near or with their mothers. The effect is stronger for men, especially unmarried men. This may be true for at least four reasons. First, young adults may leave home to

attend college and not return. Second, as shown in section 4, college educated couples are less likely to come from the same state; without a common homestate, they are more likely to live far from both mothers. Third, the college educated may participate in a geographically wider labor market and, therefore, more likely to move away for employment. Fourth, if college educated adult children are more successful in employment and earnings, time transfers to and from mothers may be less important to them.

Controlling for children's education, respondents are also less likely to live near their mothers if their mothers have a college degree. There are at least three possible explanations for this correlation. First, mothers with college degrees are more likely to live away from their own families of origin and this may affect the location decisions of their adult children. This may operate through a demonstration effect or by weakening the adult child's incentive to remain because there are fewer extended family members in close proximity. Second, mothers with more education may be better able to afford market substitutes for hands-on care by their adult children. Third, the mother's education may affect the children's location decisions if it affects the mother's value of time and, hence, her willingness to provide childcare. When we split the sample by gender, we find that the effect of mother's education is significant only for daughters, suggesting that the demonstration effect and/or the possibility of childcare may be most important.

Because gender and marital status interact, we present the results separately by gender and marital status. Although gender does not influence the probability of living in close proximity to one's mother, it does affect the probability of coresidence. Unmarried adult men are more likely than unmarried adult women to coreside with their mothers.

Married adult women are more likely than married adult men to coreside with their mothers, but this gender effect is unimportance because married adult children are very unlikely to coreside with a parent.

The age of the adult child is also an important and robust correlate of both proximity and coresidence. Regardless of marital status, younger adult children (aged 24-34) are more likely to live near and, for the unmarried, more likely to live with their mothers, compared with the base group (children aged 35-44). Children in the older age category (ages 45 and older) are less likely to live with and near their mothers, although this result is not always significant.

The regressions also show patterns by race and ethnicity. Compared with their white counterparts, blacks are more likely to live with and near their mothers. Hispanics are more likely to live with their mothers, but are no more likely to live near them. In terms of coresidence the higher probability of coresidence for both blacks and Hispanics is driven by higher coefficients for unmarried men and married women.

Our results confirm the negative effect of siblings on proximity. Only children are more likely to live closer to and with their mothers. This effect is stronger for women than for men; indeed, the results are not statistically significant for single men living near their mothers, nor for married men living either near or with their mothers. In contrast to Konrad et al. (2002), we do not find evidence that first-born children are less likely to live close to their mothers.[21]

We find no evidence that close proximity or coresidence is correlated with the presence of young children. Respondents with young children are not more likely to live

---

[21] In fact, we find that unmarried women who are first-born children are more likely to live in close proximity to their mothers.

in close proximity to their mothers, and unmarried respondents with children are less likely to live with their mothers.

Although unmarried mothers are more likely to reside in close proximity to their adult children, most other mothers' characteristics that would suggest a greater need for intergenerational transfers are not related to close proximity.[22] Coresidence is more strongly related to mothers characteristics, with a strong gender pattern: women, both married and unmarried, are more likely to live with older mothers (aged 75 and over); married men are less likely to live near older mothers and unmarried men, the group most likely to live with their mothers, are less likely to live with mothers in poor health.

6.2   Couples regressions

In table 8, we add spousal characteristics to the regressors in table 7. We restrict the sample to couples in which both mothers are alive and living in the United States (ALUS).

The strong results again come from the age and education. Proximity declines as the age of the adult children increases.[23] Education has a strong effect on proximity. Couples in which one or both spouses have a college degree are less likely to live in close

---

[22] We ran similar regressions on the sample of respondents whose mothers and fathers were both alive, living in the U.S. and married to each other. The results were similar to the full sample results.

[23] With one exception: both younger and older couples are more likely to live with her mother than the comparison group (i.e., the middle group, adult children aged 35-44). Couples with children are slightly more likely to live near his mother, although the variable is not significant at conventional levels. The presence of children increases the probability that couples live with her mother, but very few married couples coreside with either his mother or her mother. Neither the presence of siblings nor birth order was significantly related to coresidence or close proximity in the couples' regressions.

proximity to their mothers. This result is weaker if only the wife has a college degree.[24]

We now turn to the coefficients on the mothers' characteristics. Mothers' education lowers the probability of close proximity, but this is again only significant for proximity with her mother. None of the mothers' characteristics indicating need of care -- poor health, old age (75 and over), and marital status -- are correlated with proximity. Coresidence is not correlated with mothers' health, but is positively related to old age, and marital status[25]

Finally, the regression results show that when both mothers are ALUS and live in close proximity to each other, the adult children are likely to live in close proximity to them. Couples are more than three times more likely to live near her mother if they live near his mother and vice versa.   This may reflect the strong pull factor of having both families in one location, but may also reflect differences in the propensity to migrate. If individuals from different locations meet and marry, one of them is likely to have migrated prior to their meeting. Hence, the couple is likely to have a greater than average propensity to migrate again.

7.   Conclusion

In this paper, we have examined the patterns of proximity and coresidence of adult children and their mothers in the U.S. We find that Americans live surprising close to their mothers. For married couples for which both mothers are alive and living in the

---

[24] This is consistent with Compton and Pollak (2007) in which we find that the effect of college education on couples' migration behavior is largely a male effect. Power couples and couples in which only the husband has a college degree are more likely to migrate compared with low-power couples and couples in which only the wife has a college degree.

[25] Indeed, the coefficients on marital status indicate that couples are more likely to live with her (his) mother if her (his) mother is not married. There is also a cross effect. Couples are less likely to live with her (his) mother if his (her) mother is not married.

United States, the median distance to his parents is 25 miles and the median distance to her parents is 20 miles. Virtually all previous studies of proximity have treated coresidence as a limiting case of close proximity. This treatment is misleading. We find substantial differences in the correlates of proximity by gender and marital status. We find that the multinomial logit describes the data far better than the logit or the probit, both of which implicitly treat coresidence as a limiting case of close proximity. After showing the need to treat coresidence and close proximity separately, we find that the strongest correlates of proximity are age and education, with older and more highlyeducated men and women less likely to live near their mothers. Overall, coresidence of mothers and daughters may be influenced by the mothers' need for care, while close proximity is not. In contrast, coresidence and, in some cases, proximity of mothers and sons is less likely when mothers are older and in poor health.

NSFH Sample Wave 2. Includes all married (and partnered) adult children aged 25 and older. Coefficients are presented as relative risk ratios. P-values are in parentheses. Other control variables included are Region (South, Midwest, West, East (base case)), MSA indicator and, average commute time in MSA.

NSFH Sample Wave 2. Includes all married (and partnered) adult children aged 25 and older. Coefficients are presented as relative risk ratios. P-values are in parentheses. Other control variables included are only child and first-born child status for both spouses, Region (South, Midwest, West, East (base case)), MSA indicator, average commute time in MSA or county, relationship variables (Good, Poor, Average (base)).

Appendix 1: Summary of Selected Proximity Literature

	Survey; Unit of Analysis	Distance Variable	Primary Analysis	Regression Technique	Results
Clark and Wolf (1992)	National Survey of Families and Households (NSFH) Wave 1 (1987); Parent, parent-child pairs.	Grouped Distance(co-residence combined with less than or equal to 10 miles to define "Near")	Probability that elderly respondent has at least one child near; Probability that child (for each parent-child pair) lives near respondent.	Logistic Regressions	Older parents with more resources (youth, more education, living spouse) are less likely to have a child living within 10 miles. Elderly more likely to live near a child who has children than one who does not.
Glaser and Tomassini (2000)	British Retirement Survey (1994) and the Italian Indagine Multipscopo sulle Famiglie (1995); Mothers	Grouped Distance (coresidence, less than 10 miles, greater than 10 miles)	Mothers Proximity to her closest child;	Multi-nomial logit	Proximity in Britain more likely to arise from the needs of the older generation; In Italy, proximity may be more linked to culture than need.
Konrad et al (2002)	German Aging Survey (1996) Children of Respondent, respondents with one or two living children.	Grouped descriptive distances[26]	Distance between each sibling or only child and mother.	Ordinal logistic model	Elder siblings live farther than only siblings.
Lin and Rogerson (1995)	National Survey of Families and Households (NSFH) Wave 1 (1987); Parent	Natural logarithm of distances (miles) to closest and second closest child; excludes co-residents.	Factors affecting distance to closest child and second closest child.	OLG, truncated OLG for distance to second closest child.	Health and disability of parent have little effect on proximity; gender is not a factor, except for widowed mothers; older children live farther away.

---

[26] The grouped distances in Konrad et al (2002) are coresidence, in the neighborhood, in the same urban community, in a different community, but less than two hours travel time away, further away.

Appendix 1: Summary of Selected Proximity Literature

	Survey; Unit of Analysis	Distance Variable	Primary Analysis	Regression Technique	Results
Rainer and Siedler (Forthcoming)	German Socio-Economic Panel Study (GSOEP); families; children from one and two-child families and their parents. National Survey of Families and Households (NSFH) Wave 1 (1987); adult children.	Grouped descriptive distances (GSOEP)[27] Distance in Miles (NSFH)	Determinants of Child-Parent Geographic Distance. Focus on differences between siblings and only children.	Ordered Probit (GSOEP); Tobit (NSFH)	Children with siblings live farther away than only children. Impact seen only for areas of high unemployment.
Rogerson Weng and Lin (1993)	National Survey of Families and Households (NSFH) Wave 1 (1987); Children 16 years of age and older.	Natural logarithm of distance (miles). Co-residence excluded.	Distance between children and parents; separates parents by living arrangements[28].	OLS	Proximity most related to region, mobility history, education and age. Less important are siblings and living arrangement of parents.
Rogerson, Burr and Lin (1997)	National Survey of Families and Households (NSFH) Waves 1 and 2 (1987, 1993); Parents (aged 60 and over)	Distance in miles (top-coded at 300 miles);	Changes in proximity between respondent and their closest child (not necessarily the same child in both waves)	Multinomial Logit (Convergence, Divergence, No Change); Convergence then modelled separately as living independently and living dependently.	Convergence is positively related to an increase in parents' need for care. Widowhood increases likelihood of coresidence but not convergence without coresidence.

---

[27] Rainer and Siedler grouped distances for the GSOEP: whether the child lives (a) in the same household, house or neighbourhood; (b) in the same town, but more than 15 minutes walk away ; (c) in a different town, but less than one hour of travel time away; and (d) further away.

[28] Rogerson, Weng and Lin (1993) analyze separately the distance to mother and father, based on their living arrangements – parents alive and living apart, mother only alive, father only alive and both parents alive and living together.

Appendix 1: Summary of Selected Proximity Literature

	Survey; Unit of Analysis	Distance Variable	Primary Analysis	Regression Technique	Results
Silverstein (1995)	Longitudinal Study on Aging (LSOA) 1984, 1988; parents (aged 70 and over) with at least one surviving child.	Time: How quickly can the nearest child get to your house/apartment Natural logarithm of time in minutes. Coresidents included as 0 minutes.	Determinants of temporal convergence and divergence	Two-stage model: logistic regression to predict whether convergence occurs, and OLS (or Tobit) to predict size of convergence. Similarly for divergence, size of divergence.	Marital status of parents increases only the size of the convergence, not the likelihood that it will occur. Unmarried elders also tend to diverge farthest from their children.
Shelton and Grundy (2000)	British Social Attitudes Survey (BSAS) 1986, 1995; Adult children aged 18-54..	Time: About how long does it usually take to get door to door. Categories: up to half an hour (includes coresidents), between half an hour and an hour, and an hour or more.	Changes in co-residence patterns and characteristics associated with variations in proximity.	(1) Multinomial logit on three categories. Proximity to mother and father modelled separately; (2) excludes coresident children.	Siblings live farther away. Little change between 1986 and 1995.
