Abbreviations: FA, Fanconi anemia; HNSCC, head and neck squamous cell carcinoma.

Precis: Patients with Fanconi's Anemia (FA) are at increased risk of head and neck squamous cell carcinoma (HNSCC), but the prevalence of undiagnosed FA patients with HNSCC is unknown. Targeted germline sequencing of 417 patients with HNSCC identified several known FA variant mutations and several novel FA mutations; although no patients with HNSCC were found to have clinical signs of FA, FA mutations in HNSCC may explain a potential mechanism for tumorigenesis.

ABSTRACT

Background: Patients with Fanconi anemia (FA) have increased risk for head and neck squamous cell carcinoma (HNSCC). We sought to determine the prevalence of undiagnosed FA and FA carriers in patients with HNSCC and an age cutoff for FA genetic screening.

Methods: Germline DNA from 417 HNSCC patients under age 50 was screened for sequence variants by targeted next-gen sequencing of the entire length of 16 FA genes.

Results: The sequence revealed 194 FA gene variants in 185 patients (44%). The variant spectrum was comprised of 183 nonsynonymous point mutations, nine indels, one large deletion, and one synonymous variant predicted to effect splicing. 108 patients (26%) had at least one rare variant predicted to be damaging, and 57 (14%) had at least one rare variant predicted to be damaging and previously reported. Fifteen patients carried two rare variants, or an X-linked variant, in an FA gene. Overall, we did not identify an age cutoff for FA screening among young HNSCC patients, as there were no significant differences in mutation rates when patients were stratified by age, tumor site, ethnicity, smoking status, or human papillomavirus status. However, we observed an increased burden, or mutation load, of FA gene variants in FANCD2, FANCE, and FANCL in our HNSCC patient cohort relative to the 1000 Genomes population.

Conclusions: FA germline functional variants offer a novel area of study in HNSCC Tumorigenesis. FANCE and FANCL, components of the core complex, are known to be responsible for the recruitment and ubiquitination, respectively, of FANCD2, a critical step in the FA DNA repair pathway. The increased mutation load of FANCD2, FANCE, and FANCL variants in our younger HNSCC patient cohort indicates the importance of the FA pathway in HNSCC.

Keywords: Fanconi Anemia, Recessive inherited disorders, Head and Neck Cancers, Squamous Cell Carcinoma, Germline Variations

INTRODUCTION

Fanconi anemia (FA) is a rare, predominantly recessive inherited disorder with an incidence of 1 in 130,000 births and a carrier rate estimated to be 0.6% (1,2). Genetically, FA is a heterogeneous disease with 21 causative genes known so far, as five new genes were added within the past year (3,4). Phenotypically, FA is associated with congenital defects (short stature, renal defects, café au lait spots, microphthalmia, hearing difficulties and abnormal thumb or radii) and progressive bone marrow failure. In addition to the congenital anomalies, and the inevitable bone marrow failure, FA patients are at increased risk of acute myelogenous leukemia and head and neck squamous cell carcinoma (HNSCC) (5,6). However, 30% of patients fail to display the FA congenital defects (7,8), and up to 25% present with solid or hematological malignancies as the first sign of the condition (9). In many such instances, FA diagnosis is prompted after encountering severe toxicities upon initiating chemotherapy or radiation therapy to treat the malignancy (10). The pathogenesis is based on the fact that the normal function of FA genes is related to DNA repair and genome stability; bi-allelic mutations of these genes confer a 0.7-2% annual risk of cancer (5,9,11), and some, including *FANCD1* (*BRCA2*) and *FANCN* (*PALB2*), are closely associated with solid organ malignancies (12-14)

Head and neck squamous cell carcinoma is traditionally related to tobacco and alcohol consumption and recently associated with human papillomavirus; the risk is a 10 to 15-fold increase compared to those without these exposures (15,16). However, FA confers a 500-700-fold increased risk of HNSCC compared to the normal population (9,17,18). The median age of HNSCC onset in FA patients is 33 years compared to 60 years in traditional HNSCC patients; thus FA patients develop HNSCC at a significantly younger age than sporadic HNSCC (19).

Younger HNSCC patients have reduced DNA repair capacity but the prevalence of FA mutations in HNSCC patients remains unknown (20). Given 30% of patients with FA mutations do not display the congenital stigmata of FA, we sought to determine: 1) the prevalence of undiagnosed FA among HNSCC patients younger than 50 years, 2) an age cutoff for FA

screening among younger HNSCC patients, and 3) the prevalence of FA carriers (heterozygote germline mutations) among younger HNSCC patients.

METHODS

DNA extraction

DNA was isolated from blood using the Puregene kit and DNeasy blood and tissue DNA extraction kit (Qiagen), and subjected to phenol/chloroform extraction and ethanol precipitation.

Samples for sequencing

Six hundred forty-seven HNSCC patients younger than 50 years were enrolled in a prospective molecular epidemiologic study of newly diagnosed HNSCC that included completion of a prospective standardized epidemiologic questionnaire and blood draw. Patients with cancer (including known FA) prior to HNSCC diagnosis were excluded. The Institutional Review Board of the University of Texas MD Anderson Cancer Center approved this study, and all patients gave informed consent.

Of the 617 patients initially enrolled for the study (Supplemental Figure 1), DNA was available from 468 patients. DNA from 417/468 patients was of sufficient quality and quantity required for the targeted capturing and sequencing approach. Thus, DNA from 417 patients was sequenced. There is no difference between the sequenced group (417 patients) and the non-sequenced group (230 patients) in terms of age, gender, ethnicity, smoking, and alcohol drinking (Supplemental Table 1). There was a higher proportion of Larynx/Hypopharynx among those excluded and a higher proportion of Oral cavity in those included.

Targeted Next-Gen Sequencing

The genomic regions representing the entire length of 16 FA genes were targeted for capturing and sequencing (Supplemental Table 2). The exceptions were the exon 1 regions of *FANCA*, *FANCB*, and *FANCE*, which were not covered by the sequencing approach. Excessive repeat sequences prevented the successful design of probes for exon 1 of FANCA. Probes were

designed for the *FANCB* and *FANCE* exon 1 regions but did not yield product. The targeted Truseq (Illumina) capturing design, capture, and sequencing were done as previously described (21).

Variant calling and filtering

Novoalign (http://www.novocraft.com/products/novoalign/) was used for sequence alignment. The MPG ("Most Probably Genotype") genotype caller (https://research.nhgri.nih.gov/software/bam2mpg/; NHGRI Genome Technology Branch) was used to call variants, and SnpEff (22) was used to filter the high quality functional variants based on the following criteria: quality score ≥ 20, read depth ≥10, nonsense, missense, indel, splicing (+/- 2bp). The extracted functional variants were subsequently annotated and filtered using a population-specific maximum frequency, where applicable, of .5% in each of the 1000 Genomes (2,504 individuals), the NHLBI-ESP6500 (6,503 individuals), and the ExAC-nonTCGA (60,706 individuals) variant databases. The allele frequency threshold of .5% is derived from the FA carrier frequency of 1:181(2). All coordinates are in accord with human genome build 19.

Predicted damaging variants

To predict the functional consequence of a variant, we compared the results from five prediction algorithms: Sift (http://sift.jcvi.org), Polyphen-2 (http://genetics.bwh.harvard.edu/pph2), MutationTaster (http://www.mutationtaster.org/), CADD (http://cadd.gs.washington.edu), and GERP++ (http://mendel.stanford.edu/SidowLab/downloads/gerp/). We used a minimum threshold of 20 for Phred-scaled CADD scores, representing the 1% most damaging variants in the genome, and a minimum threshold of 2 for GERP++ RS scores. GERP++ was included to highlight constrained sites. Annovar (23) was used to annotate the variants with the results from all five prediction algorithms. For consideration as "Damaging", at least 4 of the 5 algorithms had to meet their specified threshold. "Benign" variants did not meet the threshold in at least 4 of the 5 algorithms. Variants lacking consensus between at least 4 algorithms were labeled as "Indeterminate" (Figure 1, Supplemental Table 3)

Previously reported variants

The following databases were used to identify previously reported variants: The Leiden Open Variation Database (LOVD) for Fanconi anemia (http://www.rockefeller.edu/fanconi/) ClinVar NCBI database (http://www.ncbi.nlm.nih.gov/clinvar/), and BIC (Breast Cancer Information Core).

Synonymous variants

Synonymous variants with quality score ≥ 20 and a read depth ≥ 10 were analyzed using SILVA-v1.1.1 (24). Variants determined to be "potentially pathogenic" by SILVA were further analyzed by NetGene2 (25) to predict splicing effects.

SNP array analysis

The patient DNA samples were run on the Illumina HumanExome Bead Chip, containing ~250,000 SNPs. The data were processed using GenomeStudio (Illumina, Inc.), and CNVs were detected using cnvPartition v3.2 (Illumina, Inc.) and Nexus v7.5 (BioDiscovery, Inc.).

Statistical analysis of mutation load

The Mann-Whitney-WIlcoxon non-parametric statistical test was used to evaluate the burden or mutation load of FA gene variants in the HNSCC patient cohort compared to the 1000 Genomes dataset. Given the HNSCC cohort was comprised predominantly of patients with Caucasian ethnicity (Table 1A), the statistical test was performed using data from the 356 Caucasian HNSCC patients and the 503 EUR 1000 Genomes individuals to create a more homogenous comparison group. We obtained the nonsynonymous and indel variant alleles from each set and implemented the test in R (26).

Low frequency variants

LoFreq (27) was implemented to call low frequency variants occurring between 5 – 40 percent with a genotype quality > 500.

RESULTS

Of the 417 patients with DNA available for sequencing, 88 (21%) were younger than 40 (a traditionally accepted definition of "young" for a patient with HNSCC), 108 (26%) were 40-44, and 221 (53%) were 45-49 years of age. Tumor site was oral cavity in 149 (36%), oropharynx in 230 (55%) and larynx in 38 (9%). The cohort was comprised of four different ethnic populations, 356 (85%) are Caucasian, 40 (10%) are Hispanic, 14 (3%) are Asian, and 7 (2%) are African American (Table 1A).

No patient in the cohort had a known diagnosis of FA, and there were very few with any potential signs of a FA phenotype. Classic phenotypes of FA were then evaluated in the cohort. Seventeen patients (4%) had a first-degree relative with a hematologic malignancy, 25 (6%) had short stature (<fifth percentile), and eight (2%) had macrocytic anemia and/or leukopenia, and among the patients who received chemotherapy, there were no grade IV toxic effects.

Germline DNA targeted capturing and next-gen sequencing of 16 FA genes revealed 11,968 initial variants. The targeted region for capturing and sequencing included the entire gene. The post sequence coverage of high quality sequence, particularly for the entire coding region of 56,120 bp, was 100% for all genes except for a total of 287 bp from the exon 1 of *FANCA*, *FANCB* and *FANCE*, with a depth of coverage around 240 reads at each base (Supplemental Table 2) (21).

Among the 11,968 initial called variants, there were 137 synonymous variants and 358 functional variants (nonsense, missense, indel, or splicing) (Figure 1). Using a population-specific variant frequency threshold of ≤ .5% in each of 1000 Genomes, NHLBI-ESP6500, and ExAC databases, the subset of functional variants was further reduced to 192 (183 SNVs and 9 indels). Functional prediction algorithms (SIFT, PolyPhen, MutationTaster, CADD, and GERP++) analyzed the 183 rare SNVs to identify which may be likely to induce deleterious functional consequences and which are likely benign. Assignment of a definitive prediction to a particular variant was dependent on at least four of the five algorithms reaching a consensus. If

a consensus was not met between at least 4 algorithms, the prediction was classified as indeterminate, and labeled as such. 80 rare SNVs were predicted to be damaging and 64 were predicted to be benign, while 39 were indeterminate. The 9 indels were presumed to be deleterious by the nature of the variant. Splicing prediction algorithms (SILVA and NetGene2) analyzed the 137 synonymous variants and identified 1 variant as likely pathogenic by creating a new donor site.

The 193 resulting variants (184 SNVs and 9 indels) were compared to variants that had been previously reported to the LOVD Fanconi anemia disease database, BIC (Breast Cancer Information Core), and/or listed in ClinVar. Forty-four percent (85/193) of variants had been previously reported in at least one of the three databases, but only 5/85 were listed, specifically, as pathogenic, while the rest were listed as either benign or uncertain significance. Variants in *BRCA2* (36) and *PALB2* (9) comprised 52% (45/85) of the reported variants. In addition to the 85 reported variants, our cohort carried 71 variants that were unreported but present at a frequency below .5% in the public databases, and 38 completely novel variants.

In addition to high throughput sequencing of the 16 FA genes, genotype data was collected by SNP array, from Illumina's HumanExome BeadChip, for all 417 HNSCC patients. Copy number analysis revealed a ~154kb heterozygous deletion of *SLX4*, spanning the entire gene, in a HNSCC patient. This patient also carried a *SLX4* missense mutation that was predicted to be damaging (Table 2).

We also implemented LoFreq to call low frequency variants occurring between 5%-40% with a quality score greater than 500 and a minor allele frequency less than .5% in public databases. It is known that revertant mosaicism in Fanconi anemia may result in the loss of a variant, or a variant being present to a lower extent, and in such cases cancer may precede the diagnosis of FA (28). However, our search for low frequency variants did not yield any potential candidates.

Of the 417 patients, 185 (44%) carried at least one rare variant (Table 1B). The 185 patients carried 194 variations (192 rare variants, a large deletion, and a synonymous variant that was predicted to affect splicing). A rare variant was observed in 42%-55% of patients from Caucasian, Hispanic, and African American ancestry, whereas 79% (11/14) of Asian patients carried a variant. A rare variant was seen in a similar proportion of patients irrespective of tumor site, Larynx (42%), Oral Cavity (44%) or Oropharynx (45%), or age group, < 40 (40%), 40-44 (49%), or 45-49 (44%) years (Table 1B,1D). The proportion of patients carrying rare predicted damaging variants was also similar irrespective of tumor site, 25%-28%, or age group, 24%-28% (Table 1C-D).

Fifteen patients (4%) had either two rare FA variants in the same FA gene or an X-linked variant of FA (Table 2). Among these 15 patients, the median age was 45 years (only 2 were <40 years), 10 (67%) had oropharyngeal primary tumors, 8 (47%) were never smokers, 2 (13%) had a first-degree relative with a hematologic malignancy, 5 (33%) had short stature (<fifth percentile), and 3 (20%) had macrocytic anemia and/or leukopenia. Relative to the entire cohort, there were no differences in age, sex, smoking status, tumor site, or human papillomavirus status between patients carrying two rare variants in the same FA gene or an X-linked FA variant or not. Of the 15 patients with two rare variants, or an X-linked variant, six carried variants that had been previously documented in either the FA mutation database, ClinVar, or BIC.

Thirty-nine patients carried a rare variant in two or more different FA genes (Supplemental Table 4). When comparing age at presentation of patients with and without multiple variants, there was no difference in age, sex, smoking, alcohol use, or HPV status.

The 194 germline variations were comprised of 176 missense, 9 indels, 6 nonsense (including one stoploss), 2 splicing (including one synonymous), and 1 large deletion (Figure 2,

Supplemental Table 3). These variants amounted to 255 occurrences throughout the HNSCC cohort (Table 3). *BRCA2*, *FANCP*, *FANCM*, *FANCA,* and *FANCI* were the most common genes to carry rare variants (21% (54/255), 14% (36/255), 11% (27/255), 9% (22/255), and 8% (20/255), respectively). Twenty-six percent of patients (108/417) carried 91 FA rare variants predicted to be damaging, where *BRCA2* had the highest proportion of occurrences at 10% (25/255), and *SLX4, FANCI, FANCM*, *FANCQ*, each accounted for 5% (12-14/255). Fourteen percent of patients (57/417) had rare variants predicted to be damaging and previously reported. *BRCA2* with 10% (25/255), and *SLX4* and *FANCQ* each with 3% (7-8/255) are the top three most prevalent carriers. Detailed characterization of each of the 194 rare variants is presented in Supplemental Table 3.

Table 4 presents the incidence of rare variants, by FA gene, among the HNSCC cohort, segregated by tumor site, ethnicity, and age group. There were no significant differences in mutation rates when patients were stratified by age, tumor site, ethnicity, smoking status, or human papillomavirus status.

Finally, we looked for an increased burden or mutation load of FA gene variants in our cohort in comparison to the 1000 Genomes dataset using the Mann-Whitney-Wilcoxon nonparametric test. Because our cohort is comprised, predominantly, of patients with Caucasian ethnicity, the statistical comparison was between the 356 Caucasian HNSCC patients and the 503 individuals of European ancestry in the 1000 Genomes dataset. This comparison revealed that *FANCD2*, *FANCE*, and *FANCL* had a significantly increased burden in our cohort (Table 5). At the same time, the mutation burden for *BRCA2*, *FANCG*, and *FANCQ* was significantly reduced in our cohort.

DISCUSSION

Though HNSCC is highly associated with FA, the prevalence of FA germline variants in younger HNSCC populations has not been explored. While the primary purpose of this study

was to define an age cutoff among patients with HNSCC to undergo genetic screening for FA, there was no correlation of younger age with FA germline variants. In a previously reported tumor genomic analysis of HNSCC in low-risk patients (nonsmokers <45 years old) and traditional high-risk patients (smokers >45 years old), age was not a marker of genome instability: rates of gene-specific mutations and copy-number alterations were similar in oral tongue cancers in low-risk patients and oral tongue cancers in traditional high-risk patients (29). Similarly, we did not see a difference in prevalence of FA germline mutations between patients younger than 40, 40-44, and 45-50 years of age or between smokers and nonsmokers.

Our patient cohort consisted of four different ethnicities, so it was important to use an approach that involved population-specific frequencies to ensure that low frequency variants were properly characterized. 185 patients carried 194 total variations, including 183 rare nonsynonymous variants, a synonymous variant predicted to affect splicing, 9 indels, and a large deletion (Figure 1). 108 patients carried at least one variant predicted to be damaging. We identified 38 novel FA germline variants, including a synonymous variant and a large deletion, not present in control populations or previously documented in disease-associated databases, 23 (61%) of which were predicted to be damaging (Figure 1, Supplemental Table 3). There were 15 patients carrying two rare alleles in the same FA gene, which included three that were known to have anemia and/or leukopenia and two presenting with short stature. FA germline variants, and genome instability, may play a broader role in HNSCC susceptibility regardless of age or traditional risk factors.

Mutations in the FA core complex (FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, FANCM, and the recently identified FANCT) affect ubiquitination of the FANCD2/FANCI complex, a critical step in the FA pathway that repairs DNA damage and maintains genomic stability (5,30). FANCL is a member of the FA core complex with E3 ligase enzymatic activity for FANCD2 mono-ubiquitination (31). FANCE recruits FANCD2 to the FA core complex for ubiquitination, and subsequent DNA repair (32). Interestingly, FANCD2, FANCL, and FANCE

homologs form a subset of the FA genes present in *Ciona intestinalis*, thought to be the closest invertebrate relative of vertebrates (33,34), and thus appear to be an evolutionarily conserved part of the FA pathway. It is likely that mutations affecting *FANCD2*, *FANCE*, or *FANCL* modify cancer susceptibility through altered DNA repair and genomic instability. In the current study, we observed an increased burden, or mutation load, of variants in *FANCD2*, *FANCL,* and *FANCE* in HNSCC patients compared to population-level estimates (Table 5). One would expect that FA patients with mutations in *FANCD2, FANCL,* and *FANCE* may be predisposed to developing HNSCC. However, it is not practical to evaluate this from clinical experience of FA patients, as *FANCL*, *FANCE,* and *FANCD2* patients represent only 0.4%, 1% and 4% of all FA patients (4), respectively, and may often succumb to other maladies, not surviving long enough to develop HNSCC. Recently, missense mutations in the FANCD2/FANCI complex have been associated with colorectal carcinoma (35). The FA pathway, FANCD2 in particular, is implicated in facilitating replication through common fragile sites (36), a critical process in maintaining genomic stability. Interestingly, a study reporting results from sequencing 190 patients with esophageal squamous cell carcinoma (ESCC) for germ line variants in 12 FA genes identified heterozygous indel variants, one each, in *FANCD2*, *FANCE*, and *FANCL* in three patients, each with a strong family history of ESCC (37). ESCC and squamous cell carcinoma of the anogenital tract, in addition to HNSCC, form the cancer spectrum displayed in FA patients (17). Germline mutations in *FANCD2*, *FANCE,* and *FANCL* may provide a novel area of study for HNSCC susceptibility and tumorigenesis.

In conclusion, our analysis of FA gene germline variations in 417 HNSCC patients under the age of 50 identified 15 patients carrying two variants in an FA gene, five of whom presented with a FA-associated phenotype, but we did not identify a specific age cut-off for FA screening. We identified 44% (185/417) of the patients in our cohort as heterozygous carriers of a rare FA gene variant, and variants in 60% of these patients (108/185) were predicted to be damaging. In addition, the increased mutation burden of FANCE, FANCL and FANCD2, key players in the

activation of the DNA repair pathway, may indicate the importance of the FA pathway in HNSCC tumorigenesis.

FIGURE LEGENDS

Figure 1. Schematics of FA gene variant analysis in HNSCC patients. Data from SNP array were analyzed for copy number variations. SNV discovery was performed from targeted sequencing of 16 FA genes. Synonymous variants were analyzed for splicing effects. Indels, nonsynonymous, and splicing variants were screened for quality and filtered using population-specific frequencies, where applicable. The resulting rare variants were screened for presence in the FA mutation database (FAmutDB) and ClinVar, and analyzed by functional prediction algorithms to determine potential pathogenicity.

^ Unreported variants were present at a frequency below .5% in the public databases but not reported to the FA mutation database, ClinVar, or BIC.

* Novel variants were not present at any frequency in the public databases used for filtering.

Figure 2. The 194 rare variants, by mutation type, observed in the 16 FA genes from 185/417 HNSCC patients

The plot shows the number and type of rare variants observed in each FA gene along with the number of rare variants that were predicted to be damaging. ^includes one stoploss; *includes one synonymous variant

Table 1: Distribution of patients by age, sex, ethnicity, and primary tumor site, as well as by prevalence of FA gene variants.

A. 417 HNSCC Patients, segregated by cancer site, age group, and ethnicity

	Oral Cavity (n=149)			Oropharynx (n=230)			Larynx (n=38)			
	<40	40-44	45-49	<40	40-44	45-49	<40	40-44	45-49	Total
Caucasian	40	32	45	23	54	129	3	9	21	356

FANCQ/ERCC4	12	17	7	12	3	7
	194	255	91	125	38	60

Rare – exists at a frequency <.5% in 1000Genomes, NHLBI-ESP6500, or ExAC

Predicted damaging – prediction algorithim (criteria); SIFT (D), Polyphen (D or P), MutationTaster (D or A), CADD (Phred-scaled score > 20), GERP++ (RS score > 2). If 4/5 of the required criteria were met, the variant was considered to be “predicted damaging”.

Predicted damaging & reported – The above criteria were met and the variant was present in either the FA mutation database and/or ClinVar.

Table 4. Distribution of rare FA gene variants among HNSCC patients, segregated by cancer site, age of onset, and ethnicity

Supplemental Table 3: Characteristics of rare variants from sequence analysis of 16 FA genes in 417 H

185/417 HNSCC patients carry 194 rare FA gene variants
Including 1 large deletion from SNP array & 1 synonymous variant

80 variants are predicted to be damaging by prediction algorithms (at least 4 out of 5 agree - SIFT, Poly
11 variants are predicted to be damaging due to the nature of the variant

65 variants are predicted to be benign by prediction algorithms (at least 4 out of 5 agree - SIFT, Polyphe

39 variants have inconsistent predictions (at least 4 out of 5 do not agree - SIFT, Polyphen, MutationTa

56 variants are present in the FA Mutation database (FAMutdb)
19 of these are predicted to be benign
27 are predicted to be damaging
10 have inconsistent predictions

SIFT	Damaging if "D"
Polyphen	Damaging if "P" or "D"
MutationTaster	Damaging if "A" or "D"
CADD	Damaging if >= 20 (top 1% most damaging variants in the genome)
GERP++	Conserved position if > 2 (RS score threshold of 2 provides high sensitivity while s
nature of variant	Damaging if variant is of the type: stopgain, indel, large deletion, synonymous pr

"reported in FAmutDB/ClinVar/BIC" -- variant is present in at least one of these databases
"unreproted rare variant" -- variant is not present in FAmutDB, ClinVar, or BIC, but is observed in the 1(
"novel" -- variant has not been reported to FAmutDB, ClinVar, or BIC, nor is it observed in the 1000 Ger

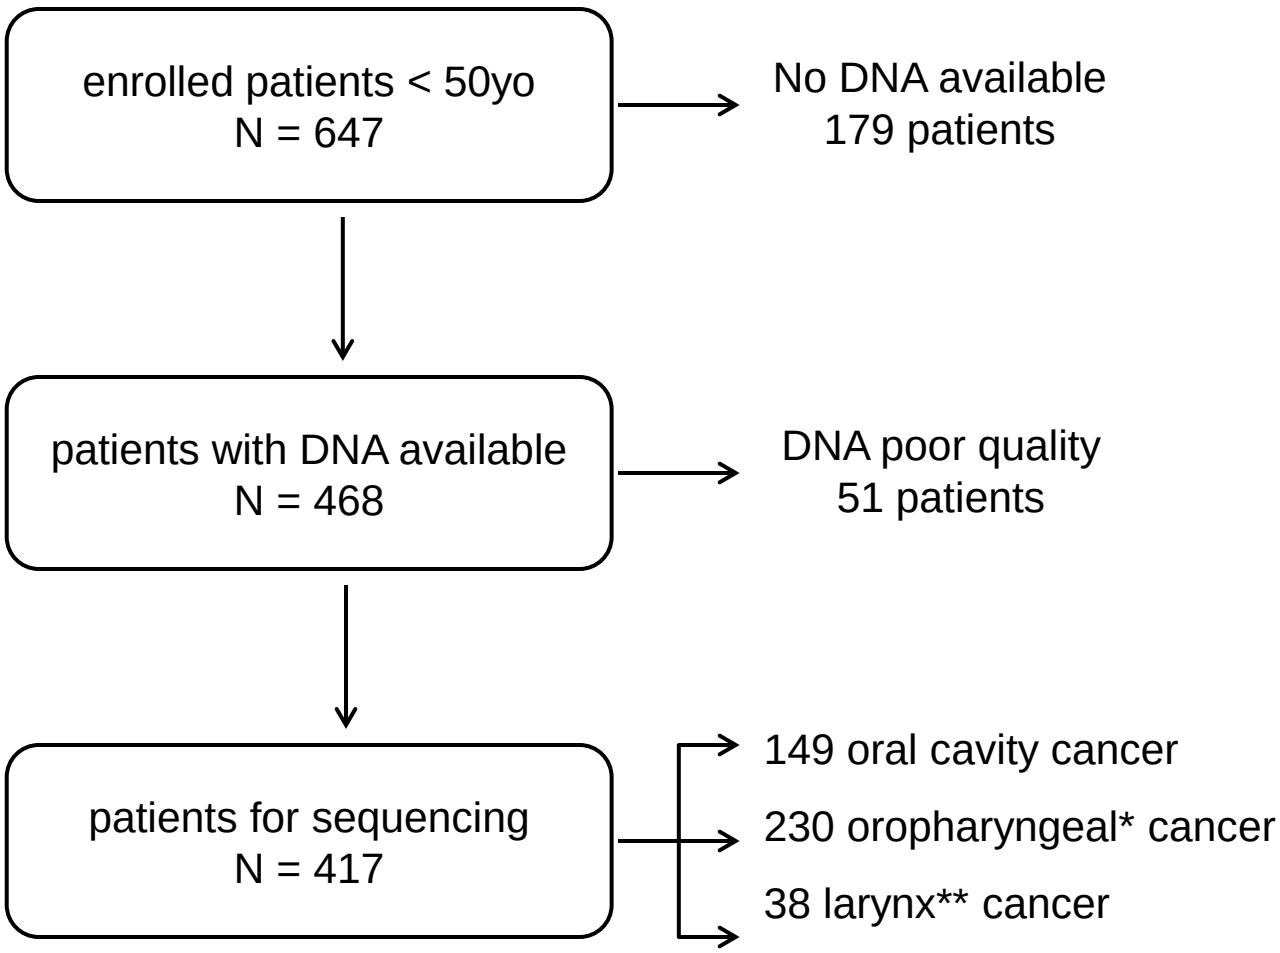
Supplemental Figure 1. Enrolled patients under 50 years of age with incident HNSCC and reason for exclusion from sequencing analysis.



*Includes 5 patients with upper neck lymph node metastasis with unidentified primary site.
**Includes 3 patients with hypopharyngeal cancer.
