## Abstract

34 Objective:

The objective of this review is to discuss the therapeutic use and differential treatment response to Levo-carnitine (L-carnitine) treatment in septic shock, and to demonstrate common lessons learned that are important to the advancement of precision medicine approaches to sepsis. We propose that significant interpatient variability in the metabolic response to L-carnitine and clinical outcomes can be used to elucidate the mechanistic underpinnings that contribute to sepsis heterogeneity.

# 41 Methods:

42 A narrative review was conducted that focused on explaining interpatient variability in L-

43 carnitine treatment response. Relevant biological and patient-level characteristics

44 considered include genetic, metabolic, and morphomic phenotypes; potential drug

45 interactions; and pharmacokinetics.

# 46 Main Results:

Despite promising results in a phase I study, a recent phase II clinical trial of L-carnitine 47 treatment in septic shock showed a non-significant reduction in mortality. However, L-48 carnitine treatment induces significant interpatient variability in L-carnitine and 49 acylcarnitine concentrations over time. In particular, administration of L-carnitine 50 induces a broad, dynamic range of serum concentrations and measured peak 51 concentrations are associated with mortality. Applied systems pharmacology may 52 explain variability in drug responsiveness by using patient characteristics to identify pre-53 treatment phenotypes most likely to derive benefit from L-carnitine. Moreover, 54 provocation of sepsis metabolism with L-carnitine offers a unique opportunity to identify 55 56 metabolic response signatures associated with patient outcomes. These approaches

can unmask latent metabolic pathways deranged in the sepsis syndrome and offer

insight into the pathophysiology, progression, and heterogeneity of the disease.

### 59 Conclusion:

60 The compiled evidence suggests there are several potential explanations for the

variability in carnitine concentrations and clinical response to L-carnitine in septic shock.

62 These serve as important confounders that should be considered in interpretation of L-

carnitine clinical studies and broadly holds lessons for future clinical trial design in

sepsis. Consideration of these factors are needed if precision medicine in sepsis is to
 be achieved.

 Epidemiology and Heterogeneity of Sepsis

Sepsis is a life threatening, dysregulated host response to infection, which is
 characterized by systemic organ dysfunction.<sup>1</sup> One in three Americans who die in the
 hospital have sepsis, and in 2017 there were an estimated 48.9 million cases
 worldwide.<sup>2</sup>

73 The sepsis syndrome is a highly heterogeneous, with patients presenting along a continuum of clinical signs, symptoms, and severity of illness.<sup>3</sup> The mechanism and 74 75 pathophysiology underlying highly variable clinical trajectories in sepsis are complex. and the precise reason(s) some patients exhibit severe dysregulated responses while 76 77 others recover from their initial infection in an uncomplicated fashion remains poorly understood. Such host-response heterogeneity muddles the interpretation of treatment 78 79 response and is a major reason why novel pharmacotherapy often fails. Absence of adequate stratification of patients based on their underlying pathophysiology may 80 contribute to this.<sup>4</sup> The need to advance mechanistic understanding of sepsis 81 heterogeneity has led to calls from the National Institute of General Medical Sciences 82 for studies that seek to determine the effect of patient characteristics on differential 83 treatment response (NOT-GM-19-054). Teasing out this variability is necessary to bring 84 about a precision medicine approach to sepsis. 85 Ample evidence suggests a hypermetabolic component and derangement of host 86

87 metabolism that is central to sepsis pathophysiology.<sup>5</sup> Recently revised consensus

guidelines define the most severe manifestation, septic shock, as infection with

sustained hypotension despite recommended evidence-based treatment interventions

(e.g., fluid resuscitation), and pertinent to this discussion, metabolic dysfunction and/or 90 tissue hypoperfusion as evidenced by an elevated blood lactate concentration.<sup>1</sup> 91 Hyperglycemia, protein catabolism, and lipolysis are similarly known to occur in sepsis 92 and contribute to poor patient outcomes.<sup>6</sup> While several studies have targeted lactate as 93 a resuscitation goal<sup>7-9</sup>, these trials have typically utilized fluids, vasopressors, or other 94 agents designed to improve organ perfusion under the assumption that lactate 95 elevations are predominantly explained by ongoing tissue ischemia, which may not 96 necessarily be true.<sup>10</sup> Current pharmacotherapy neither targets nor corrects these 97 metabolic perturbations, although restoration of host bioenergetics offers a promising 98 therapeutic target. Moreover, given the prevalence, persistent mortality, and lack of 99 specific treatment paradigms, there is a critical need to advance understanding of the 100 101 range and extent of the metabolic consequences of sepsis beyond observational studies. 102

Herein, we discuss clinical trials of L-carnitine, an important regulator of mitochondrial and metabolic homeostasis, for the treatment of septic shock. We consider how patient-level biological variables impact response to treatment and propose that provocation with L-carnitine offers a novel and unique opportunity to improve mechanistic understanding of the heterogeneity and metabolic consequences of sepsis.

### **109** Physiological Role of Carnitine and Treatment in Sepsis Patients

Carnitine is an endogenous, polar small-molecule derived from lysine and 110 methionine, which plays a well-established, crucial role in transport of long-chain fatty 111 acids into the mitochondria for  $\beta$ -oxidation. Other key roles during times of metabolic 112 113 stress include maintenance of coenzyme A homeostasis, metabolic flexibility and promotion of normal tricarboxylic acid cycle (TCA cycle) function, and further oxidation 114 of fatty acids by peroxisomes.<sup>11</sup> A full, in-depth review of carnitine and acylcarnitine 115 homeostasis and biochemistry is outside the scope of this paper, and it has been 116 extensively reviewed elsewhere.<sup>11, 12</sup> Briefly, the carnitine shuttle allows for fatty acid 117 entrance to the mitochondria for oxidation and subsequent energy production through 118 transfer of acyl groups and conversion into acylcarnitines (Figure 1). 119

In sepsis, mitochondrial dysfunction has been increasingly reported as a critical 120 factor in persistent organ failure and altered peripheral cell mitochondrial function is 121 122 known to be associated with sepsis mortality.<sup>13, 14</sup> Further evidence of mitochondrial dysfunction includes elevations of systemic acylcarnitines, indicating incomplete β-123 oxidation of fatty acids, and the presence of mitochondrial deoxyribonucleic acid (DNA) 124 in plasma.<sup>15, 16</sup> Sepsis alterations in mitochondrial function and lipid metabolism are 125 associated with kidney and liver function that are driven in part through inhibition of the 126 pyruvate dehydrogenase complex and decreased activity of carnitine 127 palmitoyltransferase I.<sup>17, 18</sup> Prior clinical studies of intravenous (IV) L-carnitine and 128 acetylcarnitine given to patients in cardiogenic and circulatory shock found an overall 129 positive effect on hemodynamic parameters and patient survival.<sup>19-21</sup> 130

131 These principles served as the basis for two recent clinical trials of L-carnitine in septic shock. The first was a phase I, randomized, double-blind clinical trial of L-132 carnitine (12 g IV) vs. saline placebo conducted in 31 patients with septic shock enrolled 133 within 16 hours of diagnosis.<sup>22</sup> Study drug was given as an IV bolus (33% of total dose), 134 135 followed by a 12-hour infusion that delivered the remaining drug. This study found no difference in the reduction of Sequential Organ Failure Assessment (SOFA) score at 24 136 137 hours, but there was an improvement in mortality at 28 days (4/16 vs. 9/15, p=0.048) and 1-year (8/16 vs. 12/15, p = 0.081) in L-carnitine treated patients. Adverse events 138 139 sometimes attributable to L-carnitine, including gastrointestinal distress, body odor, and an decreased seizure threshold were not observed in the study. In addition, serious 140 adverse events were not significantly different between the L-carnitine and placebo 141 treatment arms. A follow-up phase II multicenter, double-blind, adaptive dose-finding 142 143 trial randomized 250 patients within 24 hours of identified septic shock to IV L-carnitine (6 g, 12 g, or 18 g) vs. placebo.<sup>23</sup> In the primary analysis, the highest dose (18 g) of L-144 carnitine was not found to be superior to placebo in reducing the total SOFA score at 48 145 hours, and the predicted probability of success of a subsequent phase III trial in 146 reducing mortality at 28 days did not exceed the a priori threshold of 90%. The 6 g and 147 12 g L-carnitine doses underperformed in the trial and were adaptively dropped from the 148 randomization scheme as the trial progressed. Three, interim, pre-planned safety and 149 futility analyses were completed by an independent data safety monitoring board. 150

However, the primary endpoints of both clinical studies do not describe a critical 151 component of drug response to supplemental L-carnitine in patients with septic shock. 152 The pharmacometabolomics data from the Phase I trial reveal substantial interpatient 153 variability in serum carnitine and acetylcarnitine concentrations post-infusion.<sup>24, 25</sup> 154 Patients receiving L-carnitine in the phase I study had 24-hour post infusion (T24) 155 serum carnitine levels ranging from 30  $\mu$ M to over 1600  $\mu$ M (median = 368  $\mu$ M). The 156 temporal changes in carnitine and acetylcarnitine for the treatment and placebo arms 157 are shown in Figure 2. Critically, L-carnitine treated non-survivors (based on 1-year 158 mortality) had elevated carnitine and acetylcarnitine (C2), short chain acylcarnitines (C3, 159 C4, and C5), and long chain acylcarnitines (C14 and C16) compared to L-carnitine 160 treated survivors. This suggests the observed variability in measured peak 161 162 concentrations and metabolic response profiles are associated with clinical outcomes. As such, identification of the patient-level factors associated with peak 163 164 carnitine/acylcarnitine concentrations may help identify patients most likely to derive a mortality benefit from L-carnitine and inform the design of future clinical studies. 165 166 Candidate Mechanisms of Interpatient Variability of Drug Response in Sepsis 167 Pharmacogenomics: 168 Pharmacogenomics seeks to explain variability in drug exposure and response 169 170 based on genetic differences between individuals. Genetic variation in drug metabolizing enzymes, transporters, and targets impact an individual's exposure and/or 171 172 response to a given pharmacologic therapy, which can manifest as distinct drugresponse phenotypes. Genetic variability is also known to alter patient response across 173 174 disease states and medications commonly seen in the intensive care unit (ICU).<sup>26</sup> 175 Treatment and dosing paradigms, which incorporate patient-specific pharmacogenomic data, hold promise in decreasing adverse drug events (ADEs) and improving efficacy.<sup>27</sup> 176 Moreover, rationale clinical trial enrollment based on pharmacogenomic phenotypes can 177 foster a more homogenous patient cohort and target patient populations most likely to 178 179 benefit from therapy (Table 1). Genetic variability in a number of enzymes and transporters could contribute to 180

L-carnitine drug response including those highlighted in the carnitine shuttle (Figure 1).

Carnitine acts intracellularly and is highly sequestered in skeletal muscle and other
 tissues of the body.<sup>11</sup> Given the polar structure of carnitine, active sodium-dependent
 transport by organic cation/carnitine transporters (OCTNs) is required for entry from the
 blood into the cell and subsequent facilitation of fatty acid β-oxidation. The primary
 carnitine transporter, OCTN2, thus represents the focus of this section.

The OCTN2 transporter is encoded by the SLC22A5 gene located on 187 chromosome 5q31.1. Spanning 25 kb, the 10 exons of this gene encode the full length 188 557 amino acid protein. Numerous autosomal recessive mutations in the SLC22A5 189 gene are responsible for primary carnitine deficiency and results in low serum carnitine 190 levels due to the kidney's impaired ability to reabsorb the molecule.<sup>28</sup> Missense 191 mutations are exceedingly rare, result in severe metabolic and mitochondrial 192 dysfunction, and manifest clinically as a primary carnitine deficiency at a young age. As 193 such, loss of function mutations are unlikely to play a role in explaining variability in L-194 195 carnitine concentrations or response in clinical studies of adults with septic shock. Nonetheless, given the vital role of OCTN2 in carnitine uptake into the cell, and 196 197 considering the large doses administered in these trials, more common genetic polymorphisms in OCTN2 resulting in reduced function and / or expression may 198 199 improve understanding of the mechanisms that explain the broad dynamic range of carnitine concentrations following supplementation. 200

201 Common polymorphisms (i.e., minor allele frequency greater than 1%) in the OCTN2 gene and their impact on carnitine transport outside the context of primary 202 carnitine deficiency are rare.<sup>29-31</sup> Three SNPs (Phe17Leu, Tyr449Asp, Val481Asp) were 203 associated with reduced OCTN2 function compared to wild-type, and a SNP in the 204 205 promoter region of the gene (-207C>G) was associated with increased carnitine transport capacity and trended toward increase mRNA expression in cell lines.<sup>29</sup> Out of 206 these, only the promoter region variant (-207C>G, rs2631367) could be considered 207 common according to the National Center for Biotechnology Information database of 208 genetic variation (dbSNP).32 Further studies have observed a tissue-specificity to the -209 207C>G variant's effect on mRNA expression levels.<sup>30, 31</sup> 210

To supplement the limited literature regarding common polymorphisms effecting OCTN2, we conducted a systematic bioinformatics search for potentially relevant SNPs.

We gueried the Genotype-Tissue Expression (GTEx) Project (available at 213 https://gtexportal.org/home/), which seeks to explain variability in mRNA expression 214 levels from previously healthy human cadavers with whole genome sequencing.<sup>33</sup> The 215 goal of this query was to determine common genetic variants (i.e., SNPs) that 216 significantly alter gene expression of the OCTN2 transporter. Using expression 217 quantitative trait loci (eQTL) analysis, approximately 1500 variants were found to be 218 associated with altered gene expression at the tissue level. Summing across more than 219 6,000 SNP/tissue pairs, the variant with the largest effect on net OCTN2 gene 220 expression was the promoter region variant (-207C>G, rs2631367). 221

In previously unpublished data from our group, patients treated with L-carnitine in 222 the phase I trial<sup>22</sup> were genotyped for the OCTN2 (-207C>G) SNP. In this preliminary 223 224 study, fourteen patients had both genomic and serum carnitine concentrations measured at 24 hours (T24). Among these, four patients were wild-type (CC), while ten 225 226 carried one or two copies of the G allele. Patients with the C/G or G/G genotype trended toward lower T24 plasma levels of L-carnitine (p=0.11), suggesting that genetic variation 227 228 in the OCTN2 transporter may contribute to variability and persistent elevations in Lcarnitine following supplementation during septic shock. More pharmacogenetic studies 229 are needed and are underway in the phase II trial<sup>23</sup> to determine if variation in OCTN2 230 and other carnitine-specific enzymes and / or transporters explain interpatient variability 231 232 in L-carnitine drug response.

233

# 234 Drug Interactions:

Drug interactions occur when the activity, exposure, or effectiveness of a drug is 235 236 impacted by the presence of another drug. Co-administered drugs may inhibit or induce 237 expression of important enzymes or transporters, compete at target binding sites, or act in a synergistic or antagonistic fashion. Different combinations of drugs and their 238 interactions introduces variability in the pharmacokinetics (PK) and pharmacodynamic 239 response (PD) to pharmacologic therapy, which may put patients at increased risk of 240 ADEs and either mitigate or enhance therapeutic efficacy. Critically ill patients are at 241 increased risk of drug interactions and subsequent complications given comorbidities 242 243 and disease complications that are often present (e.g., renal failure) and the requisite

complex treatments regimens prescribed.<sup>34, 35</sup> In other disease states such as cancer,
there is a high prevalence of drug interactions in patients enrolled in clinical trials.<sup>36</sup>
Drug interactions in critically ill patients may pose a similar threat to trial validity and
patient health and should be systematically screened and considered (Table 1).

For L-carnitine, several drugs are reported to inhibit the OCTN2 transporter and 248 therefore could contribute to interpatient variability in exposure. These drugs can also 249 cause secondary carnitine deficiency through inhibition of the OCTN2 transporter in the 250 kidneys leading to decreased efficiency of reabsorption.<sup>37</sup> Of particular interest, in the 251 setting of sepsis, are two widely used classes of medications, namely antibiotics and 252 vasopressors. Previous reports have demonstrated that cefepime and levofloxacin 253 inhibit OCTN2 in vitro.<sup>38, 39</sup> While the choice of antibiotic therapy in sepsis depends on a 254 number of patient specific factors, cefepime and levofloxacin are two commonly used 255 antibiotics in the United States and are both recommended options in evidence-based 256 257 best practices. Vasopressors such as norepinephrine and other catecholamines, used to maintain blood pressure support, and other commonly used medications including 258 259 omeprazole and valproic acid inhibit OCTN2 and could similarly impact L-carnitine drug response.<sup>37</sup> In addition to omeprazole, other proton-pump inhibitors, including 260 pantoprazole and lansoprazole, have been shown to inhibit similar organic ion 261 transporters but whether they interfere with the function of OCTN2 and carnitine 262 263 transport has not been reported.<sup>40</sup>

Propofol, a short-acting hypnotic and sedative that is widely used in the ICU, may 264 also play a critical role in understanding variable drug response to L-carnitine. Propofol 265 is known to inhibit carnitine palmitoyltransferase I and the mitochondrial electron 266 267 transport chain, which leads to incomplete  $\beta$ -oxidation of fatty acids.<sup>41</sup> The induced metabolic disruptions have been linked to propofol infusion syndrome or PRIS, a severe 268 adverse effect of propofol that includes bradycardia, arrhythmias, rhabdomyolysis, 269 metabolic acidosis, hepatomegaly, hyperlipidemia, and organ failure. Moreover, animal 270 271 and *in-vitro* experiments have suggested a role for L-carnitine and acetylcarnitine in restoring propofol inhibition of fatty acid metabolism.<sup>42, 43</sup> 272

273 Variable exposure to one or more of these drugs could influence resulting blood 274 concentrations and subsequent metabolic response to supplemental L-carnitine. Other 275 mechanisms are certainly possible such that other concomitant medications and

variable patient feeding may further confound the clinical studies discussed above.

277 Presently, the clinical relevance of such interactions and how they should be managed

is currently unknown. Further investigation into the use of these drug inhibitors and the

effect on L-carnitine concentrations in the phase II study is underway.

280

### 281 <u>Pharmacometabolomics:</u>

Metabolomics seeks to identify and quantify small molecules, the full collection of 282 which define the metabolome, in a given biofluid.<sup>44</sup> The metabolome constitutes a read-283 out of underlying cellular and biochemical events that reflect the genetic makeup of the 284 host, transcriptomic and proteomic influence, as well as variability in the microbiome 285 and environmental exposure. As such, metabolomics represents the culmination of 286 these important regulators on the host. In addition, given that metabolism is dynamic on 287 288 a practical and physiological time-scale, this sensitivity can inform heterogeneity in disease trajectory and treatment response. Pharmacometabolomics exploits this 289 290 paradigm and is aimed at understanding and predicting response to drug treatment. In short, clinical application of metabolomics holds great promise in improving the 291 292 diagnosis and risk stratification of critically ill patients, furthering drug discovery through metabolic signatures of drug response and/or ADEs, and elucidating biochemical 293 294 pathways involved in the pathophysiology of critical illness (Table 1).

A pharmacometabolomic approach was utilized to understand baseline metabolic 295 differences in patients treated in the Phase I study of L-carnitine.<sup>25</sup> Patients treated with 296 L-carnitine who had low baseline levels of the ketone levels, 3-hydroxybutyrate, also had 297 298 lower post-treatment carnitine levels at 24 hours. The L-carnitine treated, low-ketone patients also had better clinical outcomes as evidenced by a timelier reduction in 299 vasopressor requirement and decreased 1-year mortality. An untargeted metabolomics 300 approach was then conducted in male patients from the Phase I study.<sup>45</sup> L-carnitine 301 treated non-survivors were found to have post-treatment elevations in metabolites 302 303 related to vascular inflammation including histamine, allysine, and fibrinopeptide A. Along with the differential metabolic response of survivors and non-survivors highlighted 304

in Figure 2, these data suggest both baseline metabolic signatures and metabolic
 profiles over time may be predictive of L-carnitine treatment responsiveness.

307

### 308 <u>Morphomics:</u>

Analytic morphomics is a new and rapidly growing scientific discipline within 309 precision pharmacotherapy that studies how variation in body size, composition and 310 structure are associated with drug and disease response.<sup>46</sup> In sepsis, two recent meta-311 analyses have observed a paradox between body composition and survival, whereby 312 particularly overweight (body mass index [BMI] between 25 kg/m<sup>2</sup> and 29.9 kg/m<sup>2</sup>), and 313 to a lesser extent obese (BMI between 30 kg/m<sup>2</sup> and 40 kg/m<sup>2</sup>), patients tend to have 314 better mortality outcomes compared to normal weight individuals (BMI between 18.5 315 kg/m<sup>2</sup> and 24.9 kg/m<sup>2</sup>).<sup>47, 48</sup> Notably, underweight (BMI less than 18.5 kg/m<sup>2</sup>) and 316 morbidly obese (BMI greater than 40 kg/m<sup>2</sup>) patients were found to have similar risk of 317 mortality relative to normal weight individuals. Neither measured peak concentrations of 318 L-carnitine nor mortality were significantly associated with BMI in patients who received 319 320 study drug in the phase I study. However, the observed "obesity paradox" reinforces the concept of a metabolic and energy-driven component to sepsis pathophysiology and 321 322 has a number of possible pathophysiological explanations including increased energy stores, anti-inflammatory mediator release from adipose tissue, and lipoprotein binding 323 of bacterial cellular components.49 324

Another possible explanation is that increased muscle mass offers energetic and 325 326 metabolic adaptability to patients within a window of the BMI spectrum. Protein catabolism and subsequent myopathy is observed in critically ill patients, and skeletal 327 328 muscle, an important energetic source to the host, experiences mitochondrial injury over the course of sepsis.<sup>50</sup> Indeed, recent studies have found an association between low 329 muscle mass and increased risk of mortality for patients with sepsis. In 74 patients with 330 liver cirrhosis and sepsis, patients with low muscle mass (defined as mid-arm muscle 331 circumference lower than the 5<sup>th</sup> percentile of the population) had increased mortality 332 compared to patients with normal muscle mass (47% compared to 26%, p=0.06).<sup>51</sup> In a 333 separate retrospective review of 627 patients with a diagnosis of sepsis and an 334 available abdominal computed tomography scan of the psoas muscle, muscle mass 335

depletion was associated with 28-day mortality in both univariate and multivariate
logistic regression (OR 2.79, p=0.01).<sup>52</sup> Given the extent of protein catabolism, the
sepsis-obesity paradox, and the known sequestering of carnitine into muscle tissue,
morphomics and variability in body composition offers a currently untapped field that
could aid in explaining the observed variability in response to supplemental L-carnitine
and patient mortality in sepsis broadly (Table 1).

342

# 343 Pharmacokinetics and Renal Function:

Pharmacokinetics (PK) as a science seeks to understand what the body does 344 with and to drugs. More specifically, it is the study of how drugs are absorbed, 345 distributed, metabolized, and eliminated from the body. Previous studies have 346 347 highlighted that there is profound sepsis-induced variation in drug PK. The reasons for this are likely multifaceted but include altered protein binding, perturbed vascular and 348 349 tissue permeability, decreased hepatic and renal blood flow, and lower activity of drug metabolizing enzymes.<sup>53</sup> High interpatient variability in drug PK in sepsis clinical trials 350 351 contributes to overall heterogeneity of the patient cohort and may confound trial results unless careful analysis of drug exposure is considered (Table 1). 352

The PK of L-carnitine has been explored, however no studies have determined the 353 precise PK of L-carnitine in sepsis or at such high intravenous doses. As discussed 354 355 above, OCTN2 is a critical carnitine transporter that is responsible for carnitine uptake into cells/tissues, however it is also responsible for reabsorption of carnitine in the 356 357 kidney proximal tubule. As such, kidney function may play a vital role in the interpatient variability in serum carnitine concentrations that result following supplementation. 358 359 Previous reviews report an average renal clearance of endogenous carnitine of 1-3 mL/min, indicating that at physiologically relevant concentrations up to 99% of carnitine 360 is reabsorbed by the kidney.<sup>54</sup> Exogenous carnitine administered to healthy volunteers, 361 increased renal clearance of carnitine and acetylcarnitine, indicating saturation of the 362 363 OCTN2 transporter and the reabsorption process, which may be relevant for supraphysiologic doses of intravenous carnitine like those given in septic shock trials.<sup>54</sup> 364 Unfortunately, urine samples were not collected in these studies, which prevents us 365 from estimating renal clearance of relevant carnitine species in these patients. Both 366

studies reported similar serum creatinine levels among survivors and non-survivors 367 indicating renal function alone does not explain heterogeneity in L-carnitine and 368 369 acylcarnitine concentrations among patients. However, the reliability of creatinine as a biomarker in the setting of acute kidney injury (AKI), sepsis and other critical illness, and 370 in drug development broadly been called into question.<sup>55, 56</sup> New investigations of 371 biomarkers of kidney injury and function are underway, but have yet to be widely 372 adapted or clinically validated. Further investigations of the variability in L-carnitine drug 373 response stratified by the presence of AKI and acute liver injury, and among other 374 measures of organ dysfunction are warranted before precise clinical recommendation 375 can be made in these patient groups. Moreover, modeling the impact of patient-level 376 biological variables such as sex, age, and race is critical to understand the observed 377 heterogeneity in L-carnitine drug response. 378

379

### 380 <u>Metabolic provocation with supplemental L-carnitine:</u>

While the approaches outlined above offer an opportunity to identify septic 381 382 patients most likely to respond to L-carnitine, understanding the metabolic response signature of L-carnitine treated patients holds value beyond a potential therapeutic 383 384 benefit. Outside of sepsis, the concept of provoked metabolic testing is used to uncover latent disease phenotypes. For example, a glucose tolerance test is used to diagnosis a 385 386 previously undetectable pre-diabetic phenotype in pregnant women. As seen in Figure 2, the metabolic response profiles of the placebo arm did not differentiate patient 387 mortality at one-year, as they did for L-carnitine treated patients. Critically, this finding 388 suggests the possibility that treatment with L-carnitine amplifies or incites a phenotype 389 390 of sepsis mortality and underlying derangement in carnitine homeostasis. Indeed, 391 elevations in plasma acylcarnitines are understood to be a measure of mitochondrial dysfunction and altered coenzyme A homeostasis in other metabolic diseases, and 392 elevated acetylcarnitine was recently found to be predictive of plasma cytokine levels. 393 blood culture positivity, multi-organ dysfunction, and mortality in patients with sepsis.<sup>57</sup> 394 395 Others have shown that short chain acylcarnitines levels are related to plasma mitochondrial DNA, an indicator of cellular damage, and that acylcarnitines are 396 predictive of mortality in critically ill patients.<sup>15, 16</sup> Together, these data suggest 397

derangements of the carnitine/acylcarnitine pool may be indicative of metabolicdysfunction and/or worsening sepsis that is predictive of mortality.

A metabolic test with supplemental L-carnitine can provoke biochemical 400 pathways in sepsis and amplify signals of underlying mitochondrial dysfunction and 401 perturbed energy pathways. A more complete investigation of other metabolite profiles 402 that are disrupted upon treatment may also lead to new insights into underlying disease 403 mechanism and pathophysiology. While there are a number of sepsis metabolomics 404 studies that confirm the substantial metabolic disturbances of the disease, they do not 405 inform distinct sepsis phenotypes in the way that a metabolic provocation test could. 406 The substantial variability in response to L-carnitine exposure and subsequent mortality 407 differences indicate phenotypic differences between groups. In aggregate, this 408 409 observation introduces the principle that even in the presence of a disease like sepsis, which is known to induce a substantial metabolic perturbation, provocation of 410 411 metabolism is required to bring the full dynamic range into view.

412

# 413 Conclusion and Future Directions

L-carnitine and acylcarnitine concentrations are highly variable following L-414 415 carnitine supplementation in septic shock, and the observed interpatient variability is associated with patient mortality. The heterogeneity of sepsis and drug response 416 417 complicates the interpretation of a therapeutic value of L-carnitine and other potential sepsis pharmacotherapies. Currently, a careful analysis of the phase II clinical trial to 418 inform the design of, and the results from, a phase III trial are needed before L-carnitine 419 treatment can be recommended for a specific sepsis patient population. However, even 420 421 though more work needs to be done, a strategy using the patient-level factors and biological variables that impact L-carnitine drug response could be used in the *a priori* 422 identification of patients who are most likely to derive the greatest benefit from 423 treatment. Well defined phenotypes of drug response could serve as inclusion-exclusion 424 criteria and aid in the design and interpretation of future phase III clinical studies of L-425 carnitine. Such information will need to be balanced with threats to clinical and external 426 validity, as well as consideration to the ability to recruit a sufficient patient population. 427

The approach outlined here is applicable to other emerging sepsis therapeutics

and could aid in developing a precision medicine approach to sepsis and the design of

early-phase clinical trials in critical illness. Moreover, provoking metabolism in septic

440

441 Figure Legends:

442 Figure 1: Overview of carnitine transport and enzymatic conversions in the cell. Carnitine enters the cell from the blood through an organic cation transporter (OCTN2), 443 after which carnitine palmitoyl transferase I (CPT-1) facilitates the conversion of 444 carnitine and long chain fatty acid-CoAs to acylcarnitines and coenzyme A (CoA). The 445 transporter carnitine-acylcarnitine translocase (CACT) moves the newly formed long-446 chain acylcarnitines into the mitochondrial matrix in exchange for free carnitine. Here, 447 long chain acyl groups are transferred back to CoA by carnitine palmitoyl transferase II 448 (CPT-II). The newly regenerated acyl-CoA undergoes  $\beta$ -oxidation into Acetyl-CoA, 449 which feeds into the TCA cycle. Alternatively, carnitine acetyl-transferase (CAT) 450 converts free carnitine and Acetyl-CoA to acetylcarnitine, which can freely diffuse 451 through CACT and OCTN2 back into the bloodstream. This latter process may be 452 enhanced during sepsis and times of metabolic stress, serving as a crucial sink for 453 excess acetyl groups that may be toxic to the cell. The ladder cartoon represents the 454 455 plasma membrane separating the blood and the cytosol of the cell, while grey boxes represent the outer and inner membranes of the mitochondria. 459 Figure 2: Carnitine treatment induces a metabolic phenotype whereby serum

460 carnitine and acetylcarnitine concentrations are elevated in sepsis non-survivors.

461 Serum concentrations of carnitine and acetylcarnitine are plotted over time for patients

treated with either L-carnitine (panels A and C) or saline placebo (panels B and D). Data

plotted are the median, 25<sup>th</sup>, and 75<sup>th</sup> percentile of observed serum concentrations, and
 the Mann-Whitney U test was used to determine significant differences between non-

survivors and survivors at each time point. All p-values are corrected for multiple

466 comparison using a false discovery rate method according to Storey and colleagues<sup>59</sup>

and are reported as q-values. L-carnitine treated non-survivors (N=7-8) at 1-year had

significantly higher concentrations of carnitine relative to survivors (N=8) at baseline

469 (BL, q=0.02); 24-hours (T24, q=0.004); and 48-hours (T48, q=0.02) post-treatment.

Similar trends were observed for acetylcarnitine (BL, q=0.01; T24, q=0.003; and T48,

q=0.02). No significant differences in carnitine or acetylcarnitine concentrations were

observed between placebo treated non-survivors (N=8-12) and survivors (n=3).
