# Gigantopithecus and Its Relationship to Australopithecus ${ }^{1}$ 

DAVID W. FRAYER<br>Department of Anthropology, University of Michigan, Ann Arbor, Michigan 48104

KEY WORDS Gigantopithecus • Australopithecus • P. Gorilla • Hominid origins.

#### Abstract

Gigantopithecus blacki and G. bilaspurensis are compared to P. gorilla and Australopithecus. The total morphological pattern of Gigantopithecus mandibles is more similar to Australopithecus than to P. gorilla. Two major points are raised. (1) G. blacki might be considered an aberrant hominid rather than an aberrant pongid. (2) G. bilaspurensis can be considered an equally likely candidate, along with Ramapithecus, for possible hominid ancestry.

Numerous taxonomic and evolutionary statements have been made concerning the genus Gigantopithecus. These interpretations have portrayed Gigantopithecus as ancestral to hominids, as an over-specialized side-branch of hominids, or as an aberrant pongid, unrelated to hominid evolution. Weidenreich was the main proponent of the ancestor/descendent relationship between Gigantopithecus and "Meganthropus" ( = Australopithecus) ('45, '46, '49). More recently, Eckhardt ('71, '72) has reopened the possibility of Gigantopithecus as a hominid forbear. Woo ('62) and von Koenigswald ('52, '58) suggested that Gigantopithecus should be considered a hominid, but that the genus represents an over-specialized side-branch which did not contribute to australopithecine evolution, but became extinct. Both of these schemes consider only G. blacki and not the recently discovered Middle Pliocene G. bilaspurensis.

Simons and Pilbeam ('65) reviewed the G. blacki material and concluded that the genus represented an aberrant pongid with peculiar hominid parallelisms. Simons' subsequent discovery of the Indian Gigantopithecus ( $G$. bilaspurensis) further confirmed, they felt, this aberrant pongid status (Pilbeam, '70; Simons and Ettel, '70; Simons and Chopra, '69a,b; Simons and Pilbeam, '72).

Throughout this debate, however, little substantive information has been given which would indicate the metrical and morphological similarity between Gigan-
topithecus and Australopithecus. Furthermore, a direct comparison between the Middle Pliocene G. bilaspurensis and Australopithecus has not been done, although Simons and Chopra ('69a) allude to some basic similarities. The metric data presented below combined with a review of morphological data are intended to clarify these relationships.

## DATA

Dental and mandibular measurements of P. gorilla, Australopithecus, and Gigantopithecus appear in Appendices 1-5. Gorilla tooth dimensions were taken by Paul E. Mahler and Milford H. Wolpoff. All mandibular measurements were taken by the author. Since all the Cleveland Museum of Natural History gorilla specimens were wild-shot, reliable sex determinations are possible. The sex of the specimens listed in Appendices 4-5, then, being determined in the field from the carcass, is quite accurate.

Except for noted cases, all australopithecine measurements were taken on the original specimens by Milford H. Wolpoff. These fossils are classified into gracile and robust categories based either on the specific site (e.g., Sterkfontein $=$ gracile) or on published accounts (e.g., robust and gracile forms from Omo). The gracile sample includes South African specimens generally described as A. africanus and

[^0]East African Lower Pleistocene specimens described as Homo. ER-992 has been included in the gracile sample with reservations. The robust sample consists of specimens published as $A$. "robustus" and $A$. "boisei." Severely crushed and distorted specimens are not included in these groups, but in some cases teeth with post-mortem, matrix-filled cracks are utilized. In these specimens the dimensions of the crack have been subtracted from the overall dimension, rendering a good representation of the true tooth size. The notable case in this regard is the East African robust specimen, ER-818. Formal descriptions of these newly discovered East African hominids appear in Leakey ('71, '72) and Leakey et al. ('71, '72).

With the exception of bicanine breadth, all measurements for Gigantopithecus blacki are taken from Woo ('62). To my knowledge published mandibular dimensions for $G$. bilaspurensis do not exist. Consequently, all dimensions on the Bilaspur mandible were taken on the YalePeabody Museum cast. Checking dental dimensions from the cast with those published by Simons and Chopra ('69a), the Yale-Peabody Museum case is within $4 \%$ of the dimensions on the original specimen. Mandibular dimensions taken from the cast for the Bilaspur mandible are assumed to be within $4 \%$ of the true values. Bicanine breadth on G. blacki is similarly accurate. Finally, dental dimensions for all Gigantopithecus mandibles are published by Simons and Chopra ('69a) and are not duplicated here.

## METHOD

The indices presented in table 1 are in most cases those used by Simons and Chopra ('69a) in their taxonomic discussion of G. bilaspurensis and G. blacki. In place of $\mathrm{P}_{3}-\mathrm{M}_{3}$ length and $\mathrm{P}_{3}-\mathrm{M}_{3}$ summed areas, I have chosen to substitute $\mathrm{P}_{4}-\mathrm{M}_{2}$ length and area. This substitution allows for a larger sample size in Gigantopithecus (G. blacki I and II lack lower third molars) and in Australopithecus. It also eliminates the comparison of lower third premolars between known pongids and hominids. Since the lower third premolar in apes is a mesiodistally elongated tooth set at an angle to the tooth row and is not directly involved in grinding and crushing, esti-
mates of posterior tooth size in gorillas are more reliable when considering only the summed areas of $\mathrm{P}_{4}-\mathrm{M}_{3}$. I have formulated the same indices using summed $\mathrm{P}_{3}-\mathrm{M}_{3}$ length and areas and have obtained results similar to those presented in table 1. The inclusion of all the measurements provides data for analysis in either manner.

Each index in table 1 intends to show morphological characteristics through metric evaluation. The three genera are represented by measurements presented in indices allowing direct comparison of metric/morphological relationships.

Bicanine breadth divided by the length of the cheekteeth $\left(\mathrm{P}_{4}-\mathrm{M}_{2}\right)$ compares the maximum external breadth outside the canines to the length of the posterior tooth row. The size of the canine (length $\times$ breadth) is normalized against the summed areas of the posterior teeth, while the area of the lower second incisor is compared to the area of the lower first molar. I have also compared lower $\mathrm{I}_{2}$ area with the summed posterior tooth areas as well as lower $\mathrm{M}_{2}$ area. All indices follow the same pattern, but for the sake of brevity, have not been included in this paper. Maximum symphyseal length is considered in regard to the height of the mandible at $\mathrm{M}_{2}$. This index is somewhat different from that described in Simons and Chopra ('69a), but again demonstrates the same morphological relationship as their index of maximum symphyseal length divided by mandible height multiplied by breadth at $\mathrm{M}_{2}$ and by the summed posterior cheek teeth area. Maximum symphyseal length divided by corpus height at $\mathrm{M}_{2}$ better separates Australopithecus from P. gorilla and, for this reason, is used in this analysis. The summed areas of $\mathrm{P}_{4}-\mathrm{M}_{2}$ divided by height $\times$ breadth of the mandible at $\mathrm{M}_{2}$ normalizes the cheek teeth relative to the robusticity of the mandible under $\mathrm{M}_{2}$. Area ( $1 \times$ b) of $\mathrm{M}_{1}$ divided by height $\times$ breadth of the corpus under $M_{2}$ provides a further check.

These indices are used to demonstrate morphological patterns through metric analysis. They provide excellent sorting criteria for separating australopithecines from gorillas. Student's t-tests performed on these two genera (Australopithecus and $P$. gorilla) using the six indices all
showed significant differences at the 0.01 level. It follows, then, since the indices separate australopithecines from gorillas, that they are useful criteria for analyzing other hominoid, and possibly related genera.

RESULTS
Three major points can be readily seen from an examination of table 1. (1) Australopithecus differs widely from gorillas, a fact which has been discussed above and by numerous authors beginning with Dart ('26). Different cultural and dietary adaptations are likely the major reasons for this metric difference. The morphological specialization of Australopithecus to small object feeding has been considered in detail by Jolly ('70). The infrequency of range overlap between Australopithecus and P. gorilla provides new evidence for determining the phylogenetic positions of $G$. blacki and G. bilaspurensis.
(2) Except in two cases (relative symphyseal length and relative $\mathrm{P}_{4}-\mathrm{M}_{2}$ area, both in G. blacki II), indices describing Gigantopithecus mandibles and tooth size fall completely within the range of Australopithecus. Both G. blacki and G. bilaspurensis overlap extensively with Australopithecus but seldom with P. gorilla. In those cases where Gigantopithecus indices have values within the P. gorilla range, Australopithecus also has values which overlap with P. gorilla.

It is interesting to note that the largest mandible of Gigantopithecus (G. blacki III), an assumed male (Simons and Chopra, '69a; Woo, '62), is well below the range in all indices describing male gorillas. In canine size, G. blacki III has canines which are relatively smaller than the canines of the presumed female, G. blacki I. Sexual dimorphism in canine size of $G$. blacki does not follow the common pongid condition where little or no overlap in relative canine size is characteristic. Consequently, relative canine size cannot be used to discriminate male from female Gigantopithecus.

The general similarity of Gigantopithecus to Australopithecus and its dissimilarity in all indices, as well as sexual dimorphism based on relative canine size, to gorillas suggests at least a dietary similarity to Australopithecus (Simons and Ettel, '70; Pilbeam, '70; Jolly, '70), but,
contra these authors, does not specifically indicate that gigantopithecines are "aberrant apes." Rather, if one has to resort to such terminology, the close metric similarity between G. blacki, G. bilaspurensis and Australopithecus would better describe an aberrant hominid.
(3) The third observation apparent from table 1 is that G. blacki and G. bilaspurensis show some different metric relationships. The relative bicanine breadth and relative symphyseal length are both smaller in G. bilaspurensis than in G. blacki I, II or III, and one would expect the index describing lower incisor area to differ also. In some cases G. bilaspurensis closely resembles Australopithecus.

This similarity is further emphasized when comparing G. bilaspurensis with two robust australopithecines from East Africa (see table 2). Here the major differences between the Bilaspur mandible, Omo 7, and ER-729 relate to absolute canine size. The smaller size of the bicanine breadth in G. bilaspurensis reflects the size of the canines rather than the size of the incisors. The internal bicanine breadth (measured from lingual surface on the canine) demonstrates this clearly. The size of the mandibular corpus under $\mathrm{M}_{2}$ is somewhat more massive in G. bilaspurensis than in robust australopithecines although recent East Rudolf finds almost equal it in crosssectional area, or are larger (see Appendix 1). At least two have mandibles greater in breadth. No gorilla specimen even approaches G. bilaspurensis or these large, robust australopithecines in mandibular corpus cross-sectional area at $\mathrm{M}_{2}$.

Measurements of the mandible and dentition of G. bilaspurensis and Australopithecus, then, closely resemble each other. Both have absolutely and relatively narrow bicanine breadths bounded by relatively small canines. The lower incisors are completely unlike gorillas, being considerably reduced. The maximum symphyseal length is greater than the corpus height at the lower second molar, but not to the extent of the condition seen in gorillas. The posterior teeth are both relatively and absolutely large as is the crosssectional area of the mandible under $\mathrm{M}_{2}$. The major metrical difference between the purported aberrant pongid and hominids is the size of the lower canine.
TABLE 1
Summary indices for Gigantopithecus, Australopithecus, and Pan gorilla. Sample size is enclosed in brackets. Standard

${ }^{1}$ Measurement from cast belonging to F. C. Howell.
${ }^{2}$ Measurement from Yale-Peabody cast.

Morphological details of Australopithecus and G. bilaspurensis are also quite similar. Besides the metrical details of the horizontal ramus under $M_{2}$, other characters of the mandibular body can be duplicated in australopithecines. Symphyseal cross-sections of Natron, ER-729, and ER-818, as well as other early hominids, show essentially the same morphological features. The middle symphyseal area is buttressed by two transverse tori, one running superior and one inferior to the genial-glossal fossa. Above the superior torus is a shelf-like area which is characteristic of most australopithecines and pongids, both fossil and recent. The inferior transverse torus of G. bilaspurensis forms a short simian shelf, more vertical than in P. gorilla with a relatively higher placement of the genial-glossal fossa.

The origin of the ascending ramus in G. bilaspurensis arises at $\mathrm{M}_{1}$ a considerable distance lateral to the buccal aspect of the tooth. The result of the condition is a wide buccinator groove similar to those found in some robust australopithecines. In the later G. blacki mandibles, the ascending ramus begins further posterior at $\mathrm{M}_{2}$ and the buccinator groove is narrower and less marked. The horizontal ramus of G. bilaspurensis increases in
depth posteriorly. This characteristic is similar to East African robust forms, ER-403, 404, and 726, but different from others. ER-818, for example, sharply decreases posteriorly in horizontal ramus depth.

The two major differences between $G$. bilaspurensis and Australopithecus in mandibular morphological details are the angle of the symphyseal region and the shape of the dental arcade. In most australopithecines the symphyseal angle is nearly perpendicular to the horizontal ramus, while in the Bilaspur mandible the area is at a $45^{\circ}$ angle to the horizontal ramus. It is noteworthy that Ramapithecus also has a non-perpendicular symphyseal angle (Andrews, '71). The contour of the tooth row in the Bilaspur mandible is V shaped, resembling its probable mid-Miocene dryopithecine ancestors which all have anteriorly convergent dental arcades. This feature differs from Australopithecus and is not unlike the palatal shape in Ramapithecus. With decrease in size of the canines and shortening of the mandible the palatal contour of G. bilaspurensis would probably resemble Australopithecus.
G. bilaspurensis has a $\mathrm{P}_{4}, \mathrm{M}_{1}, \mathrm{M}_{2}$, and $\mathrm{M}_{3}$ of similar shape to Australopithecus, but the teeth lack crenulations on the occlusal surfaces. Unworn molars are longer
than broad with bulging lingual and buccal aspects (see table 3). Comparing heav-ily-worn molars of Australopithecus to those of G. bilaspurensis as Simons does ( $72: 258$ ) only confuses the similarity of molar shape with australopithecines. On the average, $G$. bilaspurensis has length/ breadth ratios at the upper end of the Australopithecus range or just slightly beyond it.

Occlusally, the molars of G. bilaspurensis are less similar to Australopithecus, but are also completely unlike P. gorilla. The occlusal surfaces of the teeth in the Bilaspur mandible are characterized by low, broad cusps with shallow fovea separating each cusp. These teeth are not characterized by highly crenulated surfaces, although the cusp pattern can be duplicated in several robust australopithecines.

The occlusal morphology on the lower molars is strikingly similar to the description of the Ngorora $\mathrm{M}^{2}$ found in Pliocene deposits in East Africa (Bishop and Chapman, '70). This upper molar described by Leakey is also bunodont with low rounded cusps and distinct fovea separating the cusps, and appears to be about the same geological age as G. bilaspurensis. Due to the lack of other African middle Pliocene forms, this relationship is certainly tenuous.

Another similarity in dental morphology is the "plate-like" premolar and molar roots of both genera. From breaks and erosions in the Bilaspur mandible one can observe a left $P_{4}$ anterior root, a left $M_{2}$ anterior root, and a right $\mathrm{M}_{3}$ posterior root, all of which are "plate-like." Leakey et al. (71) have noted "plate-like" roots in ER-404, and Wolpoff has observed them in the originals of ER-725, 726, and 733a, and ER-818 (personal comm.).

These similarities are not meant to imply, however, that there are no differences between G. bilaspurensis and Australopithecus. There appear to me to be four main differences, three of which are functionally interrelated. (1) The size of the canine has been noted above. Simons has demonstrated that the angle of occlusal wear on the lower canines of $G$. bilaspurensis is lower than on the canines of $G$. blacki, but higher than on the canines of Australopithecus (Simons and

Chopra, '69a). A steeply inclined wear facet on the lower canine would indicate that a maxillary canine, through occlusion with the mandibular canine, was acting in life to sharpen the distal edge of the lower canine. Since the lower canines of $G$. bilaspurensis are truncated more than sharpened and since the lower third premolar lacks a large well-defined mesial contact facet, it is reasonable to infer that the maxillary canine was not large, nor similar in function compared to gorillas. Rather, since the mandibular canine was truncated during life, masticatory actions performed at the canine appear to be more involved with grinding, than with shearing and gripping functions. The absolute size, wear, and morphology of the mandibular canines on the Bilaspur mandible, then, do not completely match either P. gorilla or Australopithecus.
(2) As mentioned above, the third lower premolar of $G$. bilaspurensis also differs from hominids. This tooth in addition to having only a very small mesial contact facet, is set at an angle to the tooth row and displays at least three cusps. Most investigators have argued that this tooth is pongid-like, considering it somewhat modified from a true sectorial lower third premolar. It is important to note, however, that the model of a Pliocene hominid ancestor with bicuspid lower third premolars, is no longer supported by the data, since the Fort Ternan ramapithecine has a sectorial lower third premolar (Andrews, '71). This tooth is also set at an angle to the tooth row, and further differs from G. bilaspurensis in having a long, mesial contact facet for occlusion with the maxillary canine. The morphology of $\mathrm{P}_{3}$ on G. bilaspurensis can not be used to exclude it from the status of a possible hominid ancestor.
(3) Another morphological feature that is not found within the australopithecines is the posteriorly diverging tooth row of G. bilaspurensis. This condition demonstrates the undeniable links of the Bilaspur mandible with late Miocene/early Pliocene dryopithecines (Pilbeam, '70), but again does not eliminate it from ancestral status. Reduction in molar length and increase in molar breadth accompanying canine reduction would probably produce a more parabolic dental arcade.
(4) Lower molars of G. bilaspurensis lack the complex crenulations of the occlusal surfaces that are so characteristic of Australopithecus. These teeth tend to be long compared to breadth (see table 3), but are not without parallels in the australopithecines. Simons and Chopra ('69a) point out that the molars are unlike apes in that they have low broad cusps, and that they seem to more "closely parallel hominids and perhaps Pongo" ('69a:13).

In summary, the major differences between Australopithecus and G. bilaspurensis are the absolute size, wear, and morphology of the canine, the polycuspid lower third premolar, the posteriorly diverging dental arcade, and the lack of heavily crenulated but mesio-distally long molars. All but the last are related primarily to the anterior dentition and suggest a complex not unlike Ramapithecus, and, in light of the other similarities, not particularly crucial to the decision to accept or reject it as a possible hominid ancestor (see Andrew' reasons for retaining Ramapithecus, '71). A minimum amount of selection to reduce canine size could very plausibly produce an East Rudolf-like australopithecine from something like G. bilaspurensis.

## DISCUSSION

Recently, Eckhardt ('71, '72) has proposed that the genus Gigantopithecus could be ancestral to hominids. His main argument concerning the amount of time required for morphological change may be valid, but the inclusion of $G$. blacki as an ancestor is certainly debatable. From all indications, G. blacki is no earlier than the late Pliocene and probably as recent as Middle Pleistocene. In all probability it overlaps with Australopithecus from Africa, and very likely overlaps with Homo erectus (Pei, '60; Kahlke, '61; von Koenigswald, '52; Woo, '62). Because of this time overlap, G. blacki cannot be considered ancestral to australopithecines.
G. bilaspurensis, however, is considerably earlier (at least Late Miocene) (Simons and Chopra, '69a,b; Simons and Pilbeam, '72) and as has been demonstrated, is metrically and morphologically similar to australopithecines. It is described by most authors as a pongid occupying a savannah niche without de-
pendence upon tools. But what would happen in the Early or Middle Pliocene if a hypothetical African G. bilaspurensis began to use tools? First, the large body size which could be construed as a defensive mechanism could become smaller. Canines would reduce in size in responding to tool manipulation or possibly in response to Jolly's "phase I" adaptation ('70). Whatever the case, with smaller canines $G$. bilaspurensis or something similar to it would look very much like an ER-729 or ER-818. The mandible would lose anterior robusticity due to the smaller canines, and length reduction and breadth expansion of cheek teeth related to selection pressures of heavy mastication would result to counteract interstitial wear.

From table 3 it can be seen that $G$. bilaspurensis has a larger L/B index for $\mathrm{M}_{1}, \mathrm{M}_{2}$, or $\mathrm{M}_{3}$ than any G. blacki or the mean of either robust or gracile australopithecines. Reduction of mesio-distal length and increase in buccal-lingual breadth is reasonable when considering the amount of interstitial wear of both Australopithecus and Gigantopithecus (Wolpoff, '71b). By increasing buccal-lingual breadth, the amount of occlusal area lost by interstitial wear would be considerably less, and, hence, selectively important. Coupled with this, reduction in $\mathrm{P}_{3}-\mathrm{M}_{3}$ length would be the mechanical advantage of a shorter mandible with more forward placement of $m$. temporalis and $m$. masseter (Andrews, '71). With shorter $\mathrm{P}_{3}-\mathrm{M}_{3}$ length, canine reduction and greater breadth of all the cheek teeth, a parabolic arcade would be produced. Both G. blacki and Australopithecus demonstrate this change. In each the form of the tooth row is unquestionably parabolic (see Eckhardt, '72:103).

One of the most crucial questions concerning the relationship of G. bilaspurensis to Australopithecus is the sex of the Bilaspur mandible. Previous studies have sexed the mandible as female (Simons and Chopra, '69a: p. 6; and Simons and Ettel, '70: p. 79). I submit that the sex of a single specimen which is the sole representation of a new species cannot be accurately assessed beyond the $50 \%$ level, i.e., a guess. The Bilaspur mandible is no less likely a male, and, if it is, one would expect to find smaller females which would

TABLE 3
Length/breadth indices for lower molars of G. blacki, G. bilaspurensis, and Australopithecus. All indices are multiplied by 100. Bracketed number following mean refers to sample size. All dental measurements for Australopithecus are listed in Appendix

|  | $\mathrm{M}_{1}$ | $\mathrm{M}_{2}$ | $\mathrm{M}_{3}$ |
| :---: | :---: | :---: | :---: |
| G. blacki I | 106.0 | 106.9 | - |
| G. blacki II | 116.9 | 112.7 | - |
| G. blacki III | 102.2 | 101.0 | 113.8 |
| G. bilaspurensis IV | 119.7 | 119.4 | 121.0 |
| Australopithecus (robust) |  |  |  |
| Mean | 102.1 (28) | 106.1 (29) | 114.2 (17) |
|  | s.d. $=6.8$ | $\text { s.d. }=5.1$ |  |
| Range | (86.1-113.7) | $(90.0-116.3)$ | $(101.8-123.0)$ |
| Australopithecus (gracile) |  |  |  |
| Mean | 106.2 (23) | 106.8 (22) | 108.9 (11) |
| Range | $\begin{gathered} \text { s.d. }=9.3 \\ (80.8-119.3) \end{gathered}$ | $\begin{aligned} & \text { s.d. }=7.6 \\ & (87.6-119.2) \end{aligned}$ | $\text { s.d. }=10.9$ $(94.8-134.7)$ |

even more closely resemble australopithecines.

In the middle and late Miocene there were, at least, two possible hominid ancestors, Ramapithecus and G. bilaspurensis. Until now, no one has recognized the possibility of the species represented by the Bilaspur mandible as being ancestral to early hominids. I feel that G. bilaspurensis is a better candidate for an australopithecine forbear in that body size is an important adaptive mechanism in creatures that are exploiting a terrestrial-niche without dependence on tools. Livingstone ('62) as well as Weidenreich ('45) have previously suggested the importance of size and reduction of size in human evolution.
G. bilaspurensis closely follows an australopithecine morphological pattern in both metric and non-metric characteristics. Its only major differences are not crucial in eliminating it as a hominid ancestor since Ramapithecus evinces the same morphological differences, and in many other respects, is more apelike.

Gigantopithecus blacki, on the other hand, can best be explained as an Asiatic hominoid (an aberrant hominid) which did not use tools, but rather continued to increase in body size as it adapted to the forest conditions. From the number of teeth found in China, it would seem that this specific adaptation (size vs tools) was quite adequate. Survival into the midPleistocene attests to this. Australopithecus with smaller size and a non-hunting industrial technology could not drive $G$. blacki into extinction. Homo erectus,
though, with effective hunting technology could have caused extermination, as could have competition with the giant panda (Simons, '72). The late existence of these large primates proves their effective adaptation through size.

As a hypothesis, this suggestion will stand or fall as new specimens are discovered. It is important to realize that the issue of man's Pliocene ancestry is far from closed, and that the present evidence does not yet allow a clear decision between Ramapithecus and G. bilaspurensis. It is important that viable alternative hypotheses be considered as additional evidence is discovered.

## ACKNOWLEDGMENTS

The original version of this paper was discussed with Dr. Elwyn L. Simons (Yale University), and, although we disagree, I truly appreciate the time he spent with me. Drs. Milford H. Wolpoff and C. Loring Brace (University of Michigan) have both critically commented on this version, as has Dr. Alan Walker (University of Nairobi). Tooth and mandibular measurements compiled by Wolpoff and Mr. Paul Mahler are gratefully acknowledged. The interpretations and conclusions of this paper are those of the author.
