### Preface

This work was carried out as a special problem in the School of Forestry at the University of Michigan. It is hoped that the results of this work will increas, the existing knowledge of our South Americam woods. As there is no record of similar work ever having been done, this report may be of value to many of the wood using industries interested in the possibility of using species from South America . Although the work did not cover all possible methods of gluing, it is at least a good start. However, much more work will be necessary before definite conclusions can be drawn on the gluing possibilities of these woods.

The author wishes to thank Mr. D. W. Cleverdon for the assistance rendered by him during the testing work. The author is also indebted to Professor William Kynoch for the information and comments supplied by him, also ProfessorJ.E. Thornton for accepting this report in his English <u>6</u> course.

R.H.C.

The Shearing Strength of Glued Joints of Several Species of South American Woods Made With Commercial Glues

### Introduction

With the increased use of wood in plywood and veneer, form, a great deal more emphasis has been placed on the gluing properties of wood. At present there exists extensive knowledge on the gluing properties of most of our native woods; however there is still a great deal to be learned about these properties,

This work was undertaken to see how the technique developed for gluing our native woods would apply on several species of wood from South America. The use of these South American woods is rapidly increasing, and as the supply of our more valuable native woods becomes exhausted this demand will increase greatly. Work on the mechanical properties of these woods in solid form has already been completed and will soon be published, but there is no published account available showing results of testing these woods for gluing ability. (2) Thus this work should be accepted as an indication of what can be done, but more tests should be carried out before definitely saying <u>if</u> a particular wood can be glued or not.

### Specific Object

The specific object was stated in the "Working Plan" submitted before this work was undertaken.

l.

### Procedure

of the corre

The procedure was also discussed in detail in the "Working.Plan" However as some changes were made a discussion of these changes will now be given. The procedure previously outlined was followed up to the point of cutting the slides. When this part of the work was undertaken, it was found impossible to cut slides from some of the woods and others could only be cut in a longitudinal direction. This was due to one of two things, namely, the woodswas  $to_A^o$  hard to be cut with a micratorie knife, or the use of formaline was not a other elemical constituent successful method of softening the wood. (Formaliné has been the recommended solution for softening glued woods as it does not react with most glues and thus break the glue line. Cativo and Imbuia, the only two low-density woods tested, were successfully cut in both cross-grain and longitudinal directions. Purpleheart and Pau Roxo, two of the densisted woods tested, could not be cut in either direction. When the attempt was made ame to cut these woods the knife skipped over the surface of the blocks unless such a thick section was cut as to make it value- $\stackrel{>}{\sim}$  less for microscopic study. Some of the difficulty may have been due to the tannin in the wood reacting with the formaline as the latter was colored a deep purple from both woods. The other woods were successfully cut in a longitudinal direction in most cases. Some of the sections are quite thick, and thus the photomicrographs appear to be out of focus. This appearance, however, is entirely due to some of the wood structure being in a plane other than the one photographed.

Another factor which arose was that most of the glue joints came apart in the formaline. The only reason that can be given for this is that the tannin in the wood mixed with the glue while the latter was in a moist state. As a result most of the photomicrographs show only half of the glue line, or at best all of the glue line but only one of the pieces of wood that was bonded by the glue. Another reason for the lack of success in cutting the slides with both pieces of wood attached to the glue may be due to the hardness of the wood itself. That is, the micratorie knife had to be forced through the wood so hard that the thin glue line broke under the strain. In most cases however the photomicrographs illustrate the points desired very well.

### Results

### Explaination of Tables

Table one is a compilation of the average results obtained from the testing of each wood and glue. The data in the column "Solid Wood" was obtained from Professor Kynochand is the result of work carried out by him. (2) The other data was obtained from the tests carried out by the author, These average results should not be considered  $to_{\Lambda}^{o}$  crickically, as some of the individual joint strengths included in the average figures were abnormally low.

<sup>T</sup>ables 2 to 31 show the results of the individual tests of the glue joints, each table dealing with one species of wood and one glue. The columns of these tables are self-explanatory.

The tables are grouped as to species, and the discussion for each species will be found precedding the tables for that species. The 150 pounds pressure stated at the top of these tables is the pressure per square inch applied to the blocks while the glue is drying. The "Assembly and Time" indicated by a 15-C means 15 minutes closed assembly, that is the glue was spread on the wood and the pieces placed together for 15 minutes before applying the pressure.

### Explaination of Plates

Plate one is a graphic description of the figures in table one. Each colored bar representing a certain glue or the solid wood. A key at the bottom of the page tells what each color represents.

Plates 2 to 23 are the photomicrographs taken from the slides, when the latter could be cut. They are intended to illustrate the penetration of the glue into the wood and the thickness of the glue line.

### General Conclusions

The discussion for each individual species will be found precedding the tables and plates for that species. It is intended here to summarize those discussions and to point out some of the future work which might be attempted to produce more successful glue joints.

### General Comparison of Glues

In considering the value of the glues used for these tests no account is taken of the presence of specific adhesion between the glue and the wood. Little is known about this phenomenon in the case of wooden joints, and there is no way of measuring the value of such adhesion. It is known to exist however, and this existance is well shown by some of the photomicrographs. In many cases the joints gave good strength values, but there wasneery little penetration of the glue into the wood.

### Casein Glue

In general the casein glue gave the best results, and would be recommended to use if only one of the three glues were being selected. This glue, however, tended to be more discolored by the tannins in the woods than the others. the The higher percentage of failure in the wood with this glue indicates that the bond between the glue and the wood was also better.

### Animal Glue

In most cases this glue also gave favorable results, but the strength of the joints was below that of the casein glue on an average. This glue seemed to penetrate the wood better than the casein glue, but it was noted to be rather granular in some cases after it had become dry. This condition probably resulted from the actions of the tannins in the woods on the glue.

perhaps some other chemical emotituents a constituents

### Vegetable Glue

This glue gave very poor results in all cases and could not be used where high joint strength was necessary. However this glue was developed for use in the manufacture of plywood, and for most uses of plywood high strength is not essential. A high penetration of the glue into the wood was usually obtained, and thus plenty of mechanical anchorage was provided to produce good joints if the glue itself had been stronger. The weakness of the glue is also indicated by the fact that there was very little failure in the wood in all of the pieces tested. This glue, due to its high consistency, should be applied by mechanical means. The results would undoubtedly have been better if applied by a mechanical spreader as this means insures a more uniform glue spread.

### Suggestions for Future Works

### Treatment of Wood

The use of some chemical treatment of the wood, such as the caustic soda treatment recommended by the United States Forests Products Laboratory (1), might well be tried on these woods. This treatment has been applied to many of our native species containing a large amount of tannin, and the resulting ? glue joint strengths greatly increased thereby. As most of the woods tested contained a great deal of tannin, the same How do treatment might apply to these woods. The treatment consists Yaw of applying a ten percent solution of caustic soda to the

surfaces of the boards to be glued, after about ten minutes the surfaces are wiped with a cloth to remove any excess solution or dissolved material and allowed to dry before being glued. Milk of lime or an ammonia solution might also be tried to see what effect they would have on the joint strength.

### Increasing Pressure

As the penetration of the glues into the woods was quite slight in most cases, it might be well to apply higher pressures to these woods to see if more glue could be forced into the wood cells and thus create better mechanical anchorage. A heavier glue spread would then be necessary, however, as more of the glue would be forced from between the blocks at higher pressures and unless care was taken starved joints would result.

worked

### Summary

Although the results of this work are not as complete as was anticipated at the start of the work, they form a base around which future work can be built. If more time had been available, the suggestions mentioned above would have been tried. However, it is believed the results of these tests show quite clearly that the common commercial practices in use today in the wood gluing industries will have to be altered before these woods can be glued successfully., However, it should not be said that these woods cannot be successfully glued at all until more study has been done to support these results.

### PLATE 1

A Graphic Comparison of the Average Shear Strengths of Solid Wood and

### Discussion (Purpleheart)

The results of the tests on this wood seem to indicate that the casein glue gave the strongest bond between the wood and the glue. The data in table 3 shows that in every case at least some of the failure was in the wood, while for the other two glues the failure was almost entirely in the glue. The average shear strength of the animal glue joints show it to be the strongest however. The soy bean glue, a vegetable glue, gave by far the poorest joints; however, as this glue is intended for plywood work the demand for strength is not as great. In no case did the glued joints approach the strength of the solid wood as can be seen in table 1. The moisture content of the wood when tested in the solid state was 13.9%, while at the time of gluing the moisture content of the wood was 6.3%. This difference must be considered and indicates that the solid wood would be even stronger if tested at the moisture content when it was glued.

A caustic soda treatment applied to the wood previous to gluing would perhaps aid in producing stronger joints. This wood contains a large amount of water solugble tannin, and it was readily leached out of the wood by the moist glue. This tannin mixed with the glue undoubtedly changes the properties of the gluem and probably reduces its strength. The caustic soda treatment would reduce the leaching action of the tannins considerably.

As it was impossible to cut microscopic sections from this wood, photomicrographs could not be gotten. However an assumption can be made on the penetration of the glue into the

wood. This assumption is based on the density of this wood compared to that of some of the other woods tested. As this basis the penetration was very slight or no penetration at all. A pressure considerably greater than the 150 pounds per square inch used might increase the penetration; however, a much heavier glue spread would also be necessary. and a high glue constancy.

In conclusion it may be said this wood cannot be successfully glued by the commercial methods used at present.

### Discussion (Pau Roxo)

This wood has many properties similar to Purpleheart previously described. The bond between the wood and the glue seemed to be greater, however, as there was a largermpercentage of failure in the wood with all glues. The lower strength values of the joints with this wood over Purpleheart wasp probably due to the higher percentage of water solumble <u>tannins</u> present in the wood. The same coloration of the glues from the wood was present, but to a much higher degree. Thus again the caustic soda treatment may well be recommended as a means of increasing the joint strength. The fact that the vegetable glue gave stronger joints in this case than with Purpleheart, although the joints were still far tooweak for most purposes, also supports the belief that the glue is weak.

A comparison of the strength of thes wood in the solid form with the glued joints as shown in table one, shows the solid wood to be much stronger. When the moisture content of the wood at the times of testing is considered this difference becomes still greater. The solid wood was tested at a moisture content of 13.1% and the moisture content of the wood at the time of gluing was 6.3%.

It was also found impossible to cut microscopic slides from this wood, and thus the penetration of the glue into the wood could not be studied. It is again felt, however, that a great deal more pressure would be necessary to force the glue into the wood.

In conclusion it may be said that this wood cannot be successfully glued by the present commercial methods.

### Discussion (Morabukea)

The results from the tests on this wood indicate that both animal and casein glue work equally well on an average, the animal glue having only a slight edge. The vegetable glue again gave joints that were by far inferior to either of the others. Water solumble tannins were again present but not in such large quantities as to discolor the glue as with the two previous woods.

It was possible to cut microscopic slides of this wood, and thus obtain photomicrographs. These are shown in plates 2to 4. A study of these pictures shows that the penetration of the glues into the wood was very slight. In the case of animal glue, plate two, there was no penetration at all. The casein glue, plate three, has a wide glue line, but the openings in it indicate that the pressure was not great enough. A slight penetration is visable along the glue line of the vegetable glue joint (plate 4). The lack of penetration in all cases seems to indicate a much higher pressure is necessary.

A comparison of the strength of the solid wood and the glued joints shows that the glued wood could not be substituted for the solid wood if high strength were necessary. This difference in strength would be still greater if both tests had been made at the same moisture content; however the solid wood was tested at 14.6% moisture and the glued wood at 6.5%. This difference in moisture effects the strength of the wood considerably.

### PLATE 4

Photomicrograph of Morabukea Wood With Vegetable Glue

Longitudinal Section

The results of the glue joint strength tests on this wood were quite satisfactory. The animal glue, table 11, and casein glue, table 12, gave joints comparable in strength to that of the solid wood. One of the reasons for these favorable results is due to its lower density; thus the wood could be more easily penetrated by the glue. The photomicrographs of sections of this wood show that the glue did penetrate the wood quite deeply, see plates 5, 6, and 7.

The wood does not contain any water solugble tannins, but it does have gum producing properties. As the wood was dry, however, the gum did not interferr with the gluing.

Although this wood can be easily glued, its softness does not make it especially valuable as a wood for finished work. However it may find use as a core wood , another material for which there will be a demand after our supply of chestnut is exhausted.

### Photomicrographs of Cativo With

### Vegetable Glue

Longitudinal Section

Cross Section

#### Discussion (PaunAmarello)

The results obtained from the gluing of this wood with casein glue, table 15, were quite satisfactory. Although the joints were considerably weaker than the shear strength of the solid wood, they were the highest for all of the glues tested. It should also be stated in this connection (3) that the moisture content of the solid wood was 12.8% at the time of testing, while the moisture content of the wood when glued was 5.9%. This difference in moisture indicates that the glued joints were evem weaker than the data shows. The photomicrograph of this wood and glue, plate9, shows very little glue penetration, and thus an increase in pressure might produce even more favorable results.

The animal glue joints, table 14, were unusually low, and it is believed this may be due to an interaction between the <u>tannins</u> in the wood and the glue. The photomicrograph for this wood, and glue, plate 8, shows that the glue line broke away from the wood, and no penetration of the glue into the wood is visable. Thus a caustic soda treatment and a higher pressure might both be attempted to produce better results.

The results for the vegetable glue joints, table 16, seem to be pretty well in line with the results generally obtained with this glue. A satisfactory microscopic section could not be cut, and thus no comparison can be made between the penetration and the strength obtained.

Discussion (Greenheart)

The sesults obtained with both animal glue and casein glue were quite satisfactory with this wood. The shotomicrographs show that the glue did penetrate the wood to some extent, and thus provided mechanical anchorage. It is believed however that a caustic some treatment would increase this joint strength still more. The casein glue formed the best bond between the wood and the glue as the higher percentage of failure in the wood for this glue indicates.

The strength of the vegetable glue joints again was low, although the penetration of the glue into the wood was reasonably good.

## Photomicrograph of Greenheart With

Vegetable Glue

#### Discussion(Macacahuba)

The casein glue gave very favorable results with this wood, giving an average shear strength nearly equal to that of the solid wood. However this statement is based on the solid wood being tested at a moisture content of 10.7% and the moisture content at the time of gluing was 6.0%. Some of the individual joints were very weak however. This is believed to be due to starved joints, a fault of the operator rather than the wood or glue. The glue penetrated into the wood slightly, and thus provided some mechanical anchorage.

The animal glue joints were considerably weaker than those for the casein glue on an average, and the smaller amount of failure in the wood indicates the bond between the wood and the glue was not as good as with the casein glue. The photomicrograph indicates a deepermpenetration of this glue into the wood than was true with the casein glue, especially along the rays.

The vegetable glue joints were true to character and did not show any real joint strength. There was a good penetration of the glue into the wood however.

The caustic soda treatment might well be applied to this wood also. Although there were no signs of a coloration of the glue from the wood, the wood contains a great deal of <u>tannin</u>? which migh easily react with the glue.

PLATE 15

Photomicrograph of Macacahuba With Vegetable Glue

#### Discussion (Imbuia)

The casein glue joints gave by far the best results with this wood. It is hard to account for this superior strength with the data available. The photomicrographs for this wood and glue showing practically no penetration of the glue into the wood. The wood however contained a large amount of tannin and it is possible that this glue was not affected by it.

2

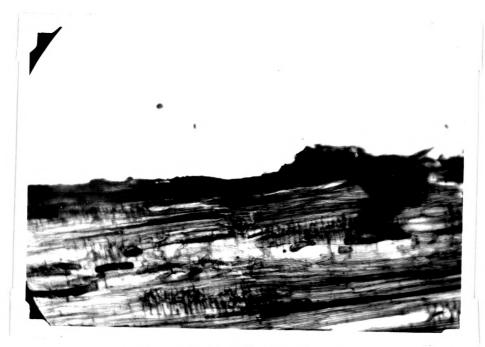

The animal glue joints were very weak compared to those of the casein glue, being about half as great. The glue penetrated the wood well however, and it is again believed ? the tannin is responsible for the poor strength. Thus caustic soda should be tried on this wood.

The vegetable glue joints remained low, although the glue penetrated the wood somewhat. The joints were strong enough however to be used for plywood, the purpose for which thenglue is intended.

## Photomicrographs of Imbuia With

### Vegetable Glue

Longitudinal Section

Cross Section

#### Discussion (Massaranduba)

The casein glue again gave the best results with this wood. Its strength however was considerably below that of the solid wood. The moisture content of the wood must also be considered with its strength. The solid wood at the time of testing was at 13.3% moisture, and the glued wood had a moisture content of 6.2%. The casein glue also exhibited the best bond with the wood. The photomicrographm indicates that there was some penetration of the glue into the wood.

The animal glue also gave favorable results, and there was considerable failure intthe wood indicating a good bond between the glue and the wood. The photomicrograph shows only a slight penetration of the glue into the wood.

The vegetable glue remained in its class and gave joint strengths comparable to that obtained with the other woods tested. The photomicrograph indicates a good penetration of the glue into the wood.

The caustic soda treatment and also an increased pressure might well be tried on this wood in an attempt to obtain greater strength from the glue joints.

Photomicrograph of Massaranduba With

Vegetable Glue

#### Discussion (Sucupira)

The casein glue again gave superior joints with this wood, although the strength did not come up to that of the solid wood. The strength for the solid wood in this case was determined at a moisture content of 12.2%, and that of the wood at the time of gluing was 6.3%. This makes the difference in strength between the solid wood and the glued wood even greater, as the shear strength of wood increases with a decrease in moisture content. A favorable penetration of the glue into the wood rays can be seen in the photomicrograph; however the vessels adjacent to the glue line contain no glue at all.

The animal glue joints, although lower in strength than the casein glue joints, were also quite satisfactory. A fair penetration of the glue into the wood can besseen in the photomicrograph.

The vegetable glue exhibited slightly higher strength with this wood than it did in most of the other woods tested. The photomicrograph also indicates a deeper penetration of the glue into the wood than has existed with most of the other woods.

This wood also contains a water solugible tannin material Which undoubtedly affected the strength of the joints. Thus the caustic soda treatment would be well worth trying, and higher pressure might also increase the strength of the joints.
