## **Implications of bank ownership for the credit channel of monetary policy transmission: Evidence from India**

### **Abstract:**

Many developing and emerging markets have high degrees of state bank ownership. In addition, the recent global financial crisis has led to significant state ownership of banking assets in developed countries such as the United Kingdom. These observations beg the question of whether the effectiveness of monetary policy through a lending channel differs across banks with different ownerships. In this paper, using bank-level data from India, we examine this issue and also test whether the reaction of different types of banks (i.e., private, state and foreign) to monetary policy changes is different in easy and tight policy regimes. Our results suggest that there are considerable differences in the reactions of different types of banks to monetary policy initiatives of the central bank and the bank lending channel of monetary policy might be much more effective in a tight money period than in an easy money period. We also find differences in impact of monetary policy changes on less risky short term and more risky medium term lending. We discuss the policy implications of the findings. Our results from India are preliminary and further studies are needed to see whether our findings can be generalized to emerging economies or developing countries in general.

## 1. Introduction

The recent financial crisis brought to the fore the debate about the bank lending channel of monetary policy transmission. Traditional macroeconomic models such as the IS-LM assume that monetary policy affects the real economic activity by changing interest rates which, in turn, affects the investment demand of the firms. This line of argument has increasingly come under scrutiny, however.<sup>1</sup> To begin with, there is evidence to suggest that investment decisions of firms are affected much more by factors such as cash flows rather than by the cost of borrowing (Bernanke and Gertler, 1995). Further, evidence suggests that banks are not passive intermediaries between the central bank and end users of money such as the firms. For example, in an early discussion of this issue, Bernanke and Blinder (1992) demonstrate that the composition of banks' portfolios change systematically in response to monetary policy initiatives. They conclude that the impact of monetary policy on the investment of firms is not entirely demand driven, and that at least part of it can be explained by the supply side or the bank lending channel. Kashyap and Stein (1993) demonstrate that if a central bank pursues tighter monetary policy, there is a decline in the amount of bank loans to firms and simultaneously a rise in the issuance of commercial paper, and conclude that contractionary monetary policy reduces loan supply.

An important issue for us in this paper is that research suggests that there might be significant heterogeneity in the reaction of banks to monetary policy initiatives. Peek and Rosengren (1995) argue that an important determinant of a bank's reaction would be its capital-to-asset ratio. If banks find it difficult (or expensive) to raise capital, for example, they would be reluctant to lend even if there is ample demand for credit in the aftermath of easing of monetary policy. This hypothesis finds significant support in the empirical literature. Kishan and Opiela (2000) find that small and undercapitalised banks are most affected by monetary policy. Gambacorta (2005) too finds that lending of undercapitalized Italian banks is adversely affected by contractionary monetary policy, even though lending is not correlated with bank size. Further, there is a directional asymmetry in the

---

<sup>1</sup> Theoretically, there have been a number of attempts to extend the IS-LM framework to a multi-asset framework with imperfect substitutability among the assets (Brunner and Meltzer, 1963, 1972; Tobin, 1963; Brainard, 1964). As such, the lending channel view of monetary policy is a special case of these extended frameworks, with money, bonds and loans as three imperfectly substitutable assets (Kashyap and Stein, 1995).

impact of monetary policy on the lending behaviour of undercapitalised banks (Kishan and Opiela, 2006). In the event of contractionary monetary policy, there is a sharp tightening in loan disbursement by undercapitalised banks, but in the event of an expansionary monetary policy there is no corresponding expansion of credit disbursement.

The reaction of banks to monetary policy would also depend on the composition of their assets. The traditional or money view of monetary policy transmission assumes that all asset classes are perfect substitutes of each other. If, therefore, contractionary monetary policy leads to a reduction in deposits, a bank is capable of substituting for this loss of deposits dollar for dollar, using other assets like CDs, such that loan supply would not be affected. Stein (1998) argues that, contrary to this view, assets included in a bank's balance sheet are not perfect substitutes. For example, since deposits are guaranteed by the FDIC (or its overseas counterpart), while CDs are not, there may be adverse selection in the market for CDs, such that banks will not use these instruments to compensate for loss of deposits dollar for dollar. This would result in a decline in loan supply. It follows that banks that have less liquid assets such that it cannot quickly and costlessly compensate for loss of deposits in the event of contractionary monetary policy or, alternatively, those that cannot raise funds quickly to the same end, would react more to monetary policy changes. Kashyap and Stein (2000) find that monetary policy has greater impact on loan supply of banks with low securities-to-assets ratios.

The literature does not, however, examine the impact of bank ownership on the lending channel of monetary policy transmission. This is hardly surprising, given that much of the literature is based on the United States and Western European experiences,<sup>2</sup> where private ownership of banks overwhelmingly dominates. However, as pointed out by La Porta et al. (2000), state-ownership of banks is ubiquitous in much of the world, especially in emerging markets. Indeed, the 2007-09 financial crisis has led to significant state ownership of banking assets even in developed countries such as the United Kingdom, and concerns about the lending activities of the de facto nationalised banks have brought into focus the impact of bank ownership on the lending channel in the developed

<sup>2</sup> See, for example, the following related recent studies focusing on Western European countries: Altunbaş, Fazylov and Molyneux (2002); Huang (2003); Hülsewig, Mayer and Wollmershäuser (2006); De Graeve, De Jonghe and Vennet (2007); and Dovern, Carsten-Patrick and Vilsmeier (In Press)

country context as well. In this paper, we address this lacuna in the literature, and examine whether the impact of monetary policy on lending differs across banks with different ownerships.

Studying how bank ownership plays a role in the credit channel of monetary policy transmission is important because public sector banks account for a significant portion of the banking assets and loan portfolio emerging economies, and, at the same time, many of these countries are fiscally constrained such that monetary policy may be the only instrument available to policy makers to induce growth. This indeed is currently the situation in a wide range of developed countries as well. Our analysis provides an empirical basis for this policy debate concerning the relative effectiveness of monetary policy when a significant proportion of the banking sector is under state ownership.<sup>3</sup> This is one of the key contributions of the paper. Further, by isolating the response of foreign-owned banks, it adds to the small but growing literature on the impact of foreign banks on credit growth, especially in emerging markets context.

Our second important contribution is that we separately examine the reaction of different types of banks (i.e., private, state and foreign) in easy and tight monetary policy regimes. As mentioned earlier, reaction of banks to monetary policy changes may be asymmetric: a change in interest rates might have very different outcomes, depending on whether these rates are low or high to begin with. If an asymmetry does exist, a greater understanding of the differences in the impact of monetary policy in easy and tight money regimes would be imperative for successful monetary policy interventions. The richness of our contribution is enhanced by the fact that, for each of these monetary policy regimes, we estimate the reaction of the different types of banks based on ownership.

Finally, we examine whether impact of monetary policy differs with respect to different maturities, and hence riskiness, of lending activities. Specifically, we examine the impact of monetary policy on disbursement of (more risky) medium term credit and (less risky) short term credit. We estimate the impact for tight and easy monetary regimes, and also for the different types of banks.

---

<sup>3</sup> Note, for example, the public policy debate in the United Kingdom, an industrialised economy, where two large banks are currently in public ownership. The easy monetary stance adopted by the Bank of England has not resulted in credit growth to the desired extent, and there is an on-going debate about the role of these nationalised banks in delinking expansionary monetary policy and credit growth, at a time when economic growth is perhaps of greater importance than inflation targeting.

We use bank-level data from India to examine these issues. We focus on India for several reasons. First, India is a fast growing emerging market that embraced the market economy in the early nineties and has since liberalised its economy substantially. Importantly, in the absence of a well developed market for corporate bonds,<sup>4</sup> banks are by far the largest source of credit for Indian companies,<sup>5</sup> and hence bank lending plays an important role in the transmission of monetary policy in India. Second, the Indian banking sector is also marked by the presence of a number of state-owned and private-owned (including foreign) banks, who compete on a level playing field. Third, the state-owned banks themselves have autonomy regarding lending decisions, and many of them have sold shares to private (and even foreign) shareholders, thereby opening themselves up to greater scrutiny. Indeed, Indian state-owned banks resemble the de facto nationalised banks of the United Kingdom much more closely than state-owned banks in former transition economies of Central and Eastern Europe (see, e.g., Bonin and Wachtel, 2002). The state maintains an arms-length relationship with the banks in which they have majority (or complete) ownership, such that these banks are autonomous and focussed on profitability.<sup>6</sup> In that respect, the state-owned and privately-owned banks are similar, and hence the presumption of profit focus that underlies the analyses of banks in the stylised literature is applicable to all Indian banks. There are, nevertheless, important differences between state-owned and privately-owned banks in terms of their customer base (Berger et al., 2008), and also in terms of factors that affect their lending (Bhaumik and Piesse, 2008). Therefore, there are likely to be differences in ways in which the state-owned and privately-owned banks react to monetary policy initiatives of India's central bank, the Reserve Bank of India (RBI).

Our results indicate that banks of different types respond very differently to monetary policies in different monetary regimes. State-owned and foreign banks cut back on lending following monetary tightening in a tight money regime but domestic private banks do not have a significant reaction to this policy initiative. By contrast, when the monetary environment is easy, state-

<sup>4</sup> Corporate bonds account for only 3 percent of the Indian bond market (Asuncion-Mund, 2007).

<sup>5</sup> Domestic credit provided by banking sector increased from 44.1 percent of GDP in 1995 to 64.2 percent of GDP in 2007 (Source: World Bank Development Indicators).

<sup>6</sup> The state-owned banks are somewhat less efficient than their privately owned counterparts (Kumbhakar and Sarkar, 2003). However, evidence suggests that, contrary to the popular wisdom about state-owned companies, ownership does not significantly affect profitability of Indian banks (Sarkar, Sarkar and Bhaumik, 1998; Bhaumik and Dimova, 2004).

owned and foreign banks either do not respond to monetary tightening, while domestic private banks respond by increasing lending. Aside from providing evidence of differences in response to monetary policy initiatives across banks of different ownership, and between easy and tight monetary regimes, our study also suggests that monetary policy initiatives have different implications for (less risky) short term lending and (relatively more risky) medium term lending. Monetary tightening in a tight money regime adversely affects both short term and medium term lending, especially by foreign banks. But a similar policy initiative in an easy money regime actually increases short term lending, without having an effect on medium term lending. We argue that to a significant extent the behaviour of the different types of banks in the two different monetary regimes can be explained by their closeness to (and hence the extent of informational asymmetry with respect to) their borrower base.

The rest of the paper is structured as follows: Section 2 provides an overview of the banking system and the operation of monetary policy in India. Section 3 explains the empirical methodology and the model specification, and discusses the data. The results are discussed in Section 4. Finally, Section 5 concludes.

## **2. Banking Sector and Monetary Policy in India**

### **2.1 Banking Sector**

Independent India inherited a weak financial system. Commercial banks mobilized household savings through demand and term deposits, and disbursed the credit primarily to large corporations (Ghosh, 1988). This lop-sided pattern of credit disbursal, and perhaps a spate of bank failures that reduced the number of banks from 566 in 1951 to 90 in 1968, led the government to nationalize the banks in 1969. The main thrust of nationalization was social banking, with the stated objective of increasing the geographical coverage of the banking system, and extension of credit to the priority sector that comprised largely of agriculture, agro-processing, and small-scale industries. This phase of banking in India was characterized by administered interest rates, mandatory syndicated lending, and pre-emption of the banks' deposit base by the government in the form of measures like high cash reserve ratio

(CRR) and statutory liquidity ratio (SLR). Banks were required to invest a significant proportion of their deposits in bonds issued by the government and “approved” (quasi-government) institutions. At the same time, between 1969 and 1990, the nationalized banks added over 55,000 branches to their network (Sarkar and Agarwal, 1997).

While the social agenda of the banking sector, measured in terms of geographical and sectoral coverage, was arguably a success, the Indian banking sector, about 88 percent of whose assets were managed by state-owned banks, was in distress. While the ratio of gross operating profit of the scheduled commercial banks rose from 0.8 percent (of assets) in the seventies to 1.5 percent in the early nineties, the net profit of the banks declined. More importantly, perhaps, financial repression involving state-owned banks was not in harmony with the agenda of real sector reforms that the government of India unleashed in the aftermath of the balance of payments crisis of 1991. The RBI, therefore, initiated reform of the banking sector in 1992, based on the recommendations of Narasimham Committee I (Reddy, 1998).

Between 1992 and 1997, the CRR was reduced from 15 percent to about 10 percent, and the SLR was reduced from 38.5 percent to 25 percent over the same period. The interest rates were gradually liberalized. Prior to 1992, the lending rates structure consisted of six categories based on the size of advances. During the 1992-94 period, the lending rates structure was rationalised to three categories, and in 1994 banks were given the freedom to determine interest rates on all loans exceeding 200,000 Indian rupees (INR). By 1998, banks were free to determine the interest rates for all loans, with the understanding that the lending rates on loans up to INR 200,000 would not exceed the declared prime lending rates (PLR) of the banks.

Prior to the initiation of reforms, banks were required to refer all loans above a size threshold to the RBI for authorization, and formation of a consortium was mandatory for all loans exceeding INR 50 million. Bank credit was delivered primarily in the form of cash credit for use as working capital, and there were significant restrictions on the ability of banks to deliver term credit for projects. Finally, the RBI implemented selective credit controls on “sensitive” commodities.

In the wake of the reforms, as early as in 1993, the threshold for the mandatory formation of consortiums was raised tenfold from INR 50 million to INR 500 million. Further, banks within

consortiums were permitted to frame the rules or contractual agreements governing the consortium lending. In 1996, selective credit controls on all sensitive commodities except sugar were removed. Banks were also allowed much greater flexibility about the proportion of the cash credit component of the loans, the new floor being 25 percent. The following year witnessed further elimination of credit controls: Banks were no longer subjected to the instructions pertaining to Maximum Permissible Bank Finance (MPBF), and were allowed to evolve their own methods for assessing the credit needs of the potential borrowers. Further, banks were no longer required to form consortiums to lend in excess of INR 500 million, and restrictions on their ability to provide term loan for projects were withdrawn. However, prudential regulations required that an individual bank not be over-exposed to any one (or group of) creditor(s).

Finally, in 1998, the RBI initiated the second generation of banking reforms, in keeping with the recommendations of Narasimham Committee II. The most important recommendation of the Committee was the creation of asset reconstruction companies (ARCs) to simultaneously improve the quality of the balance sheets of the banks and to facilitate recovery of loans. In a separate development, after a prolonged period of legal disputes, debt recovery tribunals (DRTs) began functioning in India, in earnest, by 1999.

To summarize, by 1996, banks operating in India, were, by and large, in a position to take independent decisions on the composition of their asset portfolio, and on the choice of potential borrowers. Furthermore, there is evidence to suggest that these banks, including the state-owned ones, allocated resources in a way that was consistent with optimization of risk-return tradeoffs. There are, however, significant differences across credit market behaviour of banks of different ownership. Berger et al. (2008) find that comparative advantage of Indian banks, with respect to relationship with potential borrowers, vary considerably with ownership. State-owned banks typically have banking relationship with small firms, state-owned firms and rural firms, domestic private banks have comparative advantage with respect to opaque closely held firms, and foreign banks have banking relationship with large, listed and foreign firms. The likelihood of adverse selection, therefore, varies considerably across banks, by ownership type. Bhaumik and Piesse (2008) demonstrate that bank ownership also has an impact on risk aversion among Indian banks, with foreign banks being

significantly more risk averse than domestic banks. Finally, state-owned banks retained, in principle, the ability to raise capital without being exposed to market forces. Since the impact of monetary policy on bank lending depends in large measure on the risk of adverse selection the extent of risk aversion of banks, and also on their ability to raise affordable capital, we should expect to see considerable differences in the impact of such policy on banks of different ownership.

## **2.2 Monetary Policy**

The authority to implement monetary policy in India rests with the RBI. It was established under the Reserve Bank of India Act of 1934, as a private shareholders' bank, and was subsequently nationalised in 1949. Unlike the Bank of England, which was formally granted independence in 1997, the RBI does not have de jure independence from the Government of India. However, with the phasing out of automatic monetisation of fiscal deficit by 1997 by way of ad hoc treasury bills, the central bank was granted de facto independence. There are strict limits on the ways and means advances by the RBI to the government, and the former does not participate in primary market auctions of government securities. While the RBI takes into cognizance the federal government's views about the state of the economy, it de facto sets monetary policy independently.

Originally, the bank rate and open market operations were the RBI's instruments of choice for conducting monetary policy. In the seventies and eighties, with increased accommodation of the federal government's fiscal policies by the central bank, these instruments lost their efficacy, and the cash reserve ratio (CRR) became the primary instrument for conducting monetary policy. In 1998, in light of the realisation that in an increasingly complex environment broad money supply in the medium term cannot be the sole intermediate target of monetary policy, the RBI formally adopted a multifactor approach to monetary policy. This resulted in a focus on the use of short term interest rates as the instruments of monetary policy, facilitated by the deregulation of interest rates, which was initiated as early as 1989. The bank rate, therefore, made a comeback in 1997-98, and was complemented by the rates for reverse repo (and, from 2000-01, repo) transactions. The repo and reverse repo rates have emerged as the primary instruments of monetary policy since the turn of the century. The CRR, which was reduced steadily from 15 percent in the early nineties to 5 percent by

2004, has not completely been abandoned. It is still used in situations that demand significant monetary response, or when other monetary policy options have been exhausted. The use of all monetary policy instruments of the RBI are summarised in Table 1.

It is evident from Table 1 that it is difficult to select any one instrument as the indicator of monetary policy of the RBI. This poses a problem because empirical analysis requires the use of a single monetary policy signal; the US literature on the lending channel of monetary policy focuses on changes in the federal funds rate (Kashyap and Stein, 1995, 2000), while the European literature uses short-term interest rates (Erhmann et al., 2001) or the refinancing rate (Gambacorta, 2005). Fortunately, Indian banks declare their respective prime lending rates (PLR) – the rate at which they are prepared to lend to the most credit-worthy borrowers – that is linked to their cost of funds. The average PLR of the five largest banks is quoted by the RBI. As evident from Figure 1, movements of this average PLR closely replicates movements in the bank rate, and, to a somewhat lesser extent, also the repo and reverse repo rates. Hence, we use the average PLR reported by the RBI as the basis for our measure of monetary policy. We are not alone in our use of such constructs as the basis for the measure for monetary policy. In the British context, Huang (2003) used the average of the base rates of selected banks as the indicator of monetary policy, while Hofman and Mizen (2004) eschewed the official Bank of England rate in favour of the average of the base rates of four major clearing banks.

### **3. Methodological issues**

In the traditional IS-LM model, a reduction in money supply is immediately translated into a higher equilibrium interest rate in the money market, and this in turn affects the real sector through a reduction in investment. On a bank's balance sheet, a reduction in deposits on the liability side is matched by a reduction in the bank's holding of bonds and loans on the asset side. If bonds and loans are perfect substitutes, as in the traditional Keynesian framework, there would be proportionate reduction in the bonds and loans portfolios. The impact of monetary policy on the asset composition of the banks (and the firms, the borrowers) is of no interest.

Now, suppose that bonds and loans are imperfect substitutes. For example, at least some of the banks might find it easier to both build up and unwind their loans portfolios than their bonds portfolios. In the presence of such imperfections in capital market access, a contractionary monetary policy is likely to be followed by a much greater reduction in loan supply than in sale of (or a drop in the demand for) bonds.<sup>7</sup> The literature on the bank lending channel of monetary policy transmission takes this change in the asset composition of banks into consideration.

As discussed earlier in this paper, there can be considerable cross-sectional variation in the nature of bank's reaction to monetary policy. Banks with strong linkages with their corresponding borrower pools, with resultant amelioration of the informational asymmetry and hence credit risk, might downsize (or reduce the growth of) their loan portfolios less in response to contractionary monetary policy than other banks. Similarly, less capitalised banks and smaller banks that find it more difficult to raise capital might cut back on lending (or reduce lending growth) far more than larger and well-capitalised banks. Since these cross-sectional variations affect only the supply side of the loan market – the banks and not the firms that demand credit – they can be used to circumvent identification problem of empirical modelling the bank lending channel, i.e., distinguishing between the demand and supply side effects of monetary policy on the amount of loans disbursed.

In keeping with the literature, the theoretical basis for which can be found in Ehrman et al. (2003) and Gambacorta and Mistrulli (2004), we model change in loans disbursed by bank  $i$  ( $y_i$ ) as a function of the change in the monetary policy instrument (MP) – the average PLR of the five largest Indian banks in our case. Given the aforementioned cross-sectional heterogeneity in banks' response to monetary policy based on their characteristics, we control for three different bank characteristic in our specification, namely, liquidity (LIQ), capitalisation (CAP) and profitability (PROFIT). This is consistent with the stylised literature (Gambacorta, 2005; Van den Heuvel, 2007).<sup>8</sup> In light of the

---

<sup>7</sup> Alternatively, if bonds are safer than loans, which is often the case in developing countries where the main issuer of bonds are the sovereign governments, a monetary contraction initiated by a central bank might trigger a flight to the less risky asset, with banks downsizing their loans portfolios much more aggressively than their bonds portfolios (Bernanke, Gertler and Gilchrist, 1996; Ashcraft and Campello, 2002). This is the so-called balance sheet channel of monetary transmission that, together with the bank lending channel, comprises the credit channel of monetary policy transmission.

<sup>8</sup> According to Van den Heuvel (2007), changes in bank profitability affects bank lending through the “bank capital” channel. According to this view, when bank profits decline, if equity capital is low, and it is costly to issue shares, banks may reduce lending.

evidence that suggests that bank behaviour in India can be affected by whether or not it is subjected to market scrutiny (see Bhaumik and Piesse, 2008), we also include in our specification a dummy variable (LISTING) that takes the value 1 if a bank is listed at one of the country's stock exchanges. Finally, in order to further facilitate identification to distinguish between loan demand and loan supply, we include industrial growth (IND) that affects the demand for funds much more than banks' behaviour.<sup>9</sup>

Our base specification, therefore, is as follows:

$$\begin{aligned} \Delta y_{it} = & \alpha + \beta \Delta MP_{i,t-1} + \gamma_1 \Delta CAP_{i,t-1} + \gamma_2 \Delta LIQ_{i,t-1} + \gamma_3 \Delta PROFIT_{i,t-1} + \gamma_4 LISTING_{i,t} \\ & + \gamma_5 IND_{i,t-1} + \mu_i + \varepsilon_{it} \end{aligned} \quad [1]$$

where  $t$  represents time,  $\mu_i$  is the bank-specific fixed effect and  $\varepsilon_{it}$  is the i.i.d. error term. In the literature, bank lending models are usually estimated using quarterly data. Since a change in monetary policy in quarter  $t$  is likely to affect disbursement in bank loans with at least a one-period lag,  $\Delta y_{it}$  is modelled as a function of monetary policy in the previous four quarters. However, in the Indian context, only annual data are available for banks, such that the time unit of analysis is a year, as opposed to a quarter. Therefore, we make the reasonable assumption that a change in monetary policy in a given year will affect loans disbursement with a lag, in the following year. Hence, we model  $\Delta y_{it}$  as a function of  $\Delta MP_{i,t-1}$ , the lagged change in the monetary policy instrument.

For the empirical analysis, we amend this base specification in three ways. First, since we focus on the differences in the reactions of bank with different ownership to monetary policy, we interact bank ownership dummies with  $\Delta MP_{i,t-1}$ . Second, we argue that a given change in interest rates cannot have the same impact in a tight and an easy monetary regime; a 50 basis point increase in the interest is likely to have a very different impact on loan disbursement when the initial value of the interest rate is (say) 8 percent, compared to the case when the initial value of the interest rate is (say) 2 percent. Hence, we further interact the  $\Delta MP_{i,t-1}$  variable with an indicator of the nature of the monetary

---

<sup>9</sup> In the literature, the controls for loan demand usually are GDP growth rate and the inflation rate, sometimes used together in the specification. However, there is evidence to suggest that in the Indian context bank's behaviour is influenced more by industrial growth than by GDP growth (Bhaumik and Piesse, 2008), and hence our choice. We also experimented with specifications that included the inflation rate, in isolation as well as together with the industrial growth rate. The coefficient of inflation was never significant, and hence we do not report that specification in the paper.

regime. In other words, our regression estimates identify the impact of monetary policy on loan disbursement for banks of each ownership type, for both the easy and tight monetary regimes. In order to facilitate this process further, following Huang (2003), we include in the specification interaction between  $\Delta MP_{i,t-1}$  and indicators of both these type of regimes: a dummy variable  $MCI$  that takes the value 1 in an easy monetary regime, and its inverse  $IMCI$  that takes the value 1 in a tight monetary regime. The resultant specification is as follows:

$$\begin{aligned} \Delta y_{it} = & \sum_j \alpha_j (IMCI_{t-1} \times \Delta MP_{i,t-1} \times OWN_{jit}) + \sum_j \beta_j (MCI_{t-1} \times \Delta MP_{i,t-1} \times OWN_{jit}) + \gamma_1 \Delta CAP_{i,t-1} \\ & + \gamma_2 \Delta LIQ_{i,t-1} + \gamma_3 PROFIT_{i,t-1} + \gamma_4 LISTING_i + \gamma_5 IND_{i,t-1} + \mu_i + \varepsilon_{it} \end{aligned} \quad [2]$$

where  $OWN$  is a dummy variable capturing type of bank ownership and  $j$  is the index of the types of bank ownership. In the next section we describe our data set and discuss the empirical findings.

## 4. Data and empirical results

### 4.1. Data and descriptive statistics

The data for the estimation are obtained from a number of sources. Bank balance sheets are obtained from the Indian Banks' Association. Using these financial statements, we are able to measure the change in loan disbursement by each bank during each financial year ( $\Delta y_{it}$ ). We measure  $CAP$  as the log of capital and reserves,  $LIQ$  as the log of liquid assets, and  $PROFIT$  as the return on assets. The information about year of stock exchange listing of banks is obtained from the Prowess database marketed by the Centre for Monitoring the Indian Economy. The ownership types of the banks<sup>10</sup> – public sector, old domestic private, new domestic private, and foreign – are obtained from the RBI. As mentioned earlier in the paper, the central bank is also the source for our measure of monetary policy.

We measure  $\Delta MP_{it}$  as the change in the aforementioned PLR between the beginning and end of a

---

<sup>10</sup> The nature of public sector (or state-owned) and foreign banks are easily understood, even though it should be noted that private investors own minority shares in a number of public sector banks. The distinction between the two types of domestic private banks is more complex. The *old* domestic private banks were in operation much before the initiation of the financial reforms in the early 1990s. They were typically closely held, often by members of trading communities. Subsequent to the reforms, many of these banks have floated themselves on stock exchanges and have expanded beyond their traditional geographical enclaves. The *new* private banks came into existence after the financial reforms paved the way for market entry for new banks. Many of them have links to large former or existing non-bank financial institutions. These *de novo* banks by and large have professional management, almost always are stock exchange listed, and have expanded their shares of the deposit and loans markets aggressively. For further details, see Sarkar, Sarkar and Bhaumik (1998) and Bhaumik and Dimova (2004).

financial year. Finally, the indicators of easy and tight monetary regime are obtained from the estimates of monetary conditions index of Kannan et al. (2006).

We include in our sample banks with at least two branches. This primarily leads to exclusion of foreign banks that have a solitary branch in India to finance trading activities of their respective client multinationals. We also exclude from our sample banks that experienced very large changes to their balance sheets, often on account of acquisition of non-banking assets of other financial organisations, or on account of financial distress. Our final sample consists of 58 banks, and the data covers the 2000-07 period, resulting in over 300 bank year observations. Of these, 24 are public sector banks, 21 are old private sector banks, 3 are new private sector banks and 10 are foreign banks.

Summary statistics of the variables used in the regression model are reported in Table 2, and the following can be observed: First, interestingly, old private domestic banks are much smaller, on average, than the new private and foreign banks even though they have operated in India much longer than their new competitors. Further, only 47 percent of old private banks are listed on the stock exchanges, while 65 percent of even *state-owned* banks are stock exchange listed. This is consistent with the observation, highlighted earlier in the paper, that these old private banks are closely held organisations with close links to various business and trading communities. Second, foreign banks are much better capitalised than domestic banks. The ratio of capital and reserves to total assets of foreign banks (9.3 percent) is nearly double that of state-owned banks (5.1 percent), old private banks (5.7 percent) and new private banks (5.4 percent). This could imply either that foreign banks are in a better position to take risk, or that they are more risk averse. Third, the proportion of lending by way of securities such as corporate bonds and debentures is small, and similar across the different types of banks. Bonds and debentures account for 10.1 percent of lending of state-owned banks, 12.3 percent of lending of old private banks, 13.6 percent of lending of new private banks, and 11.5 percent of lending of foreign banks. Finally, the ratio of small-term lending to medium-term lending of state-owned banks (1.08) and old private banks (1.14), a reasonable proxy for the risk appetite of the banks, is much lower than that of new private banks (1.66) and foreign banks (2.90).

## **4.2. Results and discussion**

The regression estimates for the basic model are reported in Table 3. The table has to be read as follows: we use two different measures of credit disbursed. In columns (1) – (3), the measure for credit disbursed is “advances” made by banks to borrowers, while in columns (4) – (6) the measure is the sum of advances and “debentures” when the latter includes subscription to both short term securities like commercial paper and longer term securities like coupon bonds. Further, aside from estimating our model for the entire sample (columns 1 and 4), we separately estimate the model for the public sector or state-owned banks (columns 2 and 5) and all non-state sector banks (columns 3 and 6). There are 334 bank-year observations for the entire sample, of which 144 are for the public sector banks and 190 are for our mix of privately-owned banks. Our decision to pool together the different types of domestic and foreign private sector banks was based on the small sample size for new domestic banks and foreign banks.

For each of these samples, and for each measure of credit disbursal, equation (2) is estimated using fixed effects models that control for time-invariant unobserved characteristics of the banks like their relationships with (and the quality of) the borrowers.<sup>11</sup> The regression statistics reported in the last four rows of the table suggest that overall our model specification fits the data reasonably well. The F-statistics for all the columns are significant at the 1 percent level, and the pseudo R-square values for the regression models are in the 0.23-0.34 range. These R-square values indicate that our specification works better for the models that attempt to explain variations in advances alone, as opposed to variations in the sum of advances and subscriptions to debentures by the firms. Importantly, our results are robust across the choice of the measure of credit and the choice of the sample.

In Table 3, we first report the impact of monetary policy on the growth rate of credit disbursed by banks of different types of ownership in a tight money regime. These are the regression coefficients  $\alpha_i$  in equation (2). Given that an increase in the interest rate in a tight money regime should lead to a decline in credit disbursal, we expect  $\alpha_i$  to be negative. We next report the impact of monetary policy

---

<sup>11</sup> We experimented by extending the specification in equation (2) to a dynamic panel framework, adding a lagged dependent variable to the list of explanatory variables. The coefficient of the lagged dependent variable was insignificant for both the fixed effects estimation and that involving the Arellano-Bond estimator. Hence, we dropped the lagged dependent variable from the specification and returned to the specification in equation (2).

in the growth rate of credit disbursed by the different types of banks in an easy monetary regime. These are the regression coefficients  $\beta_i$  in equation (2). In an easy money regime, when the interest rate level is relatively low, credit disbursal by banks may not be negatively affected by an increase in this interest rate. Indeed, if the monetary tightening in an easy money regime signals an attempt by the central bank to dampen the speed of expansion in a fast growing real economy, there might actually be an increase in borrowing in the near term, in anticipation of further rate rises in the future. Hence, we do not have any ex ante expectations about the signs of the estimated  $\beta_i$ . Finally, we report the coefficient estimates of the control variables.

The regression results suggest that credit disbursal by both public sector banks and foreign banks is adversely affected by a tightening in monetary policy in a tight money regime, i.e.,  $\alpha_i < 0$  for  $i \in \{\text{public sector, foreign}\}$ . To begin with, this demonstrates that, contrary to popular wisdom in the ownership literature, and in keeping with the literature on the Indian banking sector (Sarkar, Sarkar and Bhaumik, 1998; Bhaumik and Dimova, 2004), public sector banks operate on the basis of market incentives. The much larger (and negative) response of credit disbursal by the foreign banks to monetary tightening, despite the fact that these banks typically have relationship with multinationals operating in India and blue chip domestic firms (Berger et al., 2008), demonstrates that these banks are quite risk averse when it comes to credit disbursal to emerging market entities. This could be on account of the fact that foreign banks often have disadvantages in obtaining and processing information about firms in overseas markets, especially when information is costly (Stein, 2002). These banks also have a less diversified customer base in the host country and hence are more vulnerable to adverse shocks.

Importantly, credit disbursal by the old and new private sector banks are unaffected by the monetary policy action of the central bank. Given the small sample for new private banks, it is difficult to draw general conclusions about these banks. But the result for the old private banks possibly reflects the informational advantage that these banks have over other types of banks regarding their customers; they are less concerned about adverse selection. As demonstrated by Berger et al. (2008), most old private banks in India are community based and are concentrated geographically,

with a comparative advantage in lending to companies belonging to allied trading and business communities.

The coefficient estimates for  $\beta_i$ , which capture the impact of monetary policy on credit disbursement by banks during easy money periods, are entirely consistent with the estimates for  $\alpha_i$ . During easy money periods, a monetary policy induced change in the interest rate has a weak impact on credit disbursement by public sector banks (column 4) and none on the disbursement by foreign banks, but there is a noticeable increase in the disbursement of credit by old private banks. (Once again, for the reason mentioned above, we ignore the coefficient estimate for the new private banks.) In other words, if the interest rate is low, monetary tightening does not affect the credit disbursement of banks that are at an informational disadvantage – the public sector and foreign banks – because the interest rate is low to begin with. However, old private banks for whom the problem of informational asymmetry is not acute, lend more, on average, possibly accommodating greater demand for credit in anticipation of further rate increases in the future.

Of the control variables, only two are significant. Capital adequacy and liquidity of banks do not have any impact on credit disbursement. This contrasts with the literature on developed countries where capital adequacy, in particular, affects bank lending to a significant extent (Thakor, 1996; Hancock et al., 1999). Growth of credit disbursement is affected by demand for credit, as captured by industrial growth. And lending increased with profitability of private banks, even though profitability of public sector banks does not have any impact on credit. Given that our fixed effects model controls for the (arguably time invariant) quality of the borrowers, this suggests that private banks lend more if they have greater ability to absorb adverse shocks by way of loan defaults.

Next, we distinguish between less risky short term loans, those with maturity less than one year, and medium term loans, those with maturity of 1-3 years. We ignore long term loans because they constitute a very small proportion of the loan portfolio of most Indian banks. Since the results reported in Table 3 were robust to the measure of credit, for this exercise we use advances as our measure of credit. The regression estimates for these models are reported in Table 4. As before, we estimate the model for the sample of all banks and sub-samples of public sector and private sector

banks. The F-statistics are significant once again, albeit at the 5 percent level. There is also a sharp reduction in the pseudo R-square values. However, as we shall see, the results are quite suggestive.

We find that in a tight money regime a further monetary tightening by the central bank leads to a decline in disbursement of both short term and medium term credit by public sector and foreign banks. The result is especially strong for foreign banks. Further, the decline in credit disbursement by foreign banks is much larger for medium term advances than for short term advances. This is entirely consistent with the fact that medium term loans are more risky. Interestingly, while there is a sharp contraction of short term advances made by state-owned banks in the tight money regime, there is no statistically significant impact on medium term advances. A plausible explanation for this is that the pool of borrowers that receive short term credit from state-owned banks is more risky than the pool of borrowers that receive medium term credit.<sup>12</sup> As before, in the easy money regime, a monetary tightening leads to an increase in credit disbursed by old private banks. However, the increase in credit disbursed is restricted to short term loans; there is no impact on medium term loans. Interestingly, the differentiation between short term and medium term advances demonstrates that while the impact of monetary tightening in easy money regimes on overall credit disbursement by public sector banks is weak or insignificant (see Table 3), such tightening has positive impact on disbursement of short term loans.

Overall, there is support for the view that monetary tightening by the central bank leads to a reduction in credit disbursement by Indian banks, albeit only in tight monetary regimes. Given that public sector banks and foreign banks account for over 80 percent of the banking assets (and loan portfolio) in India, the bank lending channel of monetary policy transmission in India can be viewed as being fairly active during tight monetary regimes. In easy monetary regimes, however, monetary tightening can have the perverse effect of increasing credit disbursement. However, much of this increase in credit would be in the form of short term loans, thereby limiting its impact on the real sector.

Importantly, there are significant differences in the reaction of banks of different ownership to monetary policy actions of the central bank. Foreign banks are by far the most risk averse. They react to monetary tightening during tight money regimes by sharply reducing credit disbursement, and the

---

<sup>12</sup> Data permitting, it would be interesting to discover whether this increase in disbursement of medium term credit is directed towards public sector enterprises with respect to whom public sector banks may have an informational advantage, or whether it is directed to the entire range of borrowers.

decline is much greater for riskier medium term loans than for relatively safe short term loans. This is in sharp contrast to the behaviour of foreign banks in Latin America where they are much less responsive to changes in monetary policy (Arena, Reinhart and Vasquez, 2006). State-owned banks also curtail credit during these periods, albeit by a much smaller magnitude, but there is weak evidence to suggest that they may actually extend more (short-term) credit following monetary policy tightening during easy money regimes. Finally, the old private banks are least risk averse. The impact of monetary tightening on their lending is insignificant during tight money regimes, and they actually expand (short term) credit following monetary tightening during easy money regimes. This implicit ranking of the risk aversion of the different types of banks is consistent with their degree of exposure to informational asymmetries vis-a-vis their customer base. The old private banks are most closely connected to their borrower base, while foreign banks have the greatest informational disadvantage. The public sector banks are arguably somewhere in the middle, with informational advantage with respect to public sector enterprises but, given their large and diverse customer base, inevitably with informational disadvantage with respect to a section of the borrowers. We discuss the policy implications of this in the concluding section.

Thus far, we have discussed the direction of change in advances made by the different types of banks, under different monetary conditions, tight or easy. How economically meaningful, however, is the impact of monetary policy initiatives, wherever statistically significant? Consider the results reported in Table 3. The regression coefficients reported in columns (1-3) suggests that a 1 percentage point increase in PLR in a tight money regime would reduce advances made by state-owned banks by 13 percent, and advances made by foreign banks by 38-39 percent.<sup>13</sup> Given the mean advances reported in Table 2, this would indicate a total reduction in advances by approximately INR 5,143 billion.

## 5. Conclusions

---

<sup>13</sup> As highlighted by Figure 1, the PLR, our proxy for the policy rate, did not change by more than 1 percentage point during the 2001-2007 estimation period. At the same time, India experienced double digit credit growth annually, sometimes in excess of 20 percent. These *ceteris paribus* estimates of banks' reactions to interest rate changes are, therefore, entirely plausible.

There is a fairly large literature on the bank lending channel of monetary policy. But much of this literature is in the context of the United States, Europe and other developed economies where the banks are heterogeneous but are almost entirely in private sector. The emerging market economies, by contrast, have their fair share of state-owned banks, such that, in these contexts, the implications of ownership for the bank lending channel remains an important, yet largely unexplored, policy consideration. In this paper we address this issue, using bank-level data from India.

Our results suggest that there are considerable differences in the reactions of different types of banks to monetary policy initiatives of the central bank. During periods of tight monetary policy, as captured by the monetary conditions index, state-owned banks and foreign banks curtail credit in response to an increase in interest rate. The reaction of foreign banks is particularly sharp. The reactions of the domestic private banks are not statistically significant. By contrast, during easy money periods, an increase in interest rates by the central bank leads to an increase in the growth of credit disbursed by old private banks, with no significant reactions from other types of banks. The regression results also indicate that the adverse reaction to a policy initiated increase in interest rate in a tight monetary regime is much greater for medium term borrowing than for short term borrowing.

Our results have two significant implications for the literature on bank lending channel. First, it suggests that the bank lending channel of monetary policy might be much more effective in a tight money period than in an easy money period. In other words, if interest rates are low, then a central bank that desires monetary contraction may have to raise the rate substantially to witness an impact on money supply through the bank lending channel. This has implications for future analyses of the bank lending channel; the condition under which a central bank changes its policy rate should be explicitly taken into account. It has also implications for the implementation of monetary policy strategies during a business cycle period or economic crisis. For example, if the economy is going through a downturn and the authorities try to stimulate the economy towards the recovery zone, then, depending upon the type of money regime the economy is in, the policymakers need to consider making adjustments in policy rates to get the desired effects. Second, the bank lending channel is likely to function much better if the banks have arms length relationship with the borrowers, resulting in informational asymmetry between them. If banks are relatively small and closely tied to their borrower

base, monetary policy initiatives may have limited impact because the likelihood of adverse selection may not increase significantly. This has implications for the post-crisis debate about the size of banks and their relationship with borrowers.
