would not have been possible, and all the clinicians around the PECARN who enrolled children in this study.

**Abstract**

**Objective:** To compare the accuracy of the pediatric Glasgow Coma Scale (GCS) score in preverbal children to the standard GCS score in older children for identifying those with traumatic brain injuries (TBIs) after blunt head trauma.

**Methods:** This was a planned secondary analysis of a large prospective observational multicenter cohort study of children with blunt head trauma. Clinical data were recorded onto case report forms before computed tomography (CT) results or clinical outcomes were known. The total and component GCS scores were assigned by the physician at initial ED evaluation. The pediatric GCS was used for children <2 years and the standard GCS for those ≥2 years. Outcomes were TBI visible on CT and clinically-important TBI (ciTBI), defined as death from TBI, neurosurgery, intubation for more than 24 hours for the head injury, or hospitalization for 2 or more nights for the head injury in association with TBI on CT. We compared the areas under the receiver-operating characteristic (ROC) curves between age cohorts for the association of GCS and the TBI outcomes.

**Results:** We enrolled 42,041 patients of whom 10,499 (25.0%) were <2 years old. Among patients <2 years, 313/3,329 (9.4%; 95% CI 8.4, 10.4%) of those imaged had TBIs on CT and 146/10,499 (1.4%; 95% CI 1.2, 1.6%) had ciTBIs. In patients ≥2 years, 773/11,977 (6.5%; 95% CI 6.0, 6.9%) of those imaged had TBIs on CT and 572/31,542 (1.8%; 95% CI 1.7, 2.0%) had ciTBIs. For the pediatric GCS in children <2 years, the area under the ROC curve was 0.61 (95% CI 0.59, 0.64) for TBI on CT scan and 0.77 (95% CI 0.73, 0.81) for ciTBI. For the standard GCS in older children, the area under the ROC curve was 0.71 (95% CI 0.70, 0.73) for TBI on CT scan and 0.81 (95% CI 0.79, 0.83) for ciTBI.

**Conclusions:** The pediatric GCS for preverbal children was somewhat less accurate than the standard GCS for older children in identifying those with TBI on CT. However, the pediatric GCS for preverbal children and the standard GCS for older children were equally accurate for identifying ciTBI.
INTRODUCTION

The Glasgow Coma Scale (GCS) score is one of the most recognized and widely used tools for assessment of level of consciousness and severity of mental status alteration in patients with traumatic brain injuries (TBIs) and a variety of other neurological conditions. The GCS score is calculated by adding the scores of the following three components: eye response (range 1-4), verbal response (range 1-5), and motor response (range 1-6). The GCS score is used to categorize TBI severity as mild, moderate, or severe, is a component of outcome prediction models and is used to guide therapy.

Due to the need for verbal interaction, clinicians cannot use the standard GCS score to appropriately assess preverbal children. Therefore, the pediatric GCS score is a modified GCS score for use in preverbal children. The pediatric GCS uses age appropriate modifications to account for developmental differences in verbal, motor and cognitive abilities. (Table 1)

There has been very limited prospective study, however, of the accuracy of the pediatric GCS in identifying young children with TBIs, particularly in the emergency department (ED) setting. Our prior research at a single ED suggests that the pediatric GCS score in children 2 years and younger compares favorably with the standard GCS when used for the evaluation of blunt head trauma in children. These data, however, require further validation in a larger study.

We previously conducted a large prospective multicenter study to develop and validate prediction rules for identifying children with clinically-important TBIs (ciTBIs) after blunt head trauma. The standard GCS score for older children, and the pediatric GCS score for children younger than 2 years, were prospectively collected at ED presentation.

In the current sub-analysis of the parent study, we sought to compare the performance of the pediatric and standard GCS scores for identifying children with TBIs on CT and ciTBIs. The secondary objective was to compare the performance of the individual
components of the standard and pediatric GCS scores. We hypothesized that the pediatric GCS score in preverbal children would perform as well as the standard GCS score in verbal children for identifying those with TBIs.

METHODS

Study Design
This was a planned secondary analysis of a large prospective observational multicenter study of children with blunt head trauma. Information about, and methods of the parent study population are described elsewhere. The methods specific to this study are described below. The study was approved at each site IRB.

Study Setting and Population
The study was conducted between June 2004 and September 2006 at 25 pediatric EDs in the Pediatric Emergency Care Applied Research Network (PECARN). We included patients younger than 18 years who were evaluated in any PECARN participating ED after a history of nontrivial blunt head trauma. For this sub-analysis, we excluded children who did not have GCS scores recorded at the time of the initial ED evaluation.

Study Protocol
The ED clinician completed a history and physical examination on each patient and recorded the data onto a case report form before CT scan results or clinical outcomes.
were known. Two faculty or fellow physicians independently evaluated a convenience sample of 1,443 patients with all three GCS components documented by both evaluators to determine the inter-observer agreement for GCS. The second evaluation was completed within one hour of the first evaluation. We used the pediatric GCS score to evaluate children younger than 2 years and the standard GCS score for children 2 years and older.

**Measurements**

We compared the pediatric and standard GCS scores against two different outcomes: TBI on CT and ciTBI. As per the parent study, TBI on CT was defined by the presence of intracranial blood, pneumocephalus, cerebral edema, diastasis of the skull, or skull fracture depressed by at least the width of the skull. ciTBI was defined as death from TBI, a neurosurgical procedure, intubation for more than 24 hours for the head injury, or hospitalization for ≥2 nights because of the head injury in association with TBI on CT.

**Follow-up Procedures**

The records of patients admitted to the hospital were reviewed by research coordinators for outcome determination. For all patients discharged home from the ED, we conducted telephone or mail follow-up 7-90 days after the ED visit to ascertain for patients with missed TBIs. For those we could not reach by telephone or mail follow-up, we reviewed the medical records, ED process improvement records, trauma registries and county morgue records to ensure that no discharged patient was subsequently diagnosed with a ciTBI.

**Data Analysis**

Each variable was described for the pediatric and standard GCS cohorts using counts, percentages, and 95% confidence intervals (CI) for categorical variables and the median and inter-quartile ranges (IQR) (25th-75th percentile) for continuous variables. We compared the patient characteristics, rate of TBI on CT, and rate of ciTBI by GCS cohort using rate differences with 95% CI.

We used receiver operating characteristic (ROC) curves with 95% CI to test the
association of the total GCS scored and its individual components against TBI on CT and ciTBI between the two GCS cohorts. To assess for inter-observer agreement, we calculated the kappa statistics for the pediatric and standard GCS cohorts using the Fleiss-Cohen weighted kappa with standard quadratic weights. The 95% confidence limits were calculated using normal approximation methods. A 95% lower confidence limit greater than 0.4 denoted at least moderate agreement. All analyses were conducted using SAS version 9.3 (SAS Institute Inc., North Carolina).

RESULTS

The parent study enrolled 43,904 eligible patients. A total of 42,041 (95.8%) patients met the inclusion/exclusion criteria of the parent study, except that all patients with all GCS scores were eligible for the current study. Those with GCS scores available compose the study population for the current analysis. There were 10,499 patients in the pediatric GCS group and 3,329 (31.7%) had CT scans performed in the ED. In the standard GCS group, there were 31,542 patients and 11,977 (38.0%) had CT scans performed in the ED. The baseline characteristics between the pediatric and standard GCS cohorts are presented in Table 2. The median age of the pediatric GCS cohort was 1.0 years (IQR: 0.5, 1.5) and for the standard GCS cohort was 8.6 years (IQR: 4.5, 13.7). Of note, approximately 2% of the patients had GCS scores between 3 and 13.

Among the children imaged with CT, the rate of TBI on CT was significantly higher in children who were in the pediatric GCS cohort [313/3,329 (9.4%; 95% CI 8.4, 10.4%)] compared to those in the standard GCS cohort [773/11,977 (6.5%; 95% CI 6.0, 6.9%)] (risk difference 2.9%; 95% CI 1.9, 4.0%). The rate of ciTBI, however, was lower in the pediatric GCS cohort [146/10,499 (1.4%; 95% CI 1.2, 1.6%)] compared to those in the standard GCS cohort [572/31,542 (1.8%; 95% CI 1.7, 2.0%)] (risk difference -0.4%; 95% CI -0.7, -0.2%), although the difference between groups was small and likely not clinically relevant.

The area under the ROC curve for the association between the GCS score and TBI on CT was 0.61 (95% CI 0.59, 0.64) in the younger cohort and 0.71 (95% CI: 0.70, 0.73)
for the older cohort (Figure 1). The area under the ROC curve for the association
between the GCS score and ciTBI was 0.77 (95% CI 0.73, 0.81) for the younger cohort
and 0.81 (95% CI 0.79, 0.83) in the older cohort (Figure 2). The association between
the areas under the ROC curves for the individual components of the pediatric and
standard GCS scores (eye, verbal, motor) and TBI on CT, and ciTBI are presented in
Figures 3 and 4, respectively. For both TBI outcomes, the areas under the ROC curves
for the total GCS score were most similar to those for the verbal component of the GCS
score for the pediatric and standard GCS cohorts.

The inter-observer agreements as measured by the Kappa statistics for the pediatric
and standard GCS cohorts are shown in Table 3. In each GCS cohort, the total GCS
score and all individual GCS score components met the criteria for at least moderate
inter-observer agreement (Kappa 95% lower confidence limit > 0.4).

We were able to contact 79% of patients discharged home from the ED with a
telephone call or mailed follow-up form. The remaining 21% had ED chart review,
process improvement review, trauma registry review, and morgue review. No patient
discharged from the ED was subsequently found to require neurosurgery or died.

DISCUSSION

In this multicenter study of a large cohort of children with blunt head trauma in the ED
setting, the pediatric GCS score for children younger than 2 years performed similarly to
the standard GCS in older children for identifying those with ciTBI. For identifying
children with TBI on CT, however, the performance of the pediatric GCS in children
younger than 2 years was somewhat less accurate than that of the standard GCS in
older children.

These data differ from those of our previous single-site study that found similar
performance of the pediatric GCS and standard GCS for identifying children with TBI on
CT, and a better performance of the pediatric GCS compared to the standard GCS in
Modifications to the standard GCS attempt to create a pediatric GCS score which is helpful in evaluating the level of alertness in head injured, preverbal children. However, none of the previous studies besides one have evaluated the pediatric GCS score prospectively in the ED setting. The other previous studies were small, retrospective, or conducted in the inpatient / ICU setting. The pediatric GCS score evaluated in the current study is one of the earliest proposed and most widely used. The scoring for eye opening is similar to that of the standard GCS score, however, modifications are made to four of the five verbal components, and two of the six motor response components. These modifications are necessary to evaluate preverbal children who are verbally and developmentally limited, and unable to follow commands or answer questions.

Despite its nearly ubiquitous use, the GCS score has certain limitations, including variations in inter-rater reliability, predictive validity, and difficulty in assessment of intubated or sedated patients. To further explain these limitations, researchers have sought to demonstrate predictive abilities of individual components of the GCS score. Prior data in adult patients suggest the motor component is more important than the verbal or eye responses and may be as useful as the total GCS in identifying those with TBI. In the current study, of the three components of the GCS score, the verbal component demonstrated the best test performance for both outcomes in both age cohorts, whereas the motor component demonstrated the worst performance. In adults with severe head injuries, the motor component of the GCS has been shown to be the component most strongly correlated with injury severity and outcomes. One small trauma registry study of 96 children up to 18 years old with moderate-to-severe head injuries demonstrated similar findings, as did a more recent retrospective review of
seriously-injured children.\textsuperscript{22} In a previous study of children with mostly minor head trauma, however, the verbal and eye components were somewhat more important than the motor component consistently, but this did not achieve statistical significance.\textsuperscript{7} The identification of the verbal component as most strongly correlated with TBI in the current study is consistent with these previous data, likely because the great majority of patients in the current study had minor head trauma as defined by GCS scores of 14-15, as was the case for the previous study.\textsuperscript{7} The verbal component of the GCS was the component most likely not to receive the maximum score in both age cohorts. This likely supports its better discriminatory power, however, it is also likely that this variable is the most difficult to assess in preverbal children.

The pediatric GCS used in this study removes one point from the maximal verbal score for the young child who is irritable or cries. On arrival to the ED, children who have experienced traumatic injuries are frequently frightened and in pain; therefore, crying and irritability in this setting are not unexpected. This component of the GCS score is subject to modification by multiple factors including administration of analgesics, parental presence, and time to adjust to the stressful environment of the ED. Therefore, this component of the pediatric GCS is dynamic and changes in this particular GCS component may not reflect actual changes in mental status. In spite of this limitation, the pediatric GCS in the younger patients in this study demonstrated similar test performance for identifying children with ciTBIs as the standard GCS in older children.

The results of this study have pertinent clinical and research implications. This study is the only prospective multicenter study to test the pediatric GCS in preverbal children in the ED setting. The results confirm that clinicians can use the pediatric GCS when evaluating those children presenting to the ED with blunt head trauma. ED clinicians can have confidence that the age-appropriate modified pediatric GCS is as accurate as the standard GCS in identifying children with ciTBI, and the pediatric GCS can be reliably used in clinical research.

\textbf{LIMITATIONS}

This article is protected by copyright. All rights reserved
This study has certain limitations. Only 36% of the study population underwent cranial CT imaging. It is possible that some children who were not imaged may have had traumatic findings on CT. However, clinical outcomes were recorded for all patients, and our main outcome, ciTBI, is a clinical outcome that does not require neuroimaging.

In this study we used an age threshold of 2 years to define the population of preverbal patients for whom the pediatric GCS should be applied. This age threshold is somewhat conservative as some children older than 2 years may still be preverbal. Use of the 2-year age cutoff would potentially bias against the accuracy of the standard GCS and thus could worsen the performance of the pediatric GCS score. Prior studies, however, have used a similar age threshold. Finally, because we studied only one of the several versions of the pediatric GCS, it is unknown whether other modifications of the GCS for use in preverbal children may enhance its performance.

**CONCLUSIONS**

Although the pediatric GCS score for evaluation of preverbal children with blunt head trauma evaluated in the ED was somewhat less accurate than the standard GCS used for older children for identifying those with TBIs on CT, it was equally accurate for identifying children with ciTBIs. Therefore clinicians and researchers can confidently use the pediatric GCS when evaluating preverbal children for ciTBIs. **Table 1:**

\(^{a}\) Injury mechanism severity was defined as follows:

**Severe**: motor vehicle crash with patient ejection, death of another passenger, or rollover; pedestrian or bicyclist without helmet struck by a motorized vehicle; falls greater than 5 feet for patients 2 years and older or falls greater than 3 feet for those younger than 2; or head struck by a high-impact object

**Mild**: ground-level falls or running into stationary objects

**Moderate**: any other mechanism
