Abstract

Endometrioid carcinoma (EC) is a relatively indolent ovarian carcinoma subtype that is nonetheless deadly if detected late. Existing genetically engineered mouse models (GEMMs) of the disease, based on transformation of the ovarian surface epithelium (OSE), take advantage of known ovarian EC driver gene lesions, but do not fully recapitulate the disease features seen in patients. An EC model in which the *Apc* and *Pten* tumour suppressor genes are conditionally deleted in murine OSE yields tumours that are biologically more aggressive and significantly less differentiated than human ECs. Importantly, OSE is not currently thought to be the tissue of origin of most ovarian cancers, including ECs, suggesting that tumour initiation in Müllerian epithelium may produce tumours that more closely resemble their human tumour counterparts. We have developed *Ovvp1-iCreER^{T2}* mice in which the *Ovvp1* promoter controls expression of tamoxifen (TAM)-regulated Cre recombinase in oviductal epithelium – the murine equivalent of human Fallopian tube epithelium. *Ovvp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice treated with TAM or injected with adenovirus expressing Cre into the ovarian bursa uniformly develop oviductal or ovarian ECs, respectively. On the basis of their morphology and global gene expression profiles, the oviduct-derived tumours more closely resemble human ovarian ECs than do OSE-derived tumours. Furthermore, mice with oviductal tumours survive much longer than their counterparts with ovarian tumours. The slow progression and late metastasis of oviductal tumours resembles the relatively indolent behaviour characteristic of so-called Type I ovarian carcinomas in humans, for which EC is a prototype. Our studies demonstrate the utility of *Ovvp1-iCreER^{T2}* mice for manipulating genes of interest specifically in the oviductal epithelium, and establish that the cell of origin is an important consideration in mouse ovarian cancer GEMMs.

Introduction

Ovarian carcinomas are subclassified into different histological types on the basis of their morphological similarity to the different types of Müllerian epithelium lining the female genital tract. Increasingly, genetic and immunohistochemical signatures are helping to define ovarian cancer subtypes [1]. Endometrioid carcinoma (EC) is the second most common type of ovarian carcinoma, representing 7–24% of cases [2,3]. Ovarian ECs are characterized by well-formed glands that resemble endometrial glands during the proliferative phase of the menstrual cycle. Most are believed to arise from

the Müllerian epithelium associated with endometriosis or benign neoplasms known as endometrioid adenofibromas and endometrioid borderline tumours.

On the basis of both histopathological and molecular data, a ‘dualistic’ model has been proposed in which ovarian carcinomas can be divided into two main categories that reflect their pathogenetic features [4,5]. Type I ovarian carcinomas are low-grade, relatively indolent and genetically stable tumours, often arising from recognizable precursor lesions, and frequently harbouring somatic mutations that deregulate specific cell signalling pathways or chromatin remodelling complexes. Endometrioid, clear cell and mucinous carcinomas, and low-grade serous carcinomas, are considered to be Type I tumours. In contrast, Type II carcinomas

(mostly high-grade serous carcinomas) are high-grade, biologically aggressive tumours from their outset, with a propensity for metastasis from small-volume primary lesions. Type I tumours have a more favourable prognosis than the Type II tumours, largely because they are more likely to be detected and resected before they have metastasized. However, women with advanced-stage Type I carcinomas have poor overall survival, and more effective therapies are needed [6].

Histological type-specific models that reflect the heterogeneity of ovarian carcinomas could be used to improve our understanding of their biology and to investigate new prevention strategies, improve early detection, and test novel therapies. Several genetically engineered mouse models (GEMMs) of ovarian EC have been developed on the basis of neoplastic transformation of the ovarian surface epithelium (OSE) instigated by genetic lesions in the murine homologues of genes mutated in human ECs. For example, Dinulescu *et al* generated a model of EC based on conditional inactivation of *Pten* and activation of *Kras* in the OSE by injecting adenovirus expressing Cre recombinase (AdCre) into the ovarian bursal cavity [7]. Similarly, Guan *et al* reported a model of EC based on conditional inactivation of *Pten* and *Arid1a* in the OSE [8]. Human ovarian ECs often harbour mutations predicted to concomitantly activate the canonical Wnt and phosphoinositide 3-kinase–AKT signalling pathways [9,10]. We previously described a mouse EC model in which these two pathways are dysregulated by conditional deletion of the *Apc* and *Pten* tumour suppressor genes in the OSE induced by ovarian bursal injection of AdCre [9]. Following concurrent *Apc* and *Pten* inactivation, these mice uniformly and rapidly develop ovarian carcinomas with some similarities to human ECs, although the tumours are significantly less differentiated and behave more aggressively than their human tumour counterparts. The previously described mouse models of ovarian EC arising from OSE transformation have limitations, because recent studies have suggested that many, perhaps most, ovarian carcinomas do not arise from the OSE. Indeed, Kurman *et al* have proposed that both Type I and Type II ovarian carcinomas typically involve the ovaries as a metastatic site, or arise from extra-ovarian Müllerian cells that involve the ovary secondarily [11,12].

Carcinomas with endometrioid differentiation constitute the majority of uterine endometrial cancers, and can also arise in the fallopian tube, albeit uncommonly [13–17]. We have developed mice in which the oviductal glycoprotein 1 (*Ovgp1*) promoter is used to drive expression of tamoxifen (TAM)-regulated Cre recombinase specifically in the oviductal (equivalent to human Fallopian tube) epithelium, and not in the OSE. In this study, we wished to study the effects of cell of origin on the morphological and biological features of tumours arising from Müllerian epithelium versus the OSE. *Ovgp1-iCreER^{T2}* mice harbouring floxed *Apc* and *Pten* alleles were treated with TAM to induce oviductal tumour formation. Tumours were also induced in the OSE of genetically comparable mice by injecting AdCre

into the ovarian bursal cavities. Our goal was to determine which of the two model systems yields tumours that better recapitulate the morphological features, gene expression profiles and biological behaviour of human ovarian EC.

Materials and methods

Genetically modified mice and animal care

To generate *Ovgp1-iCreER^{T2}* transgenic mice, a codon-improved *iCreER^{T2}* cDNA was inserted at the translation initiation codon of *Ovgp1* within a 90-kb bacterial artificial chromosome (BAC) (RP23-169-H9) containing the entire *Ovgp1* locus, by use of the Counter Selection BAC Modification Kit (Gene Bridge, Heidelberg, Germany). Recombinant BAC DNA was microinjected into fertilized (C57BL/6 X SJL) F2 mouse eggs (University of Michigan Transgenic Animal Model Core) as described by Nagy *et al* [18]. Selected founder lines were crossed with reporter mice carrying the *Gt(ROSA)26Sor^{tm1(EYFP)Cos/J}* allele (hereafter referred to as *Rosa^{LSL-EYFP}*) (Jackson Laboratory, Bar Harbor, ME, USA) to generate *Ovgp1-iCreER^{T2};Rosa^{LSL-EYFP}* double transgenic mice. The *Ovgp1-iCreER^{T2}* mice were also crossed with *Apc^{fl/fl};Pten^{fl/fl}* mice to generate triple transgenic *Ovgp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice. The *Apc^{fl/fl};Pten^{fl/fl}* mice have been described previously in detail [9,19,20]. All strains were maintained on a mixed genetic background, and littermates were used for the *Ovgp1-iCreER^{T2}* and AdCre gene targeting. Procedures involving mice for the research described herein have been approved by the University of Michigan's Institutional Animal Care and Use Committee (PRO00006370).

Induction of oviductal and ovarian tumours

Ovgp1-iCreER^{T2} female mice were given intraperitoneal injections of TAM (Sigma-Aldrich, Indianapolis, IN, USA) to activate Cre in the oviductal murine Fallopian tube epithelium (FTE). TAM was dissolved in corn oil (Sigma-Aldrich), and injected at 0.1 g/kg of body weight twice (day 1 and day 3) when mice were aged 6–8 weeks. Alternatively, *Ovgp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice were injected with 5×10^7 plaque-forming units of replication-incompetent AdCre into both ovarian bursal cavities for ovarian tumour formation, as previously described [9].

Histopathology, immunohistochemistry (IHC), and immunofluorescence

Mice were grossly inspected for tumour location and extent at necropsy. Ovaries, oviducts, uteri, lungs, kidneys, liver, omentum and mesentery were examined microscopically in each case. Tissues were fixed in formalin and paraffin-embedded. Sections were haematoxylin and eosin (H&E)-stained for evaluation by light microscopy. IHC was performed on

formalin-fixed paraffin-embedded tissue sections with standard methods. Antigen retrieval was performed by microwaving the slides in citrate buffer (pH 6.0; Biogenex, San Ramon, CA, USA) for 15 min. Endogenous peroxidase activity was quenched with 6% hydrogen peroxide in methanol. Staining was visualized with 3,3'-diaminobenzidine tetrahydrochloride and counterstaining with haematoxylin. The primary antibodies used were rat anti-cytokeratin (CK) 8 (TROMA I, 1:100; Developmental Studies Hybridoma Bank, University of Iowa), mouse anti- β -catenin (cat. no. 610154, 1:500; Transduction Laboratories, Lexington, KY, USA), rabbit anti-PTEN (138G6/cat. no. 9559, 1:400; Cell Signaling Technology, Danvers, MA, USA), rabbit anti-PAX8 (cat. no. 10336-1-AP, 1:500; Proteintech, Chicago, IL, USA), and goat anti-OVGP1 (cat. no. SC-46430, 1:500; Santa Cruz Biotechnology, Santa Cruz, CA, USA). For immunofluorescence (IF) staining, tissues were fixed with 4% paraformaldehyde at room temperature and then embedded in paraffin. Deparaffinized sections were permeabilized with phosphate-buffered saline (PBS) containing 0.5% Triton X-100 for 10 min, blocked with PBS containing 5% normal goat serum for 1 h, and then incubated with primary rabbit anti-green fluorescent protein (GFP) (cat. no. 2956, 1:500; Cell Signaling) and rabbit anti-tubulin (cat. no. T6199, 1:1000; Sigma-Aldrich) antibodies at 4 °C overnight. After being washed with PBS, slides were incubated with secondary goat anti-rabbit IgG conjugated with fluorescein isothiocyanate 488 (for GFP) and goat anti-rabbit IgG conjugated with Alexa 594 Red (for tubulin) for 1 h at room temperature. Sections were mounted with Prolong Gold antifade reagent (Thermo Fisher Scientific, Waltham, MA, USA).

Gene expression analyses

Affymetrix Mouse Gene 2.1 ST Plate Arrays were used to profile gene expression in six FTE-derived mouse oviductal tumours and five OSE-derived ovarian tumours. Four normal whole ovary samples from *Ovgp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice that had not been injected with either AdCre or TAM were also profiled (each sample representing a pool of two normal ovaries per mouse). Total RNA was extracted from manually dissected frozen mouse tumour samples with adjacent H&E-stained sections as dissection guides, in order to ensure that each tumour sample contained at least 90% tumour cells and lacked significant necrosis. RNA was extracted with Trizol (Invitrogen, Carlsbad, CA, USA), and purified with RNeasy columns (Qiagen, Valencia, CA, USA). Quality was checked with an Agilent 2100 Bioanalyzer. Total RNA (250–400 ng) was reverse-transcribed, amplified and labelled by the use of Affymetrix PLUS kits. Following fragmentation, cDNA was hybridized for 20 h at 48 °C to Mouse Genome 2.1 ST arrays. Arrays were scanned with the Affymetrix Gene Atlas system. Transcript abundances were estimated by use of the Robust Multi-Array Average algorithm [21] with Bioconductor software in

the R-statistical programming environment. It reports log₂-transformed abundances, and subsequent analyses used the log-transformed data for 25 216 probe sets associated with mouse gene identifiers in the annotation obtained from Bioconductor. Principal component analysis was carried out, and an ANOVA model was used to identify differentially expressed genes between each pair of groups. Gene expression data from 99 human ovarian carcinomas to which the mouse tumour data were compared have been previously described in detail, and are available from the NCBI's Gene Expression Omnibus (GEO) under series accession number GSE6008 [9]. Mouse genes were mapped to human gene IDs by using one-to-one best homologs from build 68 of Homologene, yielding a total of 15 813 distinct human genes. The mouse gene expression data reported here are also available from the GEO (accession number GSE80085).

Results

Cre activation is limited to the oviductal epithelium in TAM-treated *Ovgp1-iCreER^{T2}* mice

In order to assess the *Ovgp1* promoter's suitability for directing Cre expression specifically in the FTE of adult mice, IHC was first used to assess endogenous OVGP1 protein expression in selected normal mouse tissues (Figure 1). Strong OVGP1 expression was found in the FTE, but OVGP1 expression was absent in the ovary (including the OSE), liver, lung, pancreas, spleen, and lymph node. Endometrial glandular epithelium in the portion of the uterine horns adjacent to the oviduct and tubules in the kidney occasionally showed focal weak OVGP1 staining. To generate mice allowing conditional (ligand-regulated) expression of Cre recombinase in the FTE, a BAC containing the mouse *Ovgp1* locus was engineered to include a cassette encoding Cre fused to a ligand-binding domain sequence of human *ESR1* (encoding oestrogen receptor) and the *BGH* polyadenylation signal sequence. The cassette was inserted at the translation initiation codon in the first exon of *Ovgp1*. Recombinant BAC DNA was microinjected into fertilized embryos with standard pronuclear injection techniques. Several transgenic founders were shown to yield viable and fertile male and female transgenic offspring. All of the *Ovgp1-iCreER^{T2}* mice employed in this study were derived from the same founder.

To demonstrate the specificity of Cre recombinase function in the FTE, *Ovgp1-iCreER^{T2}* mice were crossed with *Rosa^{LSL-EYFP}* reporter mice to generate double transgenic *Ovgp1-iCreER^{T2};Rosa^{LSL-EYFP}* mice. Double transgenic female mice were injected with TAM or vehicle (corn oil), and killed 1 week after the second injection. Major organs were collected and examined under a stereo fluorescence microscope. Representative tissues were examined by IF microscopy. Enhanced yellow fluorescent protein (EYFP) expression was detected only in the oviducts of TAM-treated

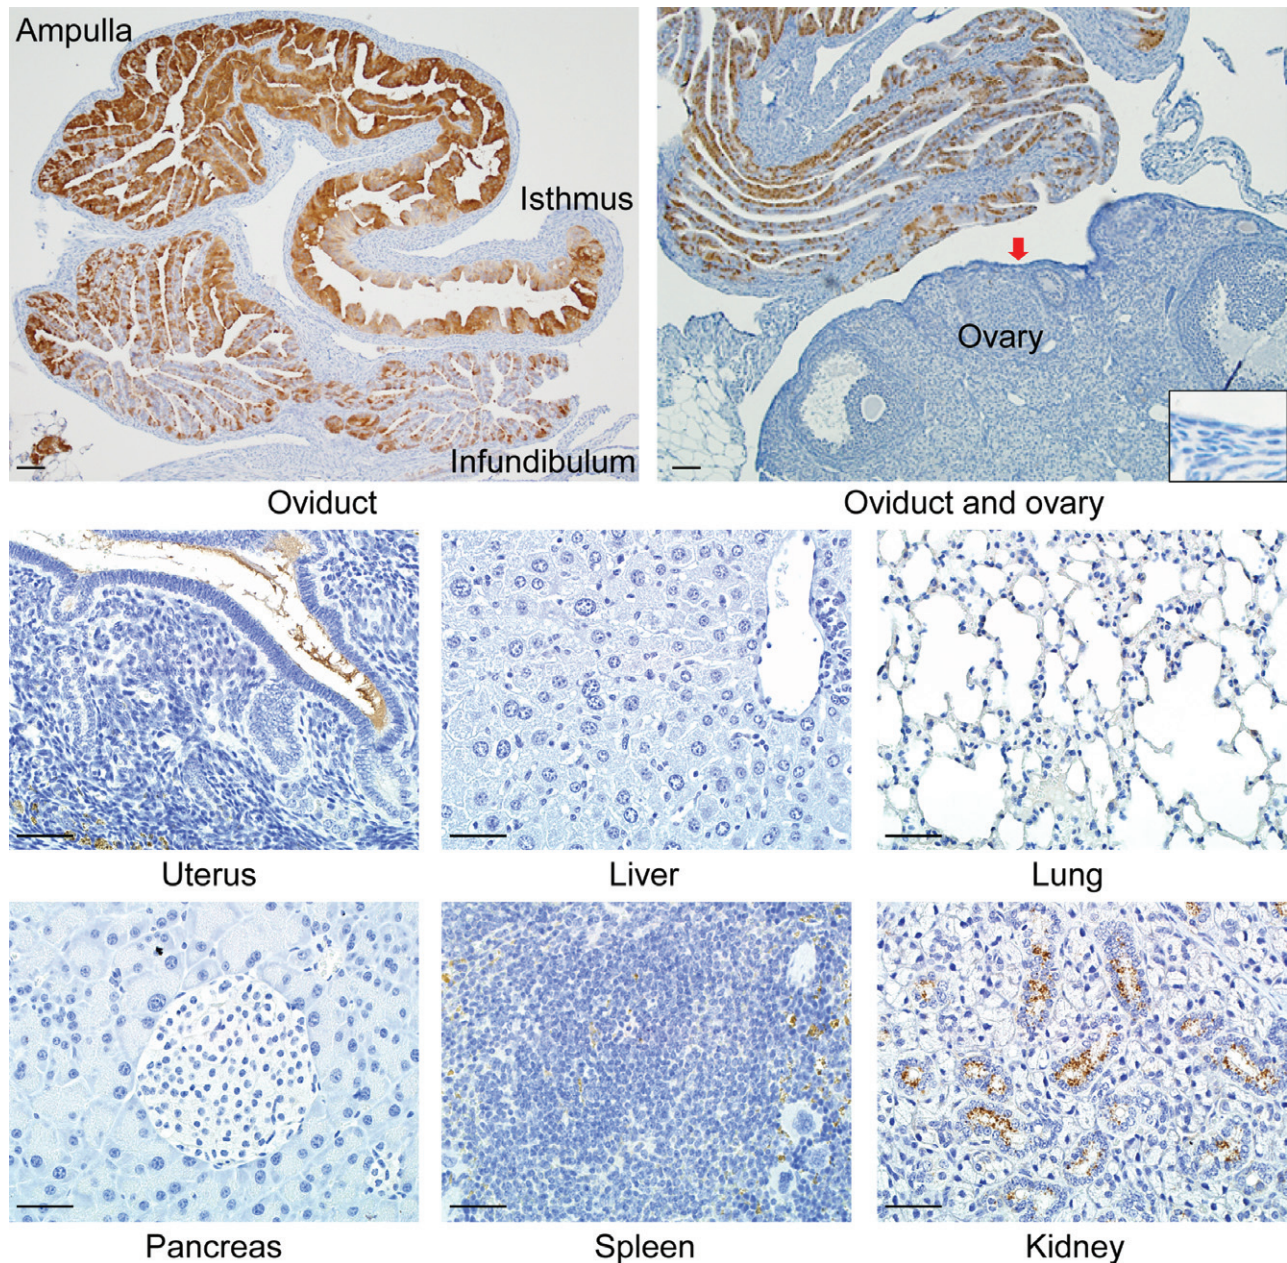

Figure 1. OVGP1 is highly expressed in oviductal epithelium but not in other tissues in the mouse. Representative sections of the adult mouse organs shown were stained with standard immunohistochemical methods and an anti-OVGP1 antibody. The red arrow highlights the absence of OVGP1 expression in the ovarian surface epithelium. Scale bars: 100 μ m.

Ovgp1-iCreER^{T2};Rosa^{LSL-EYFP} mice (Figure 2A), and not in vehicle-treated *Ovgp1-iCreER^{T2};Rosa^{LSL-EYFP}* mice (Figure 2B). EYFP fluorescence was similarly absent in the oviducts of vehicle or TAM-treated *Ovgp1-iCreER^{T2}* transgene-negative mice (not shown). To determine which oviductal epithelial cells (secretory versus ciliated) express EYFP, we carried out double IF analyses with an anti-GFP antibody and an anti-tubulin antibody, as tubulin is expressed by ciliated cells. In TAM-treated *Ovgp1-iCreER^{T2};Rosa^{LSL-EYFP}* mice, EYFP was primarily expressed in oviductal secretory cells and not in ciliated cells (Figure 2C, D). EYFP expression was not seen in other major organs, including the ovary, uterus, liver, lung, pancreas, kidney, spleen, lymph node, and brain (not shown).

Conditional bi-allelic inactivation of *Apc* and *Pten* in the FTE results in oviductal carcinomas that closely resemble human ovarian ECs

We crossed *Ovgp1-iCreER^{T2}* mice with *Apc^{fl/fl};Pten^{fl/fl}* mice to generate triple transgenic *Ovgp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice. Cohorts of 6–8-week-old females were treated with TAM and killed at regular intervals to monitor tumour development and progression (Table 1). Early changes (oviductal epithelial hyperplasia and atypia) were observed, starting ~1 month after TAM injection, and primarily affected the infundibular (comparable to human fimbriae) and ampullary (middle) portions of the oviducts. By 9–12 weeks after TAM treatment, mice developed well-formed oviductal

Figure 2. Characterization of *Ovgp1-iCreERT2* mice. (A, B) Oviductal expression of EYFP is induced by TAM (A) but not by vehicle (B) treatment in double transgenic *Ovgp1-iCreERT2;Rosa^{LSL-EYFP}* mice. Mouse oviducts are indicated by white arrows, ovaries by white arrowheads, and uterine horns by white stars. The green oviduct is seen in the TAM-treated, but not in the vehicle-treated, mouse (yellow flecks on the ovaries represent autofluorescence). (C, D) Representative low-magnification (C) and high-magnification (D) photomicrographs of double immunofluorescent staining showing EYFP (green) and tubulin (red) expression in the oviductal epithelium of TAM-treated *Ovgp1-iCreERT2;Rosa^{LSL-EYFP}* mice. EYFP is primarily expressed in non-ciliated secretory cells (representative cell indicated by white arrow) and not in the ciliated cells (representative cell indicated by white arrowhead).

EC-like tumours. The endometrium and ovaries showed no detectable alterations at comparable time points. Representative photomicrographs of EC arising in the oviducts of TAM-treated mice over time are shown in Figure 3A and supplementary material, Figure S1. Fifteen mice with oviductal ECs were followed for 16–33 weeks after TAM treatment. Tumours involved the ovaries (often extensively) in 10 mice, and a subset of these also had metastases to the omentum ($n=4$) or lungs ($n=1$). Grossly, tumours varied in diameter from 2 to 6 mm. Microscopically, the tumours were well to moderately differentiated adenocarcinomas with overt gland formation, closely resembling human ovarian ECs (Figure 3A). On the basis of the International Federation of Gynecology and Obstetrics (FIGO) criteria used for grading human ovarian ECs, 11 of the mouse oviductal tumours would be classified as grade 1 ($\leq 5\%$ solid growth) and four as grade 2 (5–0% solid growth). None was classified as grade 3 ($>50\%$ solid growth).

As expected, the oviductal tumours expressed CK8 and PAX8, and showed nuclear/cytoplasmic staining for β -catenin and loss of PTEN expression (Figure 3C). Metastases were also CK8-positive and PAX8-positive, supporting origin from an oviductal primary (supplementary material, Figure S1).

Conditional bi-allelic inactivation of *Apc* and *Pten* in the OSE of genetically comparable mice results in poorly differentiated ovarian carcinomas

In order to compare the effects of bi-allelic inactivation of *Apc* and *Pten* in the FTE versus the OSE, AdCre was injected into the ovarian bursae of *Ovgp1-iCreERT2;Apc^{fl/fl};Pten^{fl/fl}* mice from the same founder line. This approach allows direct comparison of tumours arising from Müllerian epithelial (FTE) transformation with those arising from the OSE in mice with nearly identical genetic backgrounds. AdCre-injected mice

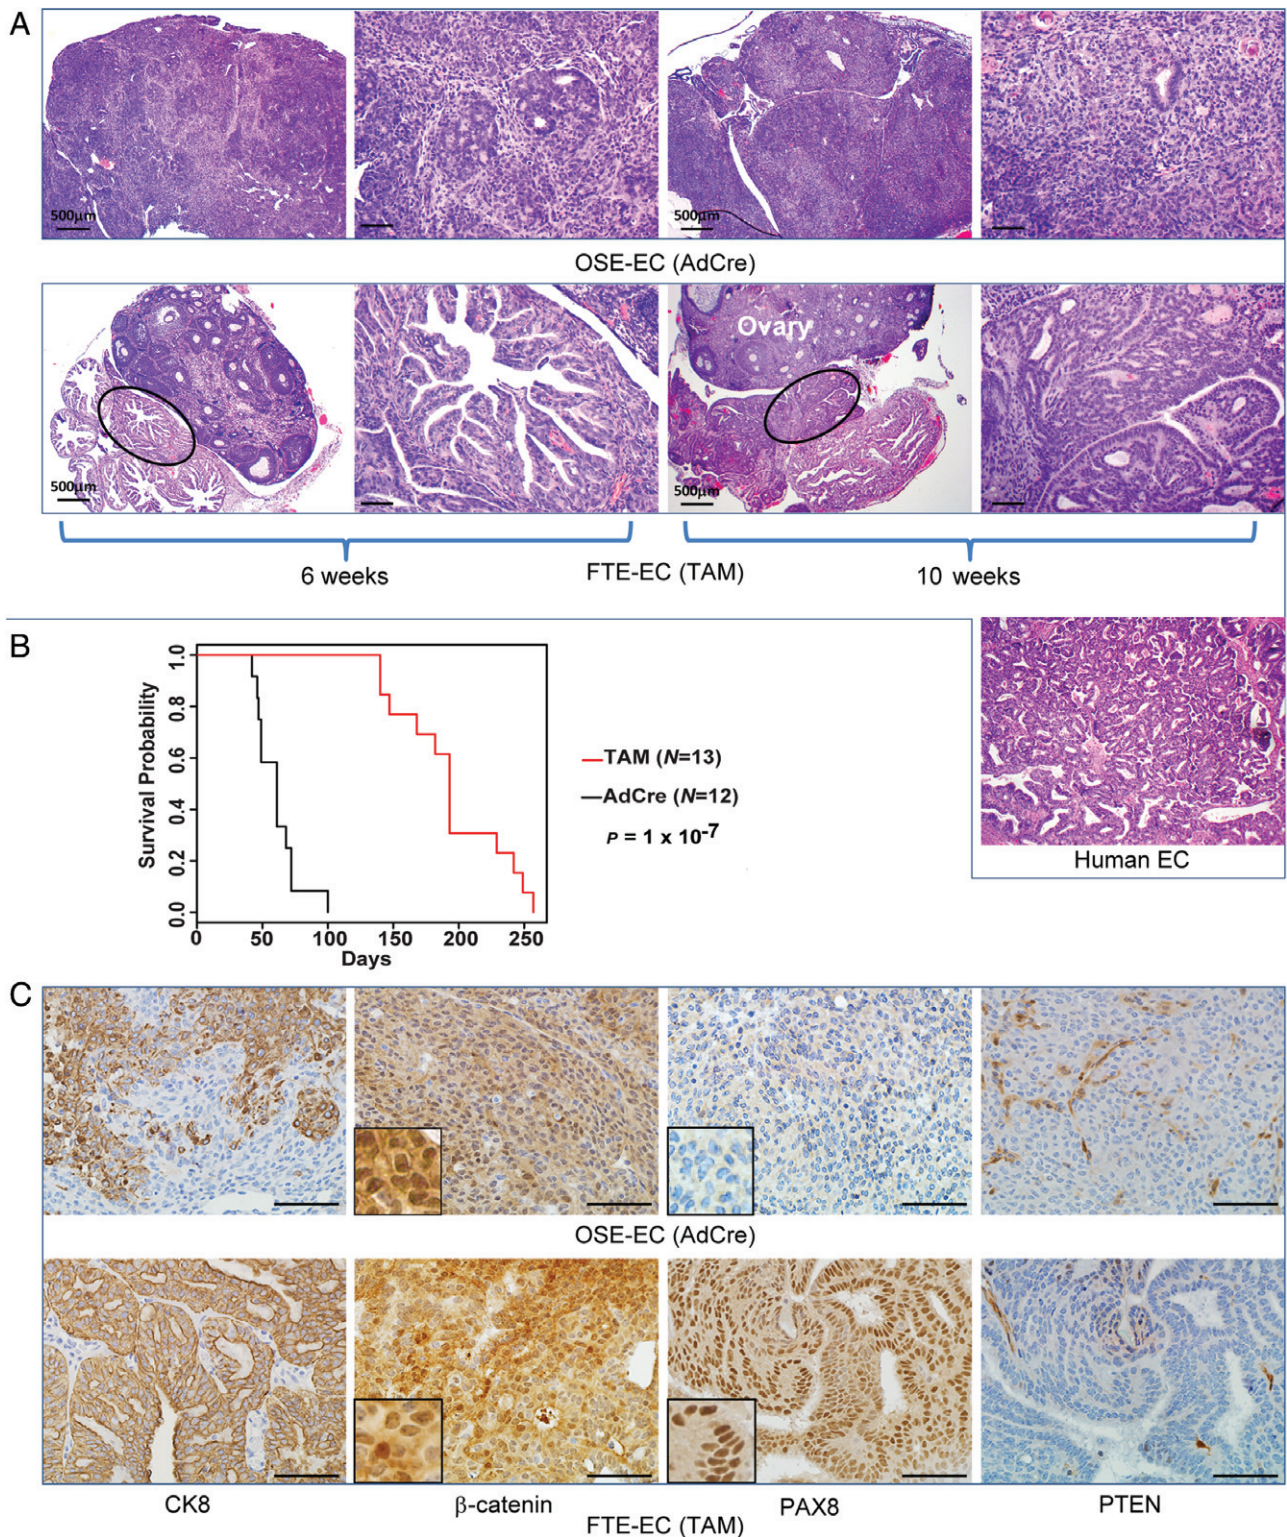

Figure 3. Comparison of OSE-derived and FTE-derived ECs in *Ovgp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice. (A) The upper panels show OSE-derived tumours and the lower panels show FTE-derived tumours at 6 weeks and 10 weeks after tumour induction with AdCre or TAM, respectively. Areas within the ellipses in the lower panels indicate oviductal regions with EC development. The histological features of a representative human ovarian EC are shown for comparison with the mouse tumours. (B) Kaplan–Meier survival curves of tumour-bearing *Ovgp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice following injection of AdCre ($n = 12$) versus TAM ($n = 13$). (C) Immunohistochemical analysis of CK8, β -catenin, PAX8 and PTEN in the OSE-derived and FTE-derived ECs, as indicated. Boxed areas are shown at higher magnification. Scale bars: 100 μ m, unless otherwise indicated.

Table 1. Summary of oviductal EC development in TAM-treated *Ovvp1-iCreER^{T2};Apc^{fl/fl};Pten^{fl/fl}* mice

Weeks post-TAM	<i>n</i>	Oviduct			Metastasis		
		FTE morphology	FIGO grade 1	FIGO grade 2	Ovary	Omentum	Lungs
2–3	2	Normal					
4–5	3	Epithelial hyperplasia					
6–7	6	Epithelial hyperplasia with atypia					
9–12	5	Adenocarcinoma	5				
16–33	15	Adenocarcinoma	11	4	10	4	1

uniformly developed tumours by 5 weeks after AdCre administration, in accordance with our previous data [9,22]. Tumour-bearing mice rapidly reached humane endpoints for tumour burden, and were killed no later than 14 weeks after AdCre injection. The OSE-derived tumours (OSE-ECs) were much larger (10–15 mm in diameter at 6–14 weeks after AdCre administration) than the FTE-derived tumours (FTE-ECs) (2–6 mm in diameter at 10–33 weeks after TAM administration). Microscopically, the OSE-ECs were very poorly differentiated (all grade 3 on the basis of FIGO criteria), with sparse glandular elements admixed with prominent spindle cell areas (Figure 3A). The OSE-ECs showed much lower CK8 expression than the FTE-ECs, and did not express PAX8 (Figure 3C). Like the oviductal tumours, the ovarian tumours expressed nuclear and cytoplasmic β -catenin, and lacked PTEN expression. Importantly, the difference in overall survival of AdCre-injected mice ($n=12$) versus TAM-treated mice ($n=13$) was quite striking (median survival: 61 days versus 193 days, respectively; $p=0.0000001$) (Figure 3B). Overall survival of the AdCre injected mice was even shorter than we previously reported [9,23], perhaps because we performed bilateral bursal injections of AdCre in the current study, in contrast to our prior work, in which only unilateral bursal injection was performed.

Global gene expression in mouse oviductal ECs more closely resembles that in human ovarian carcinomas than that in mouse ovarian ECs

We profiled gene expression in six FTE-ECs, five OSE-ECs and four normal ovary (NO) mouse samples by using Affymetrix Mouse ST 2.1 Arrays. This array approach was selected so that we could more easily compare gene expression in the mouse tumours to human tumour data collected previously with a comparable platform. The NO samples for these experiments simply serve as a common reference point for comparing gene expression in tumours from mouse and human, respectively, as comparable hybridization of mouse and human cRNAs to probe sets representing homologous genes in the mouse and human cannot be assumed. Principal component analysis showed that the dissimilarity between mouse oviductal and ovarian tumours was approximately the same as the dissimilarity between oviductal or ovarian tumours and normal controls (supplementary material, Figure S2). An ANOVA model was used to identify differentially expressed

genes between pairs of groups. Approximately 3000 probe sets (of 25 216) gave p -values of <0.001 and fold-changes of >2 for pairwise comparisons of any two groups, with false discovery rates of $<0.5\%$ (see supplementary material, Table S1, and details provided in our GEO submission). A heat map showing the top 80 differentially expressed genes between the oviductal and ovarian *Apc⁻/Pten⁻* mouse tumours is provided in supplementary material, Figure S3. Although the oviductal and ovarian tumours were based on the same genetic defects (bi-allelic *Apc* and *Pten* inactivation), tumours arising from the two sites differed in the expression of many putative Wnt signalling-regulated target genes (supplementary material, Table S2) as well as for expression of genes in other pathways.

To determine whether the oviductal or ovarian mouse tumours more closely resemble human ovarian carcinomas, we correlated the individual tumour versus average normal differences with similar tumour versus normal differences in our previous human array data from four NOs and 99 ovarian carcinomas (37 endometrioid, 41 serous, 13 mucinous, and eight clear cell), by using 10 727 genes reported to be one-to-one best homologues by NCBI's Homologene. For each gene, we selected the probe set that gave the smallest p -value for an overall F -test comparing groups within each species (three groups for mouse; five for human). We initially believed that correlating T -statistics might be better than merely correlating the distances (in log space), as this performs well as an enrichment testing technique [24]; however, we obtained nearly identical results, and report on the simpler distances. We fitted the model $R_{ijkm} = U_{ik} + A_{ij} + B_{km} + E_{ijkm}$, where R_{ijkm} is the correlation of the j th mouse from the i th mouse group with the m th human from the k th human group. The U_{ik} values are the averages for the i th mouse group and the k th human group, which can be compared by the use of F -tests from the model. A_{ij} and B_{km} are terms for each mouse and human – a highly idiosyncratic human tumour is likely to give lower correlations for every mouse tumour, and vice versa. Figure 4A demonstrates the expected variation between individual human and mouse tumours, and, importantly, shows that mouse oviductal tumours were more correlated as a group with every class of human ovarian carcinoma than mouse ovarian tumours ($p < 10^{-60}$). Only two of the 99 human tumours were more correlated with mouse OSE-ECs than with mouse FTE-ECs (Figure 4B). Correlations for all genes are modest, as the expression levels of most genes are unaltered between normal and tumour

Figure 4. Correlations of mouse FTE-ECs and OSE-ECs with each of 99 human ovarian carcinomas. (A) Heat map showing correlations of individual mouse and human tumours. Each human tumour is annotated as clear cell (OC), endometrioid (OE), mucinous (OM) or serous (OS) carcinoma. Human OEs have been sorted on the basis of the presence (yellow) or absence (blue) of *CTNNB1* mutation and/or nuclear accumulation of β -catenin, as indicated. (B) Average correlation of each human tumour with FTE-derived and OSE-derived mouse tumours.

tissues and/or between tumour groups. For our human endometrioid samples, we had previous mutation and IHC expression data for *CTNNB1*/ β -catenin (Figure 4A) [9]. A comparison of 14 ECs with mutant *CTNNB1* and/or nuclear expression of β -catenin with 23 ECs with wild-type *CTNNB1* showed significantly higher correlations in the *CTNNB1* mutant group (means: 0.240 and 0.212; $p = 0.004$). On average, mouse oviductal tumours were more correlated with human ECs and mucinous carcinomas than with clear cell and serous carcinomas ($p < 3 \times 10^{-7}$ in each possible pairwise comparison). Average correlations between mouse and human tumours are shown in supplementary material, Table S3. In short, mouse tumours derived from FTE transformation have gene expression profiles that are much more closely related to those of human ovarian carcinomas (especially ECs with *CTNNB1* mutations) than those of mouse tumours that arise from transformed OSE.

Discussion

Potential non-ovarian origins of ovarian carcinomas have been the focus of much discussion and debate, and several reviews have emphasized the need for better

model systems with which to gain mechanistic insights into the genetic, biological and physiological factors that contribute to ovarian tumour development and progression [25–27]. Many GEMMs of ovarian cancer have been reported, most based on transformation of the OSE (see [28] for a recent review). Indeed, nearly all of the Type I ovarian carcinoma GEMMs reported to date, including prior work from our group, have employed either the *Amhr2* promoter or injection of AdCre into the ovarian bursa to drive Cre-mediated recombination in the OSE [7–9, 23, 29–33]. Interestingly, van der Horst *et al* recently employed the progesterone receptor (*Pgr*) promoter to drive Cre-mediated inactivation of *Apc* in Müllerian epithelium, including the endometrium and oviduct. These mice develop endometrial hyperplasia and oviductal intraepithelial lesions and carcinomas, as well as ovarian ECs proposed to arise from ovarian inclusion cysts and glands [34]. Although we are fully aware that the majority of human ‘ovarian’ ECs are not thought to arise from the Fallopian tube, neither do they likely arise from the OSE. The studies described herein support the notion that cell of origin has profound effects on the phenotype of tumours induced by the same genetic defects. Moreover, transformation of Müllerian epithelium such as the FTE leads to tumours

that more closely resemble human ovarian carcinomas than do comparable tumours arising in the murine OSE.

Particular gene defects or combinations of defects may have cell-of-origin and tissue-specific effects on cell phenotypes, perhaps providing key insights into the origin of different histological subtypes of ovarian carcinomas. For instance, conditional inactivation of *Brca1* and *Trp53* in the murine OSE often leads to the development of leiomyosarcomas [35,36], which is not found following induction of the same genetic alterations in the mouse FTE [37]. More recently, studies employing syngeneic murine oviductal and OSE allografts have also shown that the same genetic alterations in different cell types can give rise to different cancer histotypes [38]. Here, we present data showing distinctive effects of *Apc* and *Pten* loss in the FTE as compared with the OSE *in vivo*. Specifically, ovarian bursal injection of AdCre in *Ovgp1-iCreERT2;Apc^{fl/fl};Pten^{fl/fl}* mice results in rapid OSE transformation and the development of poorly differentiated carcinomas. In contrast, when *Apc* and *Pten* loss is induced in the FTE, well-differentiated tumours develop over months rather than weeks. Mouse oviductal tumours were more correlated than mouse ovarian tumours with every class of human ovarian carcinomas, with the highest correlation being seen with human endometrioid and mucinous carcinomas. Although the similarity to human ECs (particularly those with *CTNNB1* mutations) was expected, the similarity to human mucinous carcinomas was unexpected, and remains incompletely understood. However, both are considered to be Type I tumours, and human ECs have a known propensity to show foci of mucinous differentiation, a feature that was also observed in some of the mouse oviductal, but not ovarian, tumours.

Tissue-specific effects of *Apc* and *Pten* loss are highlighted by some striking differences in the expression of Wnt signalling pathway targets in the oviductal versus ovarian *Apc⁻/Pten⁻* tumours. For example, *Mmp7* and *Sox9* are much more highly overexpressed in the oviductal tumours than in the ovarian tumours, whereas the converse is true for *Ccnd1*, *Fgf20*, and *Klf5*. *Lgr5*, a putative marker of stem/progenitor cells in ovary and tubal epithelia [39,40], is upregulated only in the oviductal tumours. Interestingly, *Ctnnb1* is upregulated in tumours from both sites, supporting our prior work providing evidence for a feed-forward role for β -catenin in canonical Wnt signalling [41].

Ovgp1 encodes a protein that is secreted by non-ciliated cells in the mammalian FTE [42]. OVGPI appears to play a role in optimizing the microenvironment for oocyte maturation and transport, fertilization, and early embryonic development [43]. Although maximum production of OVGPI has been shown to be dependent on plasma oestrogen levels in cows, baboon, sheep, pigs, and humans, this does not appear to be the case in rabbits or hamsters [44]. We did not need to pretreat our *Ovgp1-iCreERT2* mice with oestradiol prior to treating them with TAM in order to strongly activate Cre in the oviductal epithelium. In 2002, Miyoshi *et al* described the development of high-grade serous

carcinoma-like tumours arising in transgenic mice expressing SV40 Large T-Ag under control of a 2.2-kb fragment of the murine *Ovgp1* promoter [45]. Lesions arising in these mice were more recently described in detail [46]. In addition to oviductal tumours and presumptive metastases to the ovaries, epithelial and mesenchymal malignant lesions also developed in the uteri of older mice. Importantly, we did not observe endometrial carcinoma or uterine sarcoma in any of our *Ovgp1-iCreERT2;Apc^{fl/fl};Pten^{fl/fl}* mice monitored for up to 33 weeks after TAM treatment. Thus, our *Ovgp1-iCreERT2* mice provide an excellent system with which to test the effects of various genetic alterations specifically in the FTE.

Our findings provide compelling evidence that, depending on the specific tissues targeted for transformation, the same combination of genetic alterations leads to very different tumour phenotypes. Comparable studies testing other combinations of gene mutations common in EC, as well as the effects of gene combinations characteristic of high-grade serous carcinoma, are in progress and will help to establish whether models based on transformation of Müllerian (e.g. oviductal) epithelium will prove more suitable than those derived from the OSE for studying ovarian cancer biology and for translational applications.

Author contributions statement

The authors contributed in the following way: RK, ANK, PG, ERF, KRC: conceived experiments and analysed data. RW, YZ, AN, TCH: conceived and carried out experiments. All authors were involved in writing the paper and gave final approval of the submitted version.

Acknowledgements

The research reported in this article was supported in part by the National Cancer Institute of the National Institutes of Health under award numbers P30CA046592 (Transgenic Animal Model Core) and R01CA196619 (to KRC).
