31 **Abstract**

32 Weedy species provide excellent opportunities to examine the process of successful colonization  
33 of novel environments. Despite the influence of the sexual system on a variety of processes from  
34 reproduction to genetic structure, how the sexual system of species influences weediness has  
35 received only limited consideration. We examined the hypothesis that weedy plants have an  
36 increased likelihood of being self-compatible compared to non-weedy plants; this hypothesis is  
37 derived from Baker's Law, which states that species that can reproduce uniparentally are more  
38 likely to successfully establish in a new habitat where mates are lacking. We combined a  
39 database of the weed (weed/nonweed) and introduction status (introduced/native) of plant  
40 species found in the USA with a database of plant sexual systems and determined if native and  
41 introduced weeds varied in their sexual systems compared to native and introduced non-weeds,  
42 respectively. We found that introduced weeds are overrepresented by species with both male and  
43 female functions present within a single flower (hermaphrodites) whereas weeds native to the  
44 USA are overrepresented by species with male and female flowers present on a single plant  
45 (monoecious species). Overall, our results show that Baker's Law is supported at the level of the  
46 sexual system thus providing further evidence that uniparental reproduction is an important  
47 component of being either a native or introduced weed.

50

INTRODUCTION

51 Individuals colonizing a new habitat often face the fundamental problem of a lack of  
52 mates. Baker hypothesized that species with the ability to reproduce uniparentally are more  
53 likely to successfully colonize new areas compared to species that rely on mates for propagation  
54 (Baker, 1955). While the scenario of island colonization and establishment originally influenced  
55 his idea, he later applied this concept to the evolution of agrestals and ruderals, or plants that  
56 colonize agricultural fields or waste areas such as roadsides, respectively (Baker, 1965). He  
57 examined the Asteraceae family, which contains both highly selfing and self-incompatible  
58 species, and found that the weedy species in this group were typified by rapid development,  
59 rapid flowering, increased plasticity and self-compatibility (Baker, 1965). Baker's key insight  
60 that the ability to colonize was related to uniparental reproduction when mates are lacking—

61 formally known as Baker's Law—is now a cornerstone hypothesis that is supported by studies of  
62 plants and animals and has been examined in a variety of contexts, e.g., island colonization,  
63 metapopulation dynamics, invasive species, and range expansion (reviewed in Pannell & Barrett,  
64 1998; Pannell *et al.*, 2015). Strikingly, although Baker's Law has a broad reach in ecology and  
65 evolution, few explicit tests examine the hypothesis that weeds (broadly described as plants that  
66 are found in places they are not wanted (Radosevich *et al.*, 2007)) exhibit an increased capacity  
67 for self-fertilization and/or uniparental reproduction.

68 The available examinations of Baker's Law as it applies to weeds consider the frequency  
69 of self-compatibility in invasive plants, which are plants that have been introduced to new areas  
70 and are subsequently deemed problematic. These comparisons provide support for Baker's Law,  
71 but are limited to particular taxonomic groups (Iridaceae: Van Kleunen *et al.*, 2008; Asteraceae:  
72 Hao *et al.*, 2011), a restricted geographic region (South African invasives: Rambuda & Johnson,  
73 2004; European invasives: Van Kleunen & Johnson, 2007) or work that compares invasives  
74 (hereafter 'introduced weeds') to native species (Burns *et al.*, 2011). While it is surprising that  
75 few studies of introduced weeds consider Baker's Law – especially since much of its  
76 development centered around weedy plants – it is also remarkable that there are no large-scale  
77 examinations, to our knowledge, of the potential that native weeds (plants that are native to a  
78 particular habitat and deemed weedy or problematic) are more likely to exhibit an increased  
79 capacity for self-fertilization compared to native non-weeds. There are certainly similarities  
80 between introduced and native weeds that would suggest the ability to self would likewise be  
81 favored in native weeds – both types of weeds exhibit the typical set of 'weediness traits,' e.g.,  
82 high fecundity, annual life form, and rapid growth in comparison to introduced and native non-  
83 weeds (Kuester *et al.*, 2014).

84 The processes that lead to 'weediness' in these two classes of weed, however, are  
85 potentially very different. For example, introduced species are accidentally or purposefully  
86 moved across great distances, and those that establish in new areas may or may not eventually  
87 become weedy or invasive (Williamson, 1996; Richardson *et al.*, 2000b). Those that do become  
88 weedy are hypothesized to exhibit pre-existing traits that allow for uniparental reproduction in  
89 mate-limited areas (Pannell, 2015) and therefore may show a strong pattern of enrichment for  
90 hermaphroditism. In comparison, native weeds may not necessarily travel long distances (Valéry  
91 *et al.*, 2008) and may or may not be expected to experience a lack of mates that is as extreme as

92 that envisioned for introduced species and therefore may show enrichment for sexual systems  
93 that provide other benefits (such as a reduction in selfing rates). However, native weeds are  
94 generally known to be good colonizers of altered or disturbed habitats (Simberloff *et al.*, 2012),  
95 and for this reason may likewise exhibit reproductive traits that pre-adapt them for successful  
96 establishment in newly disturbed areas. Thus, different factors may be involved in the pathway to  
97 ‘weediness’ for native and introduced species, which may or may not result in different sets of  
98 traits being important to their success.

99 Furthermore, while weediness is known to be associated with a broad set of traits  
100 (Kuester *et al.*, 2014 and references therein), the potential that particular sexual systems are  
101 enriched in weedy plants compared to non-weeds has yet to be comprehensively examined in any  
102 flora. Plants that have both male and female organs within the same flower (hermaphrodites), or  
103 on separate flowers of the same plant (monoecy, andromonoecy, and gynomoecy), are more  
104 likely to produce progeny in mate-limited areas compared to species with separate sexes (dioecy,  
105 androdioecy, gynodioecy). We would thus predict, based on Baker’s Law, that weedy plants may  
106 be enriched for hermaphrodites or monoecious species compared to non-weeds as a mechanism  
107 of ensuring uniparental reproduction.

108 Here we test this prediction by combining two existing databases: a recently published  
109 sex systems database (Tree of Sex Consortium, 2014) with a database of plant species found  
110 within the US for which the weed (weed vs. non-weed) and introduction status (native vs.  
111 introduced) are known (database from Kuester *et al.*, 2014). We used this concatenated database  
112 to test for an association between sexual system (hermaphrodite, monoecy, gynomoecy,  
113 andromonoecy, dioecy, androdioecy) and weediness status for both native and introduced  
114 species. We used both taxonomic comparisons and comparisons that control for phylogenetic  
115 relatedness to test for enrichment. Our broad expectations are that both native and introduced  
116 weeds should have a larger proportion of hermaphrodites and/or monoecious species than non-  
117 weeds since these sexual systems increase the likelihood of uniparental reproduction.

## 118 119 MATERIALS AND METHODS

120  
121 The Sex System Database (Tree of Sex Consortium, 2014) was concatenated with a  
122 database of North American plant species that included introduction status (native/introduced)

123 and weed status (weedy/non-weedy) (Kuester *et al.*, 2014), in which weeds were defined as  
124 troublesome plants in agriculture, horticulture, ornamental and natural areas. Sexual systems  
125 with very few occurrences were removed (androdioecy, apomictic, gynomonoecy, other,  
126 polygamomonoecy; N=12). Many of the species in the Sex Systems Database were not in the  
127 Weed Database, leaving 1,077 species for further analyses. No statistical difference was found in  
128 the distribution of sexual systems between the full Sex Systems database and the merged  
129 database ( $\chi^2=0.09$ , d.f.=5,  $p=1.0$ ); thus, the merged data set is representative of the Sex System  
130 Database.

131 To determine the effect of sexual systems (see Table 1) on weed status we performed  
132 binomial regressions separately for each sexual system and weed status comparison. For  
133 example, using a dummy variable of hermaphroditic or not hermaphroditic as the predictor and  
134 introduced weed status (non-weed vs weed) as the dependent variable in a binomial regression,  
135 we tested whether there was a difference in the probability of being a weed between  
136 hermaphroditic and non-hermaphroditic species. Separate regressions were run for native and  
137 introduced species. We also performed a multinomial regression including all the sexual systems  
138 in Table 1, but because results from multinomial logistic regression are difficult to interpret and  
139 were qualitatively the same as the binomial regressions, we chose to report results from the  
140 binomial tests (see Sup Table 1 for multinomial regressions). All analyses were performed in R  
141 (R Core Team, 2014).

142 Preliminary examination of the database indicated that sexual systems were relatively  
143 conserved within genera but varied among genera (between 1-6 sexual systems present per  
144 family within the database). Thus, we performed a phylogenetic logistic regression (Ives &  
145 Garland, 2010) to determine if results from the above taxonomic comparison were influenced by  
146 shared evolutionary history. This method is similar to a normal logistic regression except a  
147 phylogenetic signal is added to the model (called alpha) to allow the detection of main variable  
148 effects while accounting for phylogeny. A value of alpha > -4 suggests a detectable phylogenetic  
149 signal. We created a genus level tree (i.e., all species within a genus were polytomies) using  
150 phylomaticV3 (Webb & Donoghue, 2004) and the R20120829 megatree (available  
151 at <https://github.com/camwebb/tree-of-trees/blob/master/megatrees/R20120829.new>), which  
152 resulted in a tree containing 1071 species (335 introduced species and 735 native species; 6  
153 species were not found on the megatree) in 194 genera. An ultrametric tree with time scaled

154 branches was created using the wikstrom.ages file and the bladj procedure in phylcom-4.2  
155 (Webb *et al.*, 2008). We used the phylolm package in R (Si *et al.*, 2014) to perform the  
156 phylogenetic logistic regression analysis for the three most common sexual systems (*i.e.*,  
157 hermaphroditism, dioecy and monoecy) for introduced and native species separately. We  
158 performed this analysis on these three common sexual systems since the others were represented  
159 by five species or less per weed/non-weed comparison, and preliminary results from the logistic  
160 regressions of all sexual systems indicated there were no differences between weeds and non-  
161 weeds for gynodioecy, polygamodioecy, and andromonoecy.

## 162 163 RESULTS

164  
165 The merged dataset consisted of 1,077 species in 60 families, the most common being  
166 Orobanchaceae (18%), Poaceae (10%), Amarathaceae (6%), Asteraceae (6%), Rubiaceae (6%),  
167 and Euphorbiaceae (6%). In the overall database, 61% of species were hermaphrodite, 17%  
168 dioecious, 13% monoecious, 4% gynodioecious, 2% polygamodioecious, and 1%  
169 andromonoecious (Fig 1; see Table 1 for sexual system descriptions). Many families were  
170 polymorphic for sexual system (47% of families), weediness (55% of families) or introduction  
171 status (52% of families; Fig 2; Fig S1).

172 In support of Baker's Law, we found that introduced weeds are more likely to be  
173 hermaphroditic than introduced non-weeds ( $P < 0.0001$ ; Fig 1; Fig 3); 78% of introduced weeds  
174 are hermaphroditic compared to 40% of introduced non-weeds. On the other hand, introduced  
175 weeds were less likely to be dioecious and monoecious than introduced non-weeds ( $P = 0.04$ ,  
176  $P < 0.0001$ ; Fig 1; Fig 3). Over 60% of the introduced hermaphroditic weeds were found within  
177 four families: the Poaceae, Asteraceae, Brassicaceae and Polygonaceae (Fig 2; Fig S1a).

178 Patterns in the native species were different than those in the introduced species: native  
179 weeds were more likely to be monoecious than native non-weeds ( $P < 0.0001$ ; Fig 1; Fig 3), but  
180 the two groups of native species are equally likely to be hermaphroditic ( $P = 0.21$ ; Fig 1; Fig 3).  
181 The monoecious native weeds tended to belong to the Amaranthaceae, Euphorbiaceae,  
182 Sapindaceae, and Poaceae (Fig 2; Fig S1b).

183 While we found that sexual systems were highly conserved within genera (Fig 2), the  
184 phylogenetic logistic regression provides support for the above taxonomic comparisons (Table

185 2), suggesting the patterns we uncovered are not due solely to phylogenetic relatedness. After  
186 removing the effect of phylogeny, the patterns found in the binomial regressions remained (Table  
187 2). For introduced species, weeds were more likely to be hermaphroditic than were non-weeds  
188 ( $P < 0.0001$ ) while the opposite was true for monoecy ( $P < 0.0001$ ). On the other hand, for native  
189 species, weeds were more likely to be monoecious than were non-weeds ( $P = 0.002$ ) and slightly  
190 less likely to be hermaphroditic ( $P = 0.04$ ). Thus, our phylogenetic results support the hypothesis  
191 that sexual system varies with weediness status, whether native or introduced weed.

## 192 193 DISCUSSION 194

195 Our phylogenetically controlled analysis of 1,077 species from 60 families showed that  
196 weedy plants, whether native or introduced to the US, were more likely to exhibit sexual systems  
197 that promote uniparental reproduction compared to native and introduced non-weeds. Strikingly,  
198 native and introduced weeds exhibited different sexual systems: native weeds were enriched for  
199 monoecious species whereas introduced weeds were enriched for hermaphrodites. These results  
200 support Baker's Law and the idea that certain sexual systems underlie the likelihood that a  
201 particular species will be identified as a weed.

202  
203 *Association between sexual system and weed status*

204 The two different methodologies that we presented here—one based on taxonomy and the  
205 other correcting for phylogeny—showed that weeds differ from non-weeds in their distribution  
206 of sexual systems. In particular, we found an overabundance of hermaphrodites among  
207 introduced weeds. Although being a hermaphrodite does not guarantee that a species can self-  
208 pollinate, the presence of male and female organs in each flower should increase the likelihood  
209 that a plant can reproduce in areas that may lack suitable mates. Surprisingly, we found a  
210 different pattern among native weeds, which were more likely than native non-weeds to be  
211 monoecious. We found no evidence that native weeds were more likely to be hermaphroditic  
212 compared to native non-weeds. Thus, our original expectation that weedy plants are more likely  
213 to have sexual systems that allow for uniparental reproduction appears to be correct, but native  
214 and introduced species differ in the sexual systems used to achieve this.

215 Previous studies examining the influence of sexual systems on weediness lead to  
216 conflicting conclusions. For example, Daehler (1998) compared different types of weeds (serious  
217 agricultural weeds vs widespread agricultural weeds vs natural area invaders) on a global scale  
218 and found that family level rates of dioecy or monoecy did not differ among weed types.  
219 Sutherland (2004) found little evidence that US weeds were more likely to be hermaphroditic  
220 than non-weeds, but did find that invasive introduced weeds were more likely to be monoecious  
221 than were non-invasive introduced weeds. On the other hand, in an attempt to predict weediness,  
222 Reichard and Hamilton (1997) found that among woody plants in the US having hermaphroditic  
223 flowers was associated with invasiveness. These conflicting results may be due to a variety of  
224 confounding differences, including the taxonomic groups used (all species vs only woody  
225 species), the regions covered (global vs geographically restricted) and the particular comparison  
226 (weeds compared to non weeds vs introduced weeds compared to introduced non-weeds).  
227 Broader datasets that are a true sample of the region as well as using informative comparisons  
228 are needed to further clarify the role of sexual systems on weediness more broadly.

229 The difference that we uncovered in the predominant sexual system of native versus  
230 introduced weeds is likely due, at least in large part, to phylogeny. Notably, the majority of  
231 introduced weeds were from the Poaceae (many hermaphrodites), Asteraceae (many  
232 hermaphrodites and dioecious species), and Brassicaceae (mostly hermaphrodites), whereas the  
233 majority of native weeds were from the Amaranthaceae and Euphorbaceae, many of which were  
234 either monoecious or dioecious. Our findings were similar to previous work from Kuester *et. al*  
235 (2014) showing introduced weeds in the US to be significantly overrepresented by species  
236 belonging to the Poaceae, Asteraceae, and Brassicaceae, and that native weeds were  
237 overrepresented by species belonging to Amaranthaceae (among other families). Our broad  
238 interpretation of our data is that particular groups of taxa with sexual systems that promote  
239 uniparental reproduction are more likely to be successful colonizing weeds; however, under this  
240 interpretation, other traits shared among members of these families may underlie ‘weediness’  
241 (i.e. high growth rate and/or fecundity).

242 Perhaps the difference in predominant sexual system of the introduced and native weeds  
243 provides the best support for the idea that the sexual system is related to or promotes  
244 weediness—while we found that introduced and native weeds were enriched for different sexual  
245 systems, both of these sexual systems promote uniparental reproduction. For example,

246 monoecious species are often considered to be functional hermaphrodites since they have both  
247 male and female flowers residing on a single individual (Richards, 1997). In this respect, a  
248 monoecious individual is more likely than a species with separate sexes to successfully produce  
249 progeny in the absence of other plants, especially if wind-pollinated or if colonizing an area that  
250 does not lack pollinators. Thus, although the two different groups of weeds are overrepresented  
251 or enriched by particular families, those families that exhibit hermaphroditism—whether  
252 functional hermaphroditism through monoecy or hermaphroditism proper—are more capable of  
253 colonizing new areas and becoming classified as a weed.

254

255 *What factors may explain the variation in sexual systems of native and introduced weeds*  
256 *compared to non-weeds?*

257 The steps that influence the evolution of plant reproduction in colonizing species have  
258 recently been conceptualized into three main phases—dispersal, establishment, and potential  
259 subsequent evolution (Richardson *et al.*, 2000b; Theoharides & Dukes, 2007; Pannell, 2015).  
260 Because we compare groups of plants that are already established and weedy to plants that are  
261 established and non-weedy, our data are best interpreted in light of the post-dispersal phases of  
262 establishment and potential subsequent evolution. During establishment, introduced species may  
263 be faced with both mate limitation and reductions in pollinator services if pollinators are rare or  
264 novel and as such the ability to autonomously self-pollinate during the establishment phase  
265 would be highly beneficial. Members of the *Ficus* genus, for example, are primarily monoecious  
266 or gynodioecious and are pollinated by species-specific wasp species (Nadel *et al.*, 1992).  
267 Species within this group have become invasive only when their specialist pollinators were  
268 accidentally introduced (Ramirez & Montero, 1988; McKey & Kaufmann, 1991; Nadel *et al.*,  
269 1992). Thus, introduced species without a hermaphroditic sexual system might be less likely to  
270 become weedy because their specialized pollinators did not colonize with them. Native species,  
271 on the other hand, may be more likely to retain an association with their native pollinators during  
272 establishment, and thus may be less influenced by pollinator limitation. However, some studies  
273 suggest that most invasive species (included in our introduced weed category) are generalist  
274 pollinated (Richardson *et al.*, 2000a) and are not more pollen limited than native species (but see  
275 Burns *et al.*, 2011; Razanajatovo & Van Kleunen, 2016), in which case autonomous self-  
276 pollination would not be beneficial.

277           Alternatively, and as above, the enrichment for functional hermaphrodites in weedy  
278 species could be due to selection on correlated traits during establishment that are ultimately  
279 responsible for the weediness status of a species. For example, wind-pollination is associated  
280 with unisexual flowers (Friedman & Barrett, 2008) and dioecious species tend to be woody  
281 (Vamosi *et al.*, 2003). Most studies (ours included) consider traits singly, but, as Baker clarified,  
282 there is no one “weedy” phenotype (Baker, 1965), and as such considering only a single trait at a  
283 time limits our ability to identify these possible pathways. Strikingly, our previous work found  
284 that many traits are associated with both native and introduced weeds —annual life form, high  
285 growth rate, high fruit abundance, and high seedling vigor (Kuester *et al.*, 2014). While selection  
286 for weediness could involve a host of traits, that we uncovered different predominant sex  
287 systems between introduced and native weeds, but sex systems that nonetheless may perform the  
288 same function (i.e., functional hermaphroditism), strongly suggests that traits which allow for  
289 uniparental reproduction are a key trait associated with weediness.

290           Our analysis, by necessity, assumes that hermaphroditic and monoecious species are able  
291 to reproduce uniparentally, *i.e.* self-pollinate. Although this may broadly be true, this  
292 simplification ignores a variety of mechanisms that limit selfing including self-incompatibility,  
293 morphology (e.g. herkogamy), and developmental (e.g. dichogamy) mechanisms. To completely  
294 test the hypothesis that weedy species are more likely to be able to reproduce uniparentally we  
295 would need extensive data on self-compatibility as well as the circumstances under which selfing  
296 is possible (such as harsh environmental conditions or lack of outcross pollen). Given that large  
297 data sets of this kind do not yet exist, our results are a first pass at examining this hypothesis and  
298 suggest that uniparental reproduction is indeed an important factor in the development of weeds  
299 both native and introduced.

### 300 *Conclusion*

301           Here we provide evidence that sexual systems are an important characteristic related to  
302 plant weediness. Native and introduced weeds varied from non-weeds differently, with  
303 introduced weeds enriched for hermaphrodites and native weeds enriched for monoecious  
304 species. It is notable that introduced and native species appear to be quite taxonomically  
305 different, and yet, weeds of both groups are more likely to be functional hermaphrodites  
306 compared to their respective non-weeds. Overall, our results support the idea that weedy species  
307 are enriched for particular sex systems that allow for uniparental reproduction. These results

308 show that Baker's Law is reflected at the level of the sexual system thus providing further  
309 evidence that uniparental reproduction is an important component of being either a native or  
310 introduced weed.

### 393 **Figure Legends**

394 Fig 1. The proportion of each sexual system shown according to introduction and weed status  
395 combination.

396 Fig 2. Phylogeny with sexual system (outer ring), introduction status (middle ring, and weediness  
397 status (inner ring) indicated for each species. The 17 most common families are shaded and  
398 labeled with letters.

399 Fig 3. Results of binary logistic regressions comparing sexual systems between categories of  
 400 species (e.g. introduced non-weeds vs introduced weeds). Each dot represents the log odds ratio  
 401 ( $\pm$  95% confidence interval) of a particular model.

402 Table 1. Description of sexual systems in this study, including written description, symbolic  
 403 description (parentheses denote a single plant), and the ability to possibly self-fertilize.

	Description	Symbolic description	Possibly able to self with one plant?
Hermaphrodite (N=662)	Male and female function within a single flower	(♂)	Y
Dioecy (N=182)	Male and female function on different plants	(♀) + (♂)	N
Monoecy (N=145)	Male and female function in separate flowers on a single plant	(♀ ♂)	Y
Gynodioecy (N=47)	Female plants and hermaphrodite plants	(♀) + (♂)	Y, for ♀
Polygamodioecy (N=25)	Male and hermaphrodite flowered plants and female and hermaphrodite flowered plants	(♂ ♂) + (♀ ♀)	Y
Andromonoecy (N=16)	Male and hermaphrodite flowers on a single plant	(♂ ♂)	Y

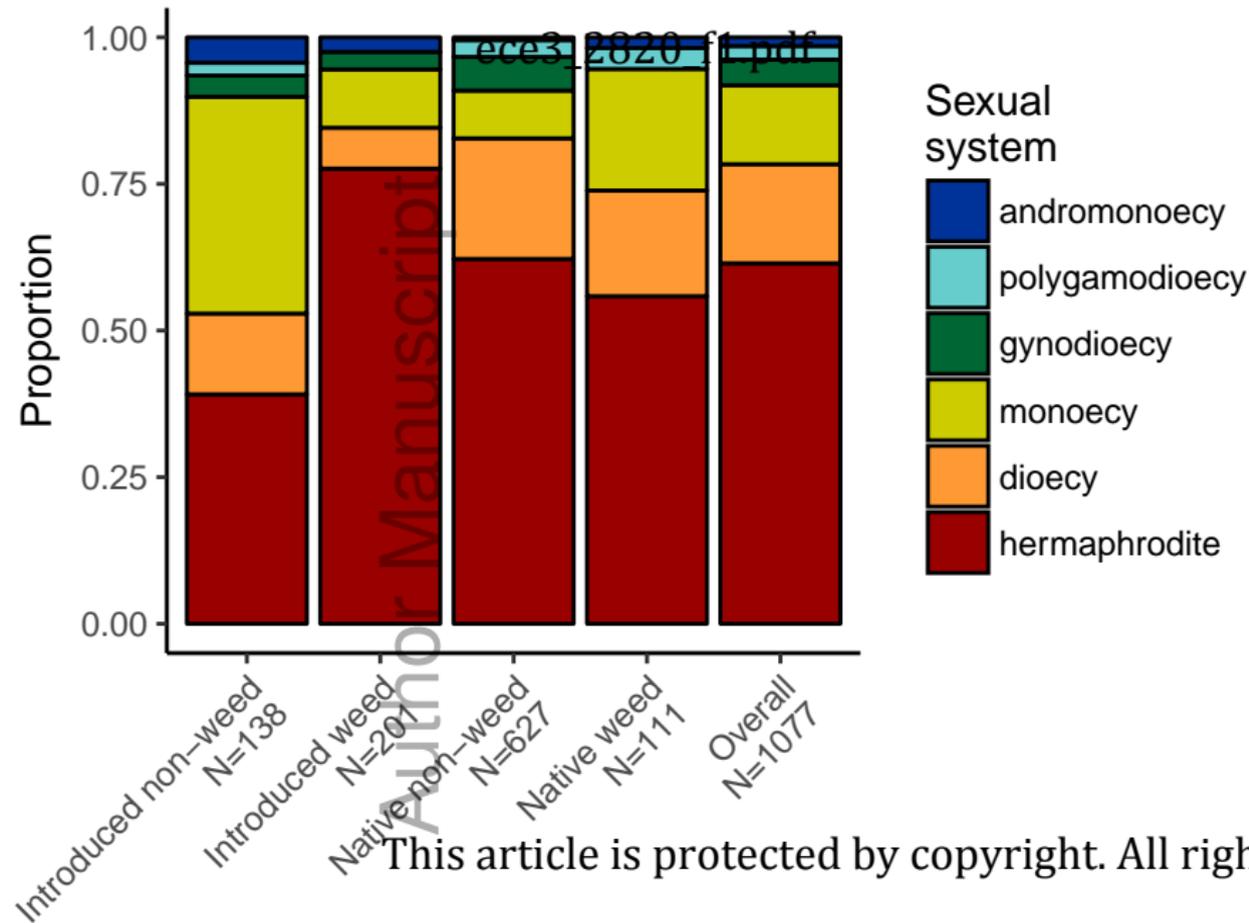

404  
 405 Table 2. Phylogenetic logistic regressions results for the effect of sexual system on weediness  
 406 likelihood for native and introduced species. Alpha is the phylogenetic signal parameter with  
 407 values greater than -4 indicating a phylogenetic signal.

	Introduced		Native	
<i>Sexual System</i>	Log odds ratio	alpha	Log odds ratio	alpha

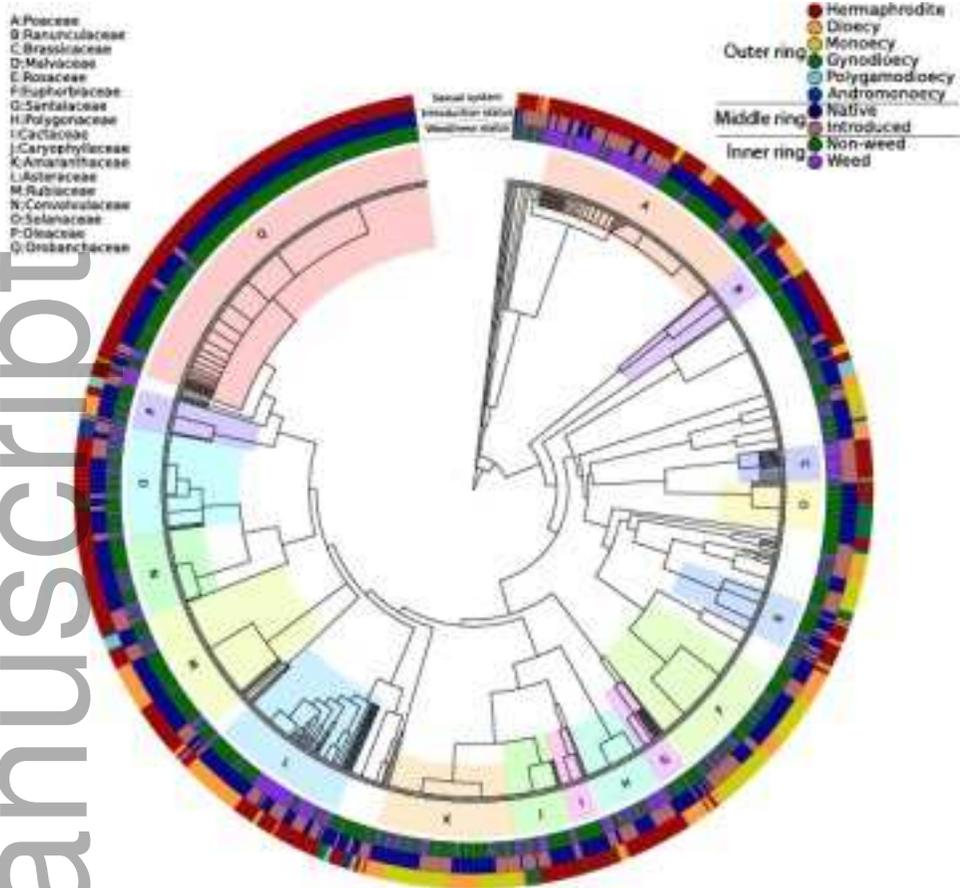

Hermaphrodite	1.56***	0.17	-0.50*	0.03
Dioecy	-0.58	0.04	-0.25	0.05
Monoecy	-1.56***	0.08	0.95*	0.04

408 \* P<0.05; \*\*\* P<0.0001
