ABSTRACT
OBJECTIVE: We hypothesized that the modulation index (MI), a summary measure of the strength of phase-amplitude coupling between high-frequency activity (>150 Hz) and the phase of slow wave (3-4 Hz), would serve as a useful interictal biomarker for epilepsy presurgical evaluation. METHODS: We investigated 123 patients who underwent focal cortical resection following extraoperative electrocorticography recording and had at least one-year of postoperative follow-up. We examined whether consideration of MI would improve the prediction of postoperative seizure outcome. MI was measured at each intracranial electrode site during interictal slow-wave sleep. We compared the accuracy of prediction of patients achieving ILAE Class-1 outcome between the full multivariate logistic regression model incorporating MI in addition to conventional clinical, seizure-onset zone (SOZ), and neuroimaging variables and the reduced logistic regression model incorporating all variables other than MI. RESULTS: Ninety patients had Class-1 outcome at the time of most recent follow-up (mean follow-up: 5.7 years). The full model had a noteworthy outcome predictive ability, as reflected by regression model fit $R^2$ of 0.409 and area under the curve (AUC) of receiver operating characteristic plot of 0.838. ‘Incomplete resection of SOZ (p<0.001)’, ‘larger number of AEDs at the time of surgery (p=0.007)’, and ‘larger MI in non-resected tissues relative to that in resected tissue (p=0.020)’ were independently associated with a reduced probability of Class-1 outcome. The reduced model had a lower predictive ability as reflected by $R^2$ of 0.266 and AUC of 0.767. Anatomical variability in MI existed among non-epileptic electrode sites, defined as those unaffected by MRI lesion, SOZ, or interictal spike discharges. With MI adjusted for anatomical variability, the full model yielded the outcome predictive ability of $R^2$ of 0.422, AUC of 0.844, and sensitivity/specificity of 0.86/0.76. SIGNIFICANCE: MI during interictal recording may provide useful information for prediction of postoperative seizure outcome.

KEY POINTS
Logistic regression model considering clinical, seizure-onset zone, and imaging variables alone predicted postoperative seizure outcome.

The full model considering interictal modulation index in addition to the aforementioned variables better predicted seizure outcome.

This article is protected by copyright. All rights reserved
Anatomical variability of interictal modulation index was suggested to exist across non-epileptic electrode sites.

Adjustment of interictal modulation index for anatomical variability minimally improved the outcome predictive ability of the full model.

The full model incorporating such adjusted modulation index had sensitivity/specificity of 0.86/0.76 for predicting seizure outcome.

INTRODUCTION: The epileptogenic zone (EZ) is conceptually defined as the region, the resection of which is necessary and sufficient to achieve seizure freedom. Many investigators emphasize the value of ictal recording, and suggest that the seizure onset zone (SOZ), defined as the region initiating ictal discharges during habitual seizures, is likely to comprise the EZ. As the sampling rate of digital recording systems have recently improved, investigators have described the value of interictal high-frequency activity at >80 Hz (HFA >80 Hz) for localizing the EZ. Specifically, resection of recording sites showing frequent episodes of HFA during invasive monitoring has been associated with excellent seizure outcome. However, whether pre-resection interictal HFA can inform post-resection clinical outcome, independently of the effects of resection size, SOZ on ictal recording, and neuroimaging data, remains an open question.

To evaluate whether interictal coupling between HFA and slow waves could be used as a preoperative electrographic biomarker, we examined whether a modulation index (MI) was associated with postoperative success rates in 123 patients with drug-resistant focal epilepsy. MI (HFA & slow wave) is a summary measure of the strength of coupling between HFA amplitude and slow wave phase. Within the SOZ of drug-resistant focal epilepsy, it is typical for 3-4 Hz slow waves to immediately follow interictal spike discharges associated with increased HFA. Our recent electrocorticography (ECoG) study demonstrated that MI (HFA >150 Hz & 3-4 Hz) was positively correlated to the occurrence rate of HFA >150 Hz at a given recording site during interictal slow-wave sleep, and that the SOZ was predicted by MI (HFA >150 Hz & 3-4 Hz) equally with MI (HFA >80 Hz & 3-4 Hz) and MI (HFA >250 Hz & 3-4 Hz). Taken together, measurement of MI (HFA >150 Hz & 3-4 Hz) was expected to effectively quantify the irritative zone, by delineating the severity and spatial gradient of interictal spike-and-wave discharges which are characterized by increased HFA >150 Hz amplitude stereotypically coupled with a phase of slow wave 3-4 Hz. The goal of the present study was to test the hypothesis that the full multivariate logistic model also incorporating MI (HFA >150 Hz & 3-4 Hz) would more accurately predict patients achieving surgical success compared to the reduced model only incorporating the conventional clinical, SOZ, and neuroimaging variables.
As an additional analysis, we determined whether anatomical variability in $\text{MI}_{ (>150 \ \text{Hz} \ \& \ 3-4 \ \text{Hz})}$ during slow-wave sleep would exist among non-epileptic electrode sites, defined as those unaffected by MRI lesion, SOZ, or interictal spike discharges. We believed this analysis was necessary for validating the application of $\text{MI}_{ (>150 \ \text{Hz} \ \& \ 3-4 \ \text{Hz})}$ in presurgical evaluation, because previous studies of non-epileptic eloquent cortex reported that the degree of phase-amplitude coupling between HFA and theta/alpha/beta activity were modulated by sensorimotor or cognitive tasks during wakefulness. If our analysis suggested that non-epileptic $\text{MI}_{ (>150 \ \text{Hz} \ \& \ 3-4 \ \text{Hz})}$ varies across regions of interest (ROIs) during slow-wave sleep, our subsequent analysis determined whether the outcome prediction with the full multivariate logistic regression model would be further improved by incorporating $\text{MI}_{ (>150 \ \text{Hz} \ \& \ 3-4 \ \text{Hz})}$ adjusted for such anatomical variability. Finally, we determined the effect of sleep staging on the $\text{MI}_{ (>150 \ \text{Hz} \ \& \ 3-4 \ \text{Hz})}$ at SOZ, to confirm the validity of usage of slow-wave sleep ECoG data in presurgical evaluation.

**METHODS**

**Patients**

The inclusion criteria was focal resective surgery following extra-operative ECoG recording with a sampling rate of 1,000 Hz at Children’s Hospital of Michigan or Harper University Hospital in Detroit between January 2007 and October 2016. Patients were excluded from the study if: (i) the EZ was determined to be present independently in both hemispheres on the basis of the non-invasive evaluation, (ii) they needed hemispherotomy or hemispherectomy, (iii) extensive brain malformations prevented analysis of consistent analysis of major anatomical landmarks, (iv) postoperative follow-up was shorter than 1 year, (v) prior resective epilepsy surgery, and (vi) age <4 years. We studied a consecutive series of 123 patients (Table 1) who satisfied the aforementioned criteria. This study protocol was approved by the Institutional Review Board at Wayne State University, and written informed consent was obtained from each patient or guardian of each pediatric patients.

**ECoG**

The principal methods of ECoG data acquisition are identical to those previously described. Platinum subdural disk electrodes (10 mm center-to-center distance) were placed on the epileptic hemisphere. Electrode placement was guided by semiology, scalp video-EEG, and neuroimaging data. Before dural closure, intraoperative photographs of the brain and subdural electrodes were taken. Following closure, surface electromyography (EMG) electrodes were placed on the deltoid muscles and electrooculography (EOG) electrodes were placed 2.5 cm below and 2.5 cm lateral to the outer canthi.
Extraoperative ECoG signals were recorded with a band-pass of 0.016 to 300 Hz for 3 to 7 days. The averaged voltage of ECoG signals from the fifth and sixth intracranial electrodes of the amplifier was used as the original reference, and signals were re-montaged to a common average reference. Antiepileptic drugs (AEDs) were discontinued, and resumed once SOZ was determined. The SOZ is defined as electrode sites initially showing sustained rhythmic ECoG changes prior to the onset of habitual clinical seizure symptoms, not explained by state changes, and clearly distinguished from interictal activity.\textsuperscript{8} Ictal patterns of epileptic spasms are characterized by fast-wave bursts quickly propagated to multiple lobes,\textsuperscript{28} whereas those of focal seizures are characterized by repetitive spike-and-wave discharges or focal fast-wave discharges followed by gradual propagation to the surrounding regions.\textsuperscript{8} Electrode sites affected by artifacts were excluded from further analysis. A total of 12,964 electrodes (mean: 105.4 electrodes per a patient; range: 32 to 152 per a patient) were included into the multivariate logistic regression analyses.

MRI
Preoperative MRI was reviewed by an experienced pediatric neuroradiologist who was blinded to scalp video-EEG data.\textsuperscript{24} A three-dimensional surface image was created with the locations of electrodes co-registered on it.\textsuperscript{25} The spatial normalization of electrode sites was performed using FreeSurfer scripts (http://surfer.nmr.mgh.harvard.edu). All electrode sites on each subject’s FreeSurfer brain surface were plotted on the averaged FreeSurfer surface image.\textsuperscript{25,26} Parcellation of cortical ROIs was performed at both individual and spatially-normalized brain surfaces (Figure 1).

Surgical decision making
Surgical resection was guided by the clinical factors, semiology, visual assessment of extraoperative ECoG, extent of lesion, and eloquent areas.\textsuperscript{8} We intended to completely remove SOZ, sites of frequent interictal spikes non-attributable to propagation from SOZ, and lesions surrounding SOZ (if present). When the SOZ was not identified, we planned to remove sites showing frequent interictal spike-wave discharges and the associated lesion. Simultaneously, we intended to preserve the eloquent areas and their associated vascular structures along sulcal boundaries. In cases where eloquent cortex overlapped with the regions presumed to be epileptogenic, the exact resection margin was determined, on an individualized basis, after intense discussion with the family of a given patient.

Measurement of the size of resection
Intraoperative photographs were obtained prior to dural closure to confirm the extent of resection. We determined whether all electrode sites marked as SOZ were completely removed. In cases where SOZ sites were located at the top of a sulcus and resection was completed up to that sulcus, the SOZ was considered to be completely removed. The extent of resection (how much percentage of the affected
hemisphere) was quantified using FreeSurfer scripts by H.M. while being blinded to the postoperative seizure outcome.

**Modulation index (MI)**

As this is a retrospective observational study, the interictal MI (>150 Hz & 3-4 Hz) did not affect our surgical decision making. Measurement of the MI was performed using EEGLAB Toolbox winPACTv.2.0 (https://sccn.ucsd.edu/eeglab/index.php). MI (>150 Hz & 3-4 Hz) during slow-wave sleep was calculated at each electrode site using the algorithm identical to that previously reported. 17,18 Ten earliest available, 30-second, least artifactual epochs of slow-wave sleep were selected from the first (or the second if needed) evening of extraoperative ECoG recording by H.M., while being blinded to the seizure outcome. All selected epochs were ≥2 hours apart from seizure events, and high-pass filtered at 150 Hz. All ECoG data points were Hilbert transformed, and used for computing MI (>150 Hz & 3-4 Hz), the strength of coupling between the amplitude of HFA >150 Hz and the instantaneous phase of local slow wave 3–4 Hz. Each electrode site was finally assigned MI (>150 Hz & 3-4 Hz) value averaged across ten 30-second epochs.

Our MI algorithm does not differentiate HFA derived from oscillations and that from non-oscillatory spike discharges. 31,32 We believe our analytic approach is justified in this clinical study, since oscillatory and non-oscillatory HFAs are both reported to be useful to localize SOZ. 33 Some reported that interictal HFA >200 Hz on clinical electrodes is mostly derived from non-oscillatory spike discharges. 32 Others reported that HFA >250 Hz disentangled from non-oscillatory spikes had insufficient sensitivity to localize the SOZ. 34 Figure 2 helps readers in comprehending the relationship between representative ECoG traces and resulting MI (>150 Hz & 3-4 Hz) values. Non-oscillatory spikes are certainly expected to contribute to increased HFA >150 Hz as well as increased MI (>150 Hz & 3-4 Hz). 35 Supplementary Figure S1 presents the distribution of MI (>150 Hz & 3-4 Hz) in (1) ‘SOZ’, (2) ‘spiking sites’ (non-SOZ but affected by interictal spike discharges), and (3) ‘non-epileptic sites’.

**Seizure outcome**

After a minimum of one year, postoperative seizure outcome was classified according to the ILAE classification. 36 Medical charts and phone calls were used by investigators unaware of the results of MI analysis. Class-1 outcome was treated as success, and others as failure. Requirement of re-operation was treated as failure, even if patients achieved Class-1 outcome following the second surgery.

**Outcome prediction using multivariate logistic regression models**

The statistical analysis was performed using SPSS Statistics 25 (IBM Corp., Chicago, IL, USA). The significance was set at p-value at 0.05. We initially determined how well patients achieving surgical success would be predicted by a multivariate logistic regression model incorporating clinical, SOZ, neuroimaging...
variables, but not an MI variable (referred to as ‘reduced model’). The outcome measure was ‘achievement of ILAE Class-1 outcome’. The predictor variables (Table 2) included: ‘age’, ‘gender’, ‘presence of daily seizures’, ‘number of oral AEDs taken immediately prior to intracranial electrode placement’, ‘affected hemisphere’, ‘cortical lesion on MRI’, ‘habitual clinical seizure events captured during extraoperative ECoG recording’, ‘incomplete resection of SOZ’, ‘necessity of extra-temporal lobe resection’, and ‘size of resection’. This analysis yielded a model fit $R^2$ (ranging from 0 to 1), indicating how much the seizure outcome can be explained by the variance of collective variables incorporated in the model. Each patient was given a predicted probability of surgical success based on her/his clinical, SOZ, and neuroimaging profiles. Receiver operating characteristic (ROC) analysis,$^8,19,34$ employed to the predicted probabilities assigned to all 123 patients, determined the accuracy of the reduced model in predicting surgical success. The area under the curve (AUC) of a given ROC plot (Figure 3) indicates the overall power of outcome prediction (0.5: random prediction; 1.0: perfect prediction).

We subsequently determined whether a multivariate logistic regression model incorporating an MI variable in addition to the aforementioned clinical, SOZ, and neuroimaging variables (referred to as ‘full model’) would improve the outcome predictive ability. The added MI predictor variable was ‘subtraction MI’, defined as ‘subtraction of MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ averaged across all preserved sites from MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ averaged across all resected sites’. A patient would be assigned a larger subtraction MI, if areas showing larger MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ were resected and those showing relatively smaller MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ were preserved. Assessment of $R^2$ and AUC on ROC plot effectively allowed us to estimate how much more accurately the full model, compared to the reduced model, predicted surgical success. Comparison of 122 ‘sensitivity × specificity’ values consisting of each ROC plot determined whether the size of AUC differed between two models (studentized bootstrap statistics).

**Variability in MI across anatomical regions and sleep stages**

We determined the spatial characteristics of MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ at non-epileptic electrode sites during slow-wave sleep as well as the effect of sleep staging on the overall MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ profiles. These additional analyses were employed to 47 patients (age range: 4 to 19 years) in whom ECoG signals were sampled from all four lobes, sleep spindles were visualized at non-epileptic frontal regions, and posterior-dominant alpha activity was noted at non-epileptic occipital regions during wakefulness. Such widespread electrode coverage, together with EOG/EMG, allowed accurate sleep staging and measurement of MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ during wakefulness, sleep stage 1, sleep stage 2, and REM sleep.$^{30}$

To determine whether interictal MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ within an ROI differed from that within the rest of regions, the mixed model analysis$^{37}$ was employed to 2,477 non-epileptic electrode sites of the 47 patients. The dependent variable was ‘MI$(>150 \text{ Hz} & 3 - 4 \text{ Hz})$ during slow-wave sleep’. The following covariates were treated as fixed effects: ‘age’, ‘gender’, ‘presence of daily seizures’, ‘number of AEDs’, ‘affected...
hemisphere’, ‘lesion on MRI’, ‘habitual clinical seizure events during extraoperative ECoG’, and ‘one of the 28 ROIs’ listed in Figure 1. ‘Intercept’ and ‘patient’ were treated as random effects. Bonferroni correction was employed for multiple comparisons across 28 ROIs.

To determine the effect of sleep stages on MI($>150$ Hz & 3-4 Hz), another mixed model analysis was subsequently employed to 4,996 sites (2,477 non-epileptic sites, 440 SOZ sites, and 2,079 spiking but non-SOZ sites) of the same cohort of 47 patients. The dependent variable was ‘MI($>150$ Hz & 3-4 Hz)’. The following covariates were treated as fixed effects: ‘age’, ‘gender’, ‘presence of daily seizures’, ‘number of AEDs’, ‘affected hemisphere’, ‘lesion on MRI’, ‘habitual clinical seizure events captured during extraoperative ECoG’, ‘SOZ’, ‘presence of interictal spike discharges’, ‘sleep or wakefulness’, ‘non-REM sleep’, and ‘slow-wave sleep’.

**Full multivariate logistic regression model incorporating MI adjusted for anatomical locations**

In case the aforementioned mixed model analysis on 47 patients revealed that MI($>150$ Hz & 3-4 Hz) at non-epileptic electrode sites within an ROI differed from that within the rest of ROIs, we modified the full multivariate logistic regression model by incorporating MI($>150$ Hz & 3-4 Hz) adjusted for the anatomical location [i.e.: aMI($>150$ Hz & 3-4 Hz)]. Specifically, MI($>150$ Hz & 3-4 Hz) was adjusted by its mixed model estimate, if a given electrode site was within one of the ROIs showing a significant difference. Using collective data from all 123 patients, we finally determined whether the outcome predictive ability would be further improved by the full model incorporating subtraction aMI, defined as ‘subtraction of aMI($>150$ Hz & 3-4 Hz) averaged across all preserved sites from aMI($>150$ Hz & 3-4 Hz) averaged across all resected sites’.

**RESULTS**

**Outcome prediction**

ILAE Class 1, 2, 3, 4, 5, and 6 outcome was noted in 90, 3, 13, 9, 8, and 0 patients, respectively (mean follow-up period: 5.7 years; range: 1.0 to 10.8 years). The reduced model had a significant outcome predictive ability ($R^2$ of 0.266; p<0.001). ‘Incomplete SOZ resection (odds ratio [OR]: 0.099; p<0.001)’, and ‘larger number of AEDs (OR: 0.466; p=0.014)’ were independently associated with a smaller chance of success (Table 2). The accuracy of outcome prediction rated by ROC analysis was AUC of 0.767 (p<0.001). When the sensitivity was set to 0.86, the specificity was 0.48 (Figure 3).

The full model, which incorporated subtraction MI, improved the outcome predictive ability ($R^2$ of 0.409; p<0.001). ‘Incomplete SOZ resection (OR: 0.039; p<0.001)’ and ‘larger number of AEDs (OR: 0.396; p=0.007)’ were associated with a smaller chance of success. ‘Larger subtraction MI’ was independently associated with a greater chance of success (Table 2), and each increase of 0.01 point increased the odds of success.

This article is protected by copyright. All rights reserved
surgical success by 48% (p=0.020). The accuracy of outcome prediction rated by ROC analysis was AUC of 0.838 and sensitivity/specificity of 0.86/0.73 (p<0.001; Figure 3). Studentized bootstrap statistics suggested that the full model had a larger AUC compared to the reduced model (t=11.826; p<0.001).

Anatomical variability in MI

The mixed model analysis employed to non-epileptic electrode sites demonstrated the existence of anatomical variability in MI (150 Hz & 3-4 Hz) during slow-wave sleep. The following six ROIs showed difference in MI (150 Hz & 3-4 Hz) compared to the rest of ROIs (p<0.001). Lingual (estimate = +0.016), cuneus (estimate = +0.018), lateral-occipital (estimate = +0.016), and fusiform regions (estimate = +0.004) had larger MI (150 Hz & 3-4 Hz) (Figure 4). Superior-temporal (estimate = -0.004) and superior-frontal regions (estimate = -0.005) had smaller MI (150 Hz & 3-4 Hz).

Outcome prediction with MI adjusted for anatomical variation

Since the anatomical variability in MI (150 Hz & 3-4 Hz) was suggested to exist among non-epileptic electrode sites, we decided to determine the outcome predictive ability of the full model incorporating aMI (150 Hz & 3-4 Hz). At a lateral-occipital site, for example, aMI (150 Hz & 3-4 Hz) was smaller by 0.016 than the original/unadjusted MI (150 Hz & 3-4 Hz). Conversely, aMI (150 Hz & 3-4 Hz) was treated to be identical to MI (150 Hz & 3-4 Hz) in regions other than the aforementioned six ROIs. The modified full model had an R² of 0.422 (p<0.001). ‘Incomplete SOZ resection (OR: 0.034; p<0.001)’ and ‘larger number of AEDs (OR: 0.388; p=0.007)’ were associated with a smaller chance of success. ‘Larger subtraction aMI’ was independently associated with a greater chance of success (Table 2); thereby, each increase of 0.01 point increased the odds of surgical success by 59.9% (p=0.014); the accuracy of outcome prediction of the modified full model was rated as AUC of 0.844 and sensitivity/specificity of 0.86/0.76 (p<0.001; Figure 3).

Effect of sleep stages on MI

The spatial characteristics of MI (150 Hz & 3-4 Hz) during each sleep stage is presented in Figure 4. The mixed model analysis demonstrated that SOZ had greater MI (150 Hz & 3-4 Hz) compared to non-SOZ (estimate = +0.045; t = +25.966; p<0.001), and non-REM sleep had greater MI (150 Hz & 3-4 Hz) compared to the other stages (i.e.: wakefulness or REM sleep) (estimate = +0.004; t = +3.149; p=0.002). No significant difference in MI (150 Hz & 3-4 Hz) was found between slow-wave sleep and other states.

DISCUSSION

Value of the irritative zone

This article is protected by copyright. All rights reserved
This study provided evidence that MI\textunderscore{\textgreater\textasciitilde}150 Hz \& 3-4 Hz may be a useful adjunct for localization of the EZ. Incorporation of MI, regardless of the usage of indices adjusted or unadjusted for anatomical variability, improved seizure outcome prediction. Specifically, the outcome predictive ability rated by AUC of the ROC plot was improved from 0.767 to 0.838 [when unadjusted MI was used] or to 0.844 [when adjusted MI was used]. One of the strengths of our study is its sample size allowing assessment of the independent effects of multiple co-variates including clinical, ictal ECoG, and neuroimaging variables. Our results support the theoretical notion that the EZ is optimally delineated by considering the spatial extents of SOZ and irritative zone.\textsuperscript{1,2} Based on their effect sizes (Table 2), we speculate that ictal recordings, compared to the interictal MI, provide more direct information to delineate the regions responsible for generation of habitual seizures.

**Significance of anatomical variability in MI**

We observed anatomical variability in non-epileptic MI during slow-wave sleep. Specifically, occipital and fusiform regions showed relatively greater MI. Relative increase of MI in non-epileptic visual pathways is likely to be partly attributed to physiological augmentation of HFA taking place preferentially at a rate of 0.5 to 1 Hz during slow-wave sleep.\textsuperscript{19} Such augmentation of HFA, preferentially locked to the trough of slow wave 0.5-1 Hz during slow wave sleep (Figure 2D), likely reflects increased cellular/synaptic activity (also known as up-states) that may play a role in low-order visual memory consolidation.\textsuperscript{29,38} In turn, each attenuation taking place between HFA augmentations likely reflects hyperpolarization and cellular silence (also known as down-states). Superior-temporal and superior-frontal sites showed relatively smaller non-epileptic MI, but the magnitude of difference in these regions was much smaller compared to that in the occipital regions.

Because the existence of anatomical variability in non-epileptic MI has been suggested, we examined how well adjustment of MI for regional variability would further improve the performance of outcome prediction with the full model. This additional analysis demonstrated that incorporation of adjusted MI only resulted in a minimal improvement of outcome predictive ability (AUC: 0.838 → 0.844; sensitivity/specificity: 0.86/0.73 → 0.86/0.76). It is possible that the ROIs used in this study may have been too large for optimal adjustment, and that MI adjusted using smaller ROIs would have more effectively improved the accuracy of outcome prediction of the full model.

**Methodological considerations**

The sample size, data availability by the time of surgery, and collinearity problems among the predictor variables need to be taken into account, for selection of predictor variables to be incorporated in the full multivariate logistic regression models. ‘Presence/absence of cortical lesions on MRI’ was selected because MRI-lesional epilepsy, compared to non-lesional, has been reported to have a better postoperative seizure prognosis.\textsuperscript{39,40} ‘Necessity of extra-temporal lobe resection’ was also selected because such surgery is...
generally associated with a less favorable prognosis compared to resection confined to the temporal lobe. Neither pathological diagnosis nor postoperative MRI was incorporated in our models, since such data are available only after resective surgery. Individual 3D surface images and intraoperative photographs allowed us to measure the size of resection prior to completion of the resective surgery. The duration of epilepsy was not incorporated in our regression models, because of the high collinearity between patient age and epilepsy duration. A larger number of oral AEDs was found to be associated with a smaller chance of success. An interpretation for this observation is that patients required to take a larger number of oral AEDs may have had more severe forms of focal epilepsy.

We are willing to share our ECoG dataset with investigators who express an interest in testing the performance of MI or other measures of their interest (e.g.: occurrence rate of interictal HFA). Our study was not designed to determine whether $MI_{150\,\text{Hz} \& 3\,-\,4\,\text{Hz}}$ is more useful than other interictal HFA measures. Some investigators suggested that characterization of the angle of slow wave phase preferentially coupled with HFA was useful in localization of SOZ. For measurement of the amplitude of HFA, the present study employed a high-pass filter of 150 Hz; thus, the amplitude of HFA$80\,-\,150\,\text{Hz}$ may have only modestly contributed to computation of $MI_{150\,\text{Hz} \& 3\,-\,4\,\text{Hz}}$. HFA$80\,-\,150\,\text{Hz}$ and HFA$>150\,\text{Hz}$ are also known as ripples and fast ripples, respectively. Several studies demonstrated that HFA$>80\,\text{Hz}$, HFA$>150\,\text{Hz}$ and HFA$>250\,\text{Hz}$ largely share similar spatial-temporal profiles. Previous ECoG studies reported that regions showing interictal spike discharges associated with increased HFA$80\,\text{Hz}$ amplitude or HFA$>80\,\text{Hz}$ coupled with slow wave 3-4 Hz often turned out to involve the SOZ, whereas high-amplitude, sharply-contoured transients at alpha/beta frequency range can be observed in non-epileptic regions.

We speculate that MI during slow-wave sleep and stage-2 sleep would yield a similar clinical utility in epilepsy presurgical evaluation. These sleep stages share a similar spatial pattern of MI (Figure 4). The mixed model analysis demonstrated that the contrast of MI between SOZ and non-SOZ was about 10 times greater than that between non-REM sleep and the other stages (estimate of SOZ: +0.045 vs estimate of non-REM sleep: +0.004).

This study is a retrospective observational study, which should be considered in the interpretation of our results. Our results by no means indicate that cortical areas showing increased MI should be blindly removed to optimize the postoperative outcome. Epilepsy surgery teams should estimate the extent of epileptogenic zone by taking into account the clinical context of a given patient. A multi-center prospective study is warranted to determine how universally useful the MI variable is in presurgical evaluation. It remains unknown how the utility of MI is altered by different electrode types (e.g.: disk vs depth electrodes), different montage (e.g.: common average reference vs bipolar montage), anesthesia conditions, and intracranial electrode placement approaches (e.g.: large vs limited coverage). A retrospective study of 54 patients reported that the occurrence of HFA$>250\,\text{Hz}$ on intraoperative ECoG immediately following cortical resection was associated with a greater risk of seizure recurrence. One logical next step would be to

determine whether quantitative measurement of MI during intraoperative ECoG recording will provide useful information to localize the EZ.

ACKNOWLEDGEMENT

This work was supported by NIH grants NS047550 (to E.A.), NS064033 (to E.A.), and NS089659 (to J.W.J.). We are grateful to Harry T. Chugani, MD, Aashit Shah, MD, Sandeep Mittal, MD, and Deniz Altinok, MD at Children's Hospital of Michigan, Detroit Medical Center, Wayne State University for the collaboration and assistance in performing the studies described above.

DISCLOSURE

None of the authors has any conflict of interest to disclose. We confirm that we have read the Journal’s position on issues involved in ethical publication and affirm that this report is consistent with those guidelines.

**FIGURE LEGEND**

Figure 1. Regions of interest (ROIs) and spatial distribution of intracranial electrode coverage.

This article is protected by copyright. All rights reserved
Figure 2. Relationship between electrocorticography (ECoG) trace and modulation index in a 7-year-old boy with frontal lobe epilepsy.

Representative ECoG waveforms are presented with their corresponding locations, time-frequency plots, and $MI_{>150 \text{ Hz} & 3-4 \text{ Hz}}$ values. (A) and (B): classified as seizure onset zone (SOZ). The spectral features seen on time-frequency plots are consistent with the notion that observed HFA$_{>150 \text{ Hz}}$ was mostly derived from non-oscillatory spikes.\textsuperscript{31,33,35} (C): classified as a site showing interictal spike discharges. (D) and (E): classified as non-epileptic sites. TC: time constant.

Figure 3. Receiver operating characteristic (ROC) plots.

ROC plots indicate the model performance to predict surgical success, defined as achievement of ILAE Class-1 outcome. Blue line: the reduced logistic regression model only incorporating clinical, SOZ, neuroimaging variables alone. Red line: the full model also incorporating $subtraction MI$ (MI unadjusted for anatomical variability). Green line: the full model also incorporating $subtraction aMI$ (MI adjusted for anatomical variability).

Figure 4. Modulation index during different sleep stages.

The spatial characteristics of $MI_{>150 \text{ Hz} & 3-4 \text{ Hz}}$ during different sleep stages are presented. (A to E) present $MI_{>150 \text{ Hz} & 3-4 \text{ Hz}}$ at 440 seizure onset zone (SOZ) electrode sites. (F to J) present $MI_{>150 \text{ Hz} & 3-4 \text{ Hz}}$ at 2,477 non-epileptic electrode sites, defined as those unaffected by MRI lesion, SOZ, or interictal spike discharges.\textsuperscript{22} (K) The spatial distribution of electrode coverage of 47 patients used for this analysis.

AEDs: antiepileptic drugs. ECoG: electrocorticography. SOZ: seizure onset zone. MI: modulation index. *Subtraction MI* is defined as ‘subtraction of MI averaged across all preserved sites from MI averaged across all resected sites’. 95%CI: 95% confidence interval. Only five of the 17 patients whose SOZ was incompletely removed achieved Class-1 outcome, whereas 85 of the remaining 106 patients achieved such surgical success. *: In other words, each increase of 0.01 point increased the odds of surgical success by 48.0% (95%CI: 6.3% to 206.2%; p=0.020). **: Each increase of 0.01 point increased the odds of surgical success by 59.9% (95%CI: 9.8% to 232.8%; p=0.014).
