Optical Outcoupling

Systematic Control of the Orientation of Organic Phosphorescent Pt Complexes in Thin Films for Increased Optical Outcoupling

Jongchan Kim, Thilini Batagoda, Jaesang Lee, Daniel Sylvinson, Kan Ding, Patrick J. G. Saris, Ushasree Kaipa, Iain W. H. Oswald, Mohammad A. Omary, Mark E. Thompson, and Stephen R. Forrest*

Orienting light-emitting molecules relative to the substrate is an effective method to enhance the optical outcoupling of organic light-emitting devices. Platinum(II) phosphorescent complexes enable facile control of the molecular alignment due to their planar structures. Here, the orientation of Pt(II) complexes during the growth of emissive layers is controlled by two different methods: modifying the molecular structure and using structural templating. Molecules whose structures are modified by adjusting the diketonate ligand of the Pt complex, dibenzo-(f,h)quinoxaline Pt dipivaloylmethane, (dbx)Pt(dpm), show an ≈20% increased fraction of horizontally aligned transition dipole moments compared to (dbx)Pt(dpm) doped into a 4,4'-bis(N-carbazolyl)-1,1'-biphenyl, CBP, host. Alternatively, a template composed of highly ordered 3,4,9,10-perylenetetracarboxylic dianhydride monolayers is predeposited to drive the alignment of a subsequently deposited emissive layer comprising (2,3,7,8,12,13,17,18-octaethyl)-21H,23H-porphyrinplatinum(II) doped into triindolotriazine. This results in a 60% increase in horizontally aligned transition dipole moments compared to the film deposited in the absence of the template. The findings provide a systematic route for controlling molecular alignment during layer growth, and ultimately to increase the optical outcoupling in organic light-emitting diodes.

DOI: 10.1002/adma.201900921

To date, studies on phosphorescent emitter orientation have largely focused on Ir complexes.^[1–9] While the common Ir(III) complexes used in organic light-emitting diodes (OLEDs) have octahedral geometries, related Pt(II) complexes have square planar geometries. In this context, there has been a rapid progress in developing high external quantum efficiency Pt complex emitters^[10,11] for phosphorescent organic light-emitting diodes (PhOLEDs) with favorable color characteristics^[12,13] and long operational lifetimes.^[14] Highly efficient PhOLEDs using these complexes have been enabled by increasing the fraction of light outcoupled from the PhOLED by aligning the transition dipole moments (TDMs) of the light-emitting molecules parallel to the substrate.^[15-17] Controlling the molecular alignment, therefore, can play a role in improving the efficiency of Pt-complexbased PhOLEDs. The planar structure of Pt complexes has a better chance of forming π -stacking networks than bulky, 3D molecules, potentially enabling control of the molecular orientation in films via external forces such as structural templating.^[18]

In this work, we control the Pt complex orientation relative to the substrate plane during the film growth using two different approaches. The first is to modify the molecular structure of heteroleptic bidentate Pt complexes to induce preferred horizontal alignment of the molecule via molecular anisotropy as illustrated in Figure 1A. Angle-dependent p-polarized photoluminescence (PL) of a film comprising dibenzo-(*f*,*h*)quinoxaline Pt dipivaloylmethane [(dbx)Pt(dpm)] (see Figure 1B), doped in the organic host, 4,4'-bis(Ncarbazolyl)-1,1'-biphenyl (CBP), revealed that the dopant TDMs are preferentially oriented perpendicular to the substrate. Studies of modified complexes of (dbx)Pt(dpm) (dpm: dipivaloylmethane) showed that the aromatic ligands control molecular orientation. The second approach achieves the preferred orientation of the emitter by predepositing a thin (<2 nm) layer of a molecular template on the substrate that promotes the horizontal alignment of subsequently deposited emissive Pt complexes (Figure 1A).^[18,19]

The relationship between TDM orientation and film morphology is investigated via a combination of angle-dependent PL and X-ray diffraction (XRD). Correlations between film crystallinity and orientation controlled via structural templating are investigated by varying the concentration of a polycrystalline host in the emissive layer, revealing that a host concentration of >70 vol% is required to achieve significant control over otherwise randomly distributed phosphor orientations. An increase of nearly 60% in horizontally aligned molecules is obtained using a molecular template compared with films deposited directly onto bare sapphire and fused silica substrates. We find that varying the details of molecular and substrate structures provides a systematic route for controlling molecular alignment during layer growth, which is promising to ultimately enhance the optical outcoupling of the emitting species, rendering these effective strategies for increasing OLED efficiency.

We study a series of bidentate Pt(II) complexes with chromophoric (C^N) and ancillary (L^X) ligands, or two or one chromophoric bidentate (N^N) or tetradentate (N^N^N) ligands, respectively, as shown in Figure 1. Density functional theory (DFT) is used to determine the TDM orientation relative to the molecular frame in these complexes. The TDM of a given (C^N)Pt(L^X) complex lies in the (C^N)Pt plane with an angle δ between the TDM and the Pt-N bond, which ranges between 20° and 45° for the (C^N)Pt(L^X) complexes.^[20] We chose (dbx)Pt(dpm) as the reference dopant molecule, comprising a chromophoric dibenzo-(f,h)-quinoxaline (dbx) aromatic ligand, and an ancillary dipivaloylmethane (dpm) aliphatic ligand. The complexes are doped into CBP at 10 vol%, and angle-dependent PL measurements of the films are analyzed to obtain the TDM orientation relative to the substrate of $\theta_{hor} = 0.54 \pm 0.01$, Figure 2A. Here, θ_{hor} corresponds to fractional contribution of the net TDM direction lying in the horizontal plane parallel to the substrate; thus, the faction in the vertical direction is 0.46. An isotropic thin film gives $\theta_{\rm hor} = 0.67$. The DFT calculation in the inset shows that $\delta = 36^{\circ}$. Shifting to a smaller ancillary ligand in (dbx)Pt(acac) (acac: acetylacetonate) shows similar alignment ($\theta_{hor} = 0.53 \pm 0.01$) to (dbx) Pt(dpm) when doped at 1 and 10 vol% in CBP; see Figure 2B,C.

Figure 3 shows the angle-dependent PL of several different (C^N)Pt(L^X) complexes doped at 10% in CBP. The film comprising (ppy)Pt(dpm) (ppy: 2-phenylpyridinate) in Figure 3A demonstrates an increased net horizontal alignment of the TDM compared to (dbx)Pt(dpm) ($\theta_{hor} = 0.62 \pm 0.01$ vs 0.54 ± 0.01). Introduction of an aromatic ancillary ligand comprising two mesityl groups attached to the acac ligand producing (dmes)Pt(dbx) (dmes: 1,3-dimesitylpropane-1,3-dione) increases the horizontal component even further to $\theta_{hor} = 0.73 \pm 0.01$. Attaching an additional Pt-dpm on the opposite side of the dbx ligand in (dbx)(Pt(dpm))₂ shown in Figure 3C results in a horizontal component of $\theta_{hor} = 0.76 \pm 0.01$.

The emission spectra of Pt-complex doped CBP films are shown in **Figure 4**. Contrary to changes in the ancillary (L^X) ligand, changes in the chromophoric (C^N, N^N, or N^N^N^N) ligand lead to marked shifts in the emission spectra. In contrast, promoting molecular alignment via substrate structural templating provides a potential route to controlling the orientation of the square planar Pt complexes within a blended film without changing the molecular structure and hence its emission spectrum. Two phosphorescent Pt complexes molecules were used to explore the templating approach; one comprising a neat PtD film and the other consisting of (2,3,7,8,12,13,17,18-octaethyl)-21*H*,23*H*-porphyrinplatinum(II) (PtOEP) doped at 10 vol% into triindolotriazine (Tint) (see Figure 1B).

Figure 5 shows the photophysical and structural characteristics of the neat PtD, Tint, PtOEP, and PtOEP-doped Tint films on sapphire substrates. The broad PL peak at a wavelength of λ_{di} = 572 nm of neat PtD in Figure 5A is due to dimer or aggregate phosphorescent emission. This feature is less pronounced in PtD diluted to 1 vol% in a poly(methyl methacrylate) (PMMA) host due to monomer triplet emission at $\lambda_{\rm m}$ = 450–480 nm. The PtOEPdoped Tint shows dominant monomer emission at $\lambda_m = 653$ nm in Figure 5B, with the triplet, T₁, TDM lying within the PtOEP molecular plane (see inset), and weak dimer emission at λ_{di} = 783 nm. Monomer emission is dominant since PtOEP molecules are diluted in the host matrix. (See Table 1 for the structural and emission information of all reference Pt complexes.) Furthermore, steric hindrance between the PtOEP ethyl groups reduces coupling between the dopants. X-ray diffraction patterns of films deposited onto a sapphire substrate in Figure 5C exhibit intense (200), (001), and (220) diffraction peaks of PtD, PtOEP, and Tint, respectively (see Figures S1 and S2 in the Supporting Information for crystal structures and diffraction patterns of PtD and Tint).

Film morphology was also controlled via structural templating using a self-organized, 1.5 nm (\approx 5 monolayer) thick 3,4,9,10-perylenetetracarboxylic dianhydride (PTCDA) layer.^[18,21] The PTCDA grows in the flat-lying α -phase (102) (i.e., molecular planes of PTCDA lie parallel to the substrate), thus increasing the possibility of π -stacking with the subsequently deposited molecules.^[22] For the angle-dependent PL measurement in **Figure 6**A, a neat layer of 1,4,5,8-naphthalenetetracarboxylic dianhydride (NTCDA) of the same thickness (1.5 nm) was deposited on the PTCDA prior to deposition of the emissive layer. The NTCDA/PTCDA bilayer transfers its structure to the subsequently deposited molecules (Figure S4, Supporting Information) while also blocking excitons formed in the emissive layer from quenching at PTCDA with its relatively low singlet exciton energy (1.95 eV).^[23]

The PtD film deposited on the NTCDA/PTCDA template shows a decreased horizontal orientation ($\theta_{hor} = 0.33 \pm$ 0.01) of the PtD dimer TDM compared to deposition on a bare fused silica substrate with $\theta_{\rm hor}$ = 0.91 ± 0.01 (see Figure 6A). To determine the relationship between TDM orientation and film morphology, X-ray pole figures of the (200) and (020) planes are provided in Figure 6B,C. The configuration of each plane within the PtD crystal is shown in Figure 6D. The film deposited directly on the sapphire substrate in Figure 6B shows the (200) diffraction peak (2θ = 8.2–8.5°) at a radial angle of $\psi = 0^\circ$, suggesting that the (200) plane lies parallel to the substrate. The (200) plane lies perpendicular to the PtD molecular plane; hence, the (200) diffraction peak at $\psi = 0^{\circ}$ indicates the molecular plane is vertically aligned to the substrate. The (020) plane ($2\theta = 26.6^{\circ}$) parallel to the molecular plane shows a diffraction peak at $\psi = 0^{\circ}$ for the film on the template layer, indicating that the PtD molecules lie with their molecular planes parallel to the templating molecules. The X-ray diffraction patterns of the 30 nm thick film of PtD deposited on sapphire, ITO, and PTCDA are shown in Figure S5 in the Supporting Information.

with a range of concentrations deposited on the NTCDA/ PTCDA template, showing the controlled morphology of the film at PtD concentration of >70 vol%.

Orientation studies have been conducted for other complexes whose chemical structure and PL maxima are shown in Table 2. The orientations of the blended film comprising PtOEP doped in Tint at 10 vol% deposited on the template and on a bare sapphire substrate are compared by X-ray diffraction in Figure 8A. A monolayer of PTCDA is used as a template layer for X-ray diffraction. The neat Tint film deposited on the template compared to the bare substrate shows a peak shift from $2\theta = 27.0^{\circ}$ to $2\theta = 27.5^{\circ}$, corresponding to a morphological change from $(\overline{220})$ to (120) diffraction plane. This peak shift of Tint molecules is also observed in the PtOEP:Tint blends. In the blended films, PtOEP peaks also shift when deposited on the template, from $2\theta = 25.7^{\circ}$ to $2\theta = 20.5^{\circ}$, corresponding to a change from (212) to (111) plane. The crystal structures and diffraction planes of PtOEP and Tint are shown in Figure 8B,C. We also measured the TDM orientation of the blended film deposited on the NTCDA/PTCDA template showing an increased θ_{hor} compared to a bare substrate, from 0.22 \pm 0.02 to 0.80 \pm 0.01 as shown in Figure 8D.

The orientation of heteroleptic bidentate Pt complexes demonstrates the relative interactions of the two ligands with the organic surface. Specifically, if the interaction of both ligands with the surface is relatively weak, the molecular orientation is random. If the interaction of both ligands is similarly strong, a horizontal orientation relative to the substrate is promoted. However, if one ligand has a stronger interaction with the organic surface than the other, the molecule aligns vertically. Another possible way for the dopant molecule to self-organize is by aggregation with adjacent molecules, forming polycrystalline islands within the film.^[25]

In Figure 2A, the TDM of (dbx)Pt(dpm) shows a disproportionate vertical orientation. Since $\delta = 36.1^{\circ}$ is close to the c_2 axis, the vertically aligned TDM shows that one ligand of the (dbx) Pt(dpm) has a markedly stronger interaction via edge-to-surface

at 1 vol% showed similar alignment ($\theta_{hor} = 0.53 \pm 0.01$) to that for the 10 vol% doped (dbx)Pt(acac) and (dbx)Pt(dpm) with no spectral redshift. The similar orientation of (dbx) Pt(acac) with (dbx)Pt(dpm), regardless of the doping concentration, shows that the vertical orientation of the Pt complexes is not due to dopant aggregation.

It is known that the intermolecular interaction strength is directly proportional to the size of the aromatic system.^[26] Therefore, the smaller aromatic surface of ppy compared to dbx leads to a weaker interaction of (ppy)Pt(dpm) with the organic surface than the dbx-based materials, and hence a reduced vertical molecular orientation relative to (dbx)Pt(dpm). To investigate whether the fraction of aromatic surface area in the ligand is tied to the molecular alignment, (dbx)Pt(dmes) with C^N and L^X ligands having substantial aromatic character. The horizontal component increased to θ_{hor} = 0.73 ± 0.01 , leading to a net preferred horizontal alignment. The emission spectrum was unchanged since the chromophoric ligand also remained unchanged (Figure 4). Adding a second Pt(dpm) to the dbx ligand, producing (dbx)(Pt(dpm))₂, results in a further increase in θ_{hor} to 0.76 ± 0.01, Figure 3C, relative to (dbx)Pt(dpm). This is contrary to the hypothesis that the lower aromatic fraction of (dbx)(Pt(dpm))₂ promotes perpendicular alignment. Unlike the (C^N)Pt(L^X) complexes, the TDM of (dbx)(Pt(dpm))₂ lies at $\delta = -11^{\circ}$ relative to the Pt–N and Pt–C bonds (see inset, Figure 3C). If (dbx)(Pt(dpm))₂ is aligned perpendicularly to the substrate, θ_{hor} will be close to unity. The spectrum of (dbx) (Pt(dpm))₂ redshifts due to the extended π -conjugation of the larger ligand.^[27,28]

The work of Hunter and Sanders^[29,30] suggests that the (dbx)Pt(dpm) molecule achieves vertical orientation via a balance between π – σ attraction (the attraction of the negatively charged π -electrons and a positively charged σ -framework), and π -electron repulsion. The edge-on geometry requires a strong π – σ attraction, whereas π – π repulsion and quadrupole attraction dominate in a cofacial, π -stacked geometry.^[31,32] The dbx ligand shows a high net positive σ -framework due to the electron-deficient π -system caused by two electron-withdrawing N atoms,^[32] leading to its edge-

 π – π interactions with the organic surface. To confirm that the vertical alignment is not due to aggregation, (dbx)Pt(acac) was doped at 10 and 1 vol% into the host matrix in Figure 2B,C. The ancillary dpm ligand was replaced by an acac ligand to promote aggregation, which is evident from the redshifted spectrum of the 10 vol% film in Figure 4. As a result, (dbx)Pt(acac) doped

on geometry. We calculated the electrostatic potential surface of (dbx)Pt(dpm) in Figure S7 in the Supporting Information to compare the relative π - σ attraction of the two ligands. The average potential of the dbx ligand σ -framework shows 12.3 kcal mol⁻¹, with a peak potential of 17.9 kcal mol⁻¹ near the N atoms. On the other hand, the dpm ligand shows an average of 3.5 kcal mol⁻¹.

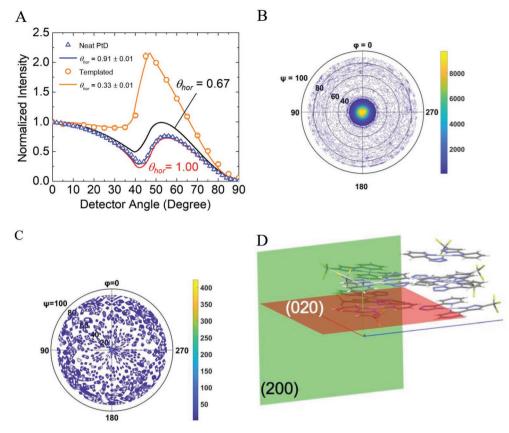

Figure 6. Control of the PtD transition dipole moment via templating. A) Angle-dependent p-polarized photoluminescence of a neat PtD film grown on sapphire substrate and on a predeposited template layer. B) X-ray pole figure of the (200) plane ($2\theta = 8.4^{\circ}$) for a neat PtD film on sapphire. C) X-ray pole figure of the (020) plane ($2\theta = 26.6^{\circ}$) for a neat PtD film on a PTCDA template layer. D) PtD crystal structure showing the (200) (green) and (020) (red) planes.

Pt complex molecules have planar structures, leading to strong π - π interactions with the surrounding environment, such as the host molecules. Thus, the orientation of the Pt complex dopants is influenced by the host matrix. According to Huh et al.,^[33] there is a lower fraction of horizontally aligned TDMs for Pt dopants in CBP compared to the other hosts. Therefore, changing the host molecule from CBP may increase the fraction of horizontal alignment of Pt dopant molecules.

Density functional theory was used to investigate the relationship between the TDM of the PtD dimer and the molecular orientation in a neat crystalline PtD film (see Figure 6). Calculations indicate that the TDM of the dimer lies perpendicular to the PtD monomer planes. The crystal structure of PtD features two unique emissive dimer configurations: one with a Pt-Pt separation of 3.35 Å and the other with 3.41 Å, henceforth referred to as 3.35-dimer and 3.41-dimer, respectively. The DFTcalculated energy of the 3.35-dimer triplet (T_1) is 2.25 eV, compared with 2.27 eV for the 3.41-dimer (details can be found in Figure S8 in the Supporting Information). Also, the oscillator strength computed for T₁ of the former is almost twice that of the latter, indicating that emission in neat crystalline PtD films is likely to originate predominantly from the 3.35-dimer. The red arrow in Figure 5A, inset, indicates that the 3.35-dimer TDM subtends a polar angle of 10° with the *z*-axis, which lies along the Pt-Pt axis, and at an azimuthal angle of 99° with the *x*-axis that passes through the Pt-N(pyrazole-ring) bond of one of the monomers. The results from the DFT calculation and XRD data show that the TDM orientation is, indeed, controlled via templating.

In Figure 7A, the PtD (200) diffraction peak shifts toward an increased lattice constant with the reduced PtD domain size. The increased density of grain boundaries for smaller grains results in an increased lattice constant compared to bulk single crystals as a result of lattice strain relaxation.^[34] The relaxed lattice also results in the hypsochromic shift of the dimer emission (Figure S9, Supporting Information), with results summarized in Table 2.

Time-resolved photoluminescence of the films of PtD doped into CzSi at various doping concentrations was measured with results in Figure S10 in the Supporting Information. The data show a broad photoluminescence peak at $\lambda = 572$ nm that originates from the dimeric species. At 1 vol% PtD, a monomer peak appears at $\lambda = 450$ nm (Figure S9, Supporting Information), showing biexponential decay with distinct exciton decay lifetimes ($\tau_{dimer} = 0.88 \pm 0.12 \ \mu s \ vs \ \tau_{monomer} = 0.10 \pm 0.01 \ \mu s)$, as shown in Figure S10 in the Supporting Information. This feature shows that monomer and dimer excitons coexist in 1 vol% film, which corresponds to the spectrum in Figure S9 in the Supporting Information. However, single exponential decay is observed at higher doping concentrations with exciton

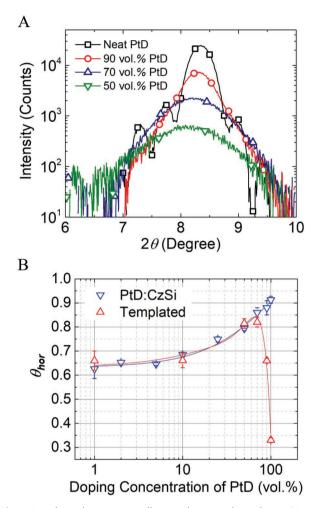

Figure 7. Relation between crystallinity and structural templating. A) XRD patterns of PtD doped CzSi films as a function of PtD concentration. Background counts of the 50 vol% PtD:CzSi film removed for clarity. B) Measured θ_{nor} for the dimer emission transition dipole moment of PtD versus concentration in CzSi. The blue and red curves show θ_{nor} of films deposited on a bare substrate and on a predeposited PTCDA template, respectively.

lifetimes similar to the dimer exciton at 1 vol%. Since only a broad photoluminescence peak at $\lambda = 550$ nm is observed at these higher concentrations, we conclude that the broad photoluminescence originates from dimer emission.

The TDM orientation was measured for PtD:CzSi blends with a range of concentrations deposited on the NTCDA/ PTCDA template in Figure 7B. The XRD results in Figure 7A show that PtD molecules form highly crystalline films due to their discotic molecular structure that enables efficient π -stacking. In the PtD:CzSi blend, however, the CzSi molecules interrupt the π -stacking of the PtD molecules at CzSi concentrations >30 vol%, and hence the orientation of the template is not transferred to the PtD molecules. In contrast, for CzSi concentrations <30 vol%, the disruption of the stacks is limited, enabling the efficient transfer of the template orientation to PtD. Therefore, a concentration of the polycrystalline discotic phosphorescent molecule of >70 vol% is required to control the morphology of the blended film.

Figure 8A shows the controlled morphology of PtOEP doped in Tint deposited with the PTCDA template by X-ray diffraction. The X-ray diffraction peaks of Tint ($\overline{220}$) and PtOEP (212) planes in the film are shifted compared to the bulk (Tint $(\overline{2}20)$). $2\theta = 27.2^{\circ}$; PtOEP (212), $2\theta = 26.0^{\circ}$) due to the lattice relaxation at grain boundaries. The blended film deposited on the bare substrate shows the edge-on diffraction for both Tint and PtOEP molecules (Figure 8B,C, green).^[35] This geometry is caused by aggregation with adjacent molecules forming polycrystalline islands in the film, as Loi et al. showed with the α -sexithiophene.^[27] A neat Tint film on a PTCDA template shows its largest diffraction feature for the (120) plane, which is due to Tint crystallites (Figure 8B, red) lying parallel to the substrate. The reorientation is due to matching to the α -phase PTCDA template (2 θ = 27.5°) with a strain of ($a_{\text{film}} - a_{\text{temp}}$)/ a_{temp} = 0.7%, where $a_{\rm film}$ and $a_{\rm temp}$ are lattice constants of the Tint and PTCDA layers, respectively. Note that a peak appears at $2\theta =$ 27.5°, which corresponds to the α -phase PTCDA. Similarly, the PtOEP diffraction peak shifts to $2\theta = 20.5^{\circ}$, consistent with the $(1\overline{11})$ plane being parallel to the substrate (Figure 8C, red). This morphological control of the PTCDA template was also demonstrated via doped films deposited on the NTCDA/PTCDA template and bare substrate, showing an increased θ_{hor} from 0.22 ± 0.02 to 0.80 ± 0.01 (Figure 8D), consistent with the X-ray diffraction data.

Although PTCDA plays a central role in initiating structural templating, it has a low exciton energy, and therefore tends to quench excitons formed within the emissive layer. Identifying a molecule that has optimal energetics for an OLED while showing similar morphological characteristics as PTCDA remains a challenge.

B) Tint crystal structure and diffraction planes from single-crystal X-ray diffraction measurements. The diffraction peaks at $2\theta = 27.0^{\circ}$ and 27.3° correspond to the (20) plane (green), (120) plane (red), respectively. C) PtOEP crystal structure and diffraction planes from Cambridge Crystallographic Data library (CCDC-1167542). The diffraction peaks at $2\theta = 25.9^{\circ}$ and 20.5° correspond to (212) (green), (111) (red) planes, respectively. D) Angle-dependent p-polarized photoluminescence of PtOEP.Tint films.

We demonstrated that the interaction between the aromatic regions of the ligands and the organic surface drives the orientation of dihedral phosphor Pt complexes during the vacuum deposition. Accordingly, the molecular structure of the vertically aligned reference Pt complex, (dbx)Pt(dpm), was modified to increase the fraction of horizontally aligned TDM in the blended film. In one example, we introduced two mesityl groups to the ancillary ligand to increase the attraction of the molecule to the organic surface. In a second approach, the TDM of a binuclear Pt complex, (dbx)(Pt(dpm))₂, was shown to align parallel to the substrate due to the attraction of its aromatic region. Both methods showed an \approx 20% increased fraction of horizontally aligned TDMs compared to the reference Pt complex.

We also found that seeding the growth habit of the molecules in the blended emissive layer via an ordered NTCDA/PTCDA template results in a preferred horizontal alignment of the Pt(II) phosphor square-planar molecules. Polycrystalline emissive layers comprising single molecules or mixed host-dopant molecules were both shown to conform to the template orientation. The net horizontal fraction of the dopant transition dipole moment in the mixed host-dopant layer deposited on the template increased by \approx 60% compared to the film deposited directly onto bare sapphire and fused silica substrates. Our findings demonstrate an efficient molecular design strategy and a method to control the optical outcoupling efficiencies of the organic light-emitting devices comprising Pt(II) complex phosphors.

Experimental Section

Sample Preparation: Thin films were deposited at 1.0 Å s⁻¹ on 0.2 mm thick fused silica glass by vacuum thermal evaporation in a chamber with a base pressure of 1×10^{-7} torr. The deposition rate and film thicknesses were controlled using a quartz crystal thickness monitor. Following deposition, devices were encapsulated using an epoxy seal around the edge of a cover glass in a N₂ environment. The samples for angle-dependent optical characterization consisted of 1.5 nm PTCDA/1.5 nm NTCDA/30 nm emissive layer. PTCDA, NTCDA, PtOEP, and CBP were purchased from Luminescence Technology, Corp.

Optical Measurements: Samples were excited with a He–Cd laser at a wavelength of 325 nm. Alignment of the transition dipole moment was inferred from the angle-resolved photoluminescence of the phosphor-doped films.^[36,37] The emission from horizontally aligned TDMs was decomposed into transverse electric (TE_{hor}) and magnetic (TM_{hor}) modes, whereas the vertically aligned TDM emitted into the TM_{ver} mode. The ratio of horizontal-to-vertical transition dipole moments (θ_{hor}) is

$$\theta_{\rm hor} = \frac{{\rm TE}_{\rm hor} + {\rm TM}_{\rm hor}}{{\rm TE}_{\rm hor} + {\rm TM}_{\rm hor} + {\rm TM}_{\rm ver}} \tag{1}$$

leading to $\theta_{hor} = 0.67$ for random alignment (TE_{hor} = TM_{hor} = TM_{ver}), and $\theta_{hor} = 1.0$ for TDMs oriented parallel to the substrate.

The θ_{hor} was obtained from the intensity ratio of TM_{hor} to TM_{ver} modes by removing TE_{hor} using a polarization filter. This was compared to the simulated values calculated based on the dyadic Green's function in a birefringent medium.^[38] A least-squares algorithm was used to fit the measured photoluminescence data to the simulation. The 0.2 mm thick fused silica substrate was placed perpendicular to the plane of detection **IDVANCED**

and the emission was outcoupled from the substrate using a 2 cm radius, half-cylindrical lens. A motorized stage was used to position the detector. The refractive indices and extinction coefficients of materials were measured using variable-angle spectroscopic ellipsometry.

X-Ray Diffraction Measurements: X-ray measurements for thin film samples were performed in the Bragg–Brentano geometry using the Cu K α radiation source operated at 40 kV and 44 mA in a Rigaku Ultima IV X-Ray Diffractometer.

Single Crystal Structure Determination: The plates of PtD, Tint, and (dbx)Pt(dpm) were grown by three-zone thermal gradient vacuum sublimation. The zone temperatures for PtD and Tint were 240/210/180 °C and 200/165/135 °C, respectively. PtD and Tint crystals of dimensions of 0.04 \times 0.01 \times 0.01 $\,mm^3$ and 0.01 \times 0.01 \times 0.01 mm³ were mounted on a Rigaku AFC10K Saturn 944+ charge coupled device (CCD)-based X-ray diffractometer equipped with a low temperature device and Micromax-007HF Cu-target microfocus rotating anode ($\lambda = 1.54187$ Å) operated at 1.2 kW (40 kV, 30 mA). The X-ray intensities were measured at 85 K with the detector placed at a distance of 42.00 mm from the crystal. Rigaku d*trek images were exported to CrysAlisPro for processing and corrected for absorption. A transparent, prism-like 0.11 mm \times 0.18 mm \times 0.35 mm crystal of (dbx)Pt(dpm) was used for the X-ray crystallographic analysis. The X-ray intensity data were obtained using a Bruker APEX DUO system equipped with a fine-focus tube (MoK α , $\lambda = 0.71073$ Å) and a TRIUMPH curved-crystal monochromator. The frames were integrated with the SAINT V8.37A (Bruker AXS, 2013) algorithm. Data were corrected for absorption using the multiscan method (SADABS). The structures for the three compounds were solved and refined with the Bruker SHELXTL (version 2016/6) software package. Additional details are given in CIF files.

DFT Calculations of TDM and Molecular Orbitals: The ground (S₀) and triplet state (T₁) geometries of PtD and PtOEP were optimized at the B3LYP/LACV3P** level using the Jaguar (v. 9.4 release 15) program within the Material Science suite developed by Schrödinger, LLC.^[39] Time-dependent density functional theory (TDDFT) with the zero order regular approximation (ZORA) approach^[40] was implemented in Jaguar to compute the TDMs for phosphorescent (T₁ \rightarrow S₀) emission. The ZORA Hamiltonian incorporates spin–orbit coupling (SOC) effects that are associated with triplet (T₁ \rightarrow S₀) emission. The SOC-TDDFT calculations were performed on the T₁-optimized structures using the B3LYP functional and a mixed basis set in which the DYALL-2ZCVP-ZORA-J-Pt-Gen set was used for the Pt, while the 6-31G** set was used for the remainder of the atoms.

To simulate the T_1 state relaxation of the PtD excimers/dimers (3.41-dimer and 3.35-dimer) within the crystalline matrix, geometry optimization was performed on each dimer constrained by a molecular shell consisting of all its immediate neighbors (based on the crystal structure packing data) modeled as a rigid classical force field. This was done using a two-layer hybrid QM/MM with an n-layered integrated molecular orbital and molecular mechanics (NIOM) scheme in which the central dimer was treated at the B3LYP/LanL2Dz level while the universal force field (UFF) molecular mechanics force field was used to model the surrounding molecular shell which was kept frozen during the optimization. All NIOM calculations were performed using the Gaussian 09 program.^[41] Subsequently, SOC-TDDFT calculations were performed on the T1 (NIOM:B3LYP/LanL2Dz:UFF) optimized structure of both dimers to obtain the TDVs associated with dimeric/excimeric emission. The surrounding molecular shell was ignored for the SOC-TDDFT calculations.

Synthesis: Information for the molecular synthesis is included in Figure S11 and surrounding text thereof in the Supporting Information.
