Objectives: To compare three-dimensional (3D) skeletal and dentoalveolar effects of the Herbst and Pendulum appliances followed by fixed orthodontic treatment in growing patients.

Setting and sample population: A sample of 35 adolescents with cone beam computed tomography scans obtained prior to Herbst and Pendulum treatment (T1) and immediately after fixed appliance treatment (T2).

Materials and Methods: Patients with Class II malocclusion was assessed retrospectively and divided into two treatment groups: Herbst group (n=17, age: 12.0±1.6 years); and Pendulum group (n=18, age:12.1±1.5 years), with a mean treatment duration of 2.8±0.8 years and 2.5±0.7 years, respectively. Reconstructions of the maxillomandibular and dentoalveolar regions and data in 3D were obtained relative to cranial base, maxillary and mandibular regional superimpositions. Treatment outcomes (T2-T1) were compared between both groups using t tests for independent samples (p<.05).

Results: Significant increase in mandibular length was observed in the Herbst group (7.3 ±3.5 mm) relative the Pendulum group (4.6±4.5 mm). Inferior and anterior displacements of Pogonion were 2.2 mm and 1.6 mm greater in the Herbst group, respectively. The mesial displacement of the lower first molars was significantly greater in the Herbst group (1.9 mm). The upper first molars had contrasting results in sagittal displacement, with 0.6 ±1.7mm of distal displacement with the Pendulum, and 1.4 ±2.1mm of mesial displacement with the Herbst. Lower incisors projection and proclination were similar between groups.

Conclusions: The Herbst and Pendulum appliances followed by comprehensive orthodontic treatment effectively corrected Class II malocclusion in growing patients, but with differing skeletal and dentoalveolar effects.

Keywords: Angle Class II malocclusion, Herbst appliance, Pendulum appliance, three-dimensional images, cone beam computed tomography.

Article type : Original Article

INTRODUCTION

Over the years, both fixed and removable intraoral appliances have become increasingly popular for the correction of Class II malocclusion, with the Herbst appliance being one of the most widely used worldwide. Unlike removable appliances and elastics, the Herbst appliance is fixed to the teeth and reduces the need for active patient compliance.¹ The Pendulum appliance is another alternative to treat Class II malocclusion that does not require patient cooperation.^{2,3} However, both devices presumably handle Class II treatment differently. The Herbst appliance produces a forward repositioning of the lower jaw as the patient closes into occlusion; increased growth rates and decreased facial convexity have been reported.¹ The Herbst appliance has also been shown to distalize and intrude the maxillary first molars.^{4,5} The Pendulum appliance is designed primarily for maxillary molar distalization in non-extraction cases.²

Due to their presumably different paths to treat Class II malocclusion, it is expected that Pendulum and Herbst appliances may produce different specific skeletal and dentoalveolar changes. Previous 2D studies of the Pendulum appliance have noted clockwise mandibular rotation secondary to distalization of the maxillary molars.² Moreover, a significant restriction of anterior maxillary displacement has been observed.⁶ Molar distalization accounted for 63-76% of the space opening, and 24-37% was due to maxillary second premolar mesialization.^{2,7}

Herbst treatment studies have reported restriction of maxillary growth, mandibular rotation changes, as well anterior positioning of the glenoid fossa⁸⁻¹⁰ and a favorable impact on the advancement of the chin.⁸⁻¹¹ Recently, a 3D study conducted with cone beam computed tomography (CBCT) images have demonstrated that patients with different

vertical facial patterns and Class II malocclusion show similar patterns of mandibular and maxillary changes when treated with the Herbst appliance relative to the magnitude and direction of condylar growth,¹² as compared to fixed appliances and Class II intermaxillary elastics.¹³

Clinical questions remain regarding whether patients treated with the Herbst and Pendulum appliances present greater skeletal or dentoalveolar effects and following comprehensive treatment with fixed appliances.^{4,5,14} Three-dimensional (3D) assessment of the skeletal and dentofacial changes with Pendulum treatment compared to Herbst treatment followed by comprehensive fixed appliances may further the clinician's understanding of their treatment choice for each patient. Thus, the aims of this study were to use 3D imaging and superimposition techniques to assess skeletal and dentoalveolar changes associated with Class II correction in growing children treated either with the Herbst or Pendulum appliance followed by comprehensive treatment using fixed appliances.

SUBJECTS AND METHODS

The Health Sciences and Behavioral Sciences Institutional Review Board at University of Michigan determined that this observational retrospective study was exempt from IRB oversight (HUM00123010).

The sample was selected from a single orthodontic office, using information following inclusion criteria: (1) pretreatment Class II Division 1 malocclusion defined by at least an end-to-end molar relationship; (2) cervical vertebral maturation (CVM) stage of CS2-4;¹⁵ (3) treatment with Herbst or Pendulum therapy (Phase 1) immediately followed by preadjusted edgewise appliance treatment (Phase 2), where both treatment options were presented to the patients and parents based on the orthodontist evaluation of mandibular retrusion, (4) no permanent teeth extracted before or during treatment; and (5) CBCT images of good quality and with adequate field of view (FOV) taken before treatment (T1) and immediately after removal of the preadjusted edgewise appliances (T2) and (6) post-treatment images showing Class I relationship of canines and molars. Exclusion criteria included (1) T1 to T2 interval was greater than 48 months; (2) T1 to T2 interval was less

than 12 months; (3) history of previous orthodontic treatment and, 4) use of temporary anchorage devices during treatment.

Table 1 shows the starting forms for sex, CVM stage, age, skeletal and dentoalveolar variables at baseline (T1) from both Herbst and Pendulum groups.

The sample size calculation (a minimum of 17 patients in each group) was based on a power of 80%, an alpha of 0.05, a difference of 2.0 mm for the anterior displacement of Pogonion (Pog to Nasion perpendicular) and a standard deviation for this variable of 2.0 mm (pooled standard deviation between Pendulum and stainless-steel-crown Herbst groups was derived from a previous study).¹⁴

Herbst Protocol

The Herbst group (n=17) had the same Herbst appliance design with bilateral telescopic tubes and plungers attached to a maxillary and mandibular metal framework. This rigid framework was soldered to thick stainless-steel crowns cemented on the maxillary first molars and the mandibular first premolars; occlusal rests also were bonded to the lower first molars. The fixed design of the Herbst ensured full-time wear of the appliance.

The Herbst treatment protocol for all patients consisted of: 1) Herbst appliance installation and adjustment of the upper and lower incisors close to an edge-to-edge (0 mm overjet) relationship at the start of treatment; 2) evaluation for adequate mandibular advancement by the treating orthodontist every 3 months until Herbst removal; 3) Herbst appliance was maintained for 12 months; and 4) removal of the Herbst appliance and bonding of fixed appliances for comprehensive treatment.

Pendulum Protocol

The Pendulum Group (n=18) received a Pendulum appliance as described by Hilgers³ that consisted of bilateral distalizing springs anchored to the dorsal portion of the palatal acrylic button, made of 0.032" titanium molybdenum alloy (TMA) wire. The treatment protocol consisted of the following: 1) the distalizing springs were placed in their pre-activate state into palatal sheaths of the molar bands; 2) initial activation of 60° to 70° (about the width of one molar) was incorporated to generate approximately 250 g of force

per side; 3) patients were monitored every 4 to 6 weeks until adequate distalization with achievement of Class I molar relationship was determined by the treating orthodontist; 4) after distalization, the appliance was removed, and a Nance button banded to the molars was placed along with fixed orthodontic appliances.

All patients in both groups had a subsequent phase of fixed preadjusted edgewise appliances immediately following the respective Phase I treatment. Class II elastics were worn during the phase of fixed preadjusted edgewise appliances as needed to achieve final canine Class I intercuspation.

Image Analysis

CBCT scans had been taken for diagnostic and clinical purposes for all subjects in T1 and T2, using an iCat unit (Imaging Sciences International, Hatfield, PA), with 40 second scan time, as well as a 23×17- cm FOV and a voxel size of 0.4 mm³, following the ALARA principle. All images were exported as DICOM files.

An orthodontist examiner, previously trained in using the following method, performed all image analysis procedures. 3D surface models were created following 10 image analysis steps:

1. DICOM files were converted to GIPL files in order to decrease the file size using ITK-SNAP, an open source software (version 2.4.0; www.itksnap.org);
2. The 0.4 mm³ original voxel size was converted to 0.5mm³ using 3D Slicer (version 4.0; www.slicer.org) to decrease the computational power and time for cranial base registration;
3. Volumetric label maps of the entire cranial complex at T1 and T2 were created using ITK-SNAP;
4. 3D surface models at T1 were created using 3D Slicer;
5. Head orientation of T1 model using the 3D standardized coordinate system of the 3D Slicer software as reference, setting the Frankfort plane (bilateral Orbitale and Porion) perpendicular to the midsagittal plane (Glabella, Crista Galli and Basion), as described by Ruellas et al.¹⁶

6. The T2 scan was approximated to the oriented T1 scan using three different regions as reference, one at a time;
 - Cranial base: using the anterior cranial fossa as a best-fit reference in order to evaluate the skeletal positional or growth changes of maxilla and mandible;¹⁷
 - Maxilla: using the maxillary palatal plane and anterior nasal spine as a best fit reference to evaluate the upper dentoalveolar changes;¹⁸
 - Mandible: using the mandible base and symphysis as a best fit reference in order to evaluate the lower dentoalveolar changes;¹⁹
7. Fully automated voxel-based registrations of the cranial base, maxilla, and mandible were performed in 3D Slicer using the respective scans and segmentation of T2 approximated;
8. Pre-labeling: landmarks (Figure 1) were pre-labeled¹⁸ using the multiplanar views, axial, coronal and sagittal, at T1 and T2 using ITK-snap and were positioned using at least two sectional views simultaneously for orientation.
9. Virtual 3-dimensional (3D) surface models with landmarks were created for T1 and T2 using 3D slicer

The linear distances and angles, as well the 3D changes (Table 2) were determined, and the amount of directional changes in each plane of 3D space were measured between corresponding coordinates of landmarks placed in the T1 and T2 surface models using 3D Slicer Q3DC (Quantification of 3D Components) tool in the 3D Slicer. The skeletal and dentoalveolar variables are also described in Table 2.

Statistical Analysis

To determine intra-rater reliability, 10 patients were selected randomly from both groups and tested using Intraclass Correlation Coefficients (ICC) test with 95% CI. The measurements were repeated 2 weeks later. Data normality was tested by the Shapiro-Wilk test. Chi-square and Fisher's exact tests compared, respectively, CVM stage and sex, and t tests for independent samples were used to compare all other variables. All data were

analyzed with a social science statistical package (SPSS, Version 25.0, SPSS, Inc., Chicago, Illinois), and the significance was tested at $P < 0.05$.

RESULTS

The ICC test resulted in excellent repeatability scores for all skeletal and dentoalveolar measurements (Table 3). Descriptive statistics including means and standard deviations for each group at the start of treatment are presented in Table 1. The direction of all measurements was described using the 3D-slicer software. Positive values represented anterior, superior, counter clockwise, mesial angulation and buccal inclination displacement changes. Negative values showed posterior, inferior, clockwise, distal angulation and lingual inclination changes. The analysis of starting forms revealed that the two groups were statistically similar in cephalometric measurements, CVM stage, chronological age, and treatment duration. The only exception was gender, where female patients were more prevalent in the Pendulum group (Table 1).

Skeletal changes

Table 3 shows the comparison of maxillary and mandibular skeletal changes (T2-T1) relative to cranial base and regional superimpositions in both treatment groups. Maxillomandibular skeletal changes showed an overall forward and downward displacement in both groups.

Maxillary changes differed significantly between the two groups. The Herbst group presented greater anterior (mean difference at Point ANS by 1.4 mm), inferior (mean difference at Point A by 1.8 mm) and 3D (mean difference at Point ANS by 2.0 mm and Point A by 2.0 mm) displacements, as well greater changes in maxillary length (ANS-PNS 1.4 mm mean group difference). The palatal plane angle showed minor changes in the Herbst ($-0.6 \pm 2.2^\circ$) and Pendulum ($-0.1 \pm 1.7^\circ$) groups, with no differences between groups.

The Herbst group presented significantly greater mandibular skeletal changes (7.3 ± 3.5 mm) than the Pendulum group (4.6 ± 4.5 mm), with a mean difference of 2.9 mm. The Herbst group also demonstrated a larger downward displacement at Pogonion of 2.2 mm, a vector displacement at Pogonion of 3.1 mm, as well as greater mandibular length (CoGn of 2.9 mm). The anteroposterior changes also revealed greater anterior displacement of Pogonion in the Herbst group (3.3 ± 2.9 mm) that was not significantly different when compared to the Pendulum group (1.8 ± 2.0 mm; Table 3). Similarly, relative to the palatal plane, the mandibular plane angle showed small changes in the Herbst ($-0.6 \pm 2.2^\circ$) and Pendulum ($-0.1 \pm 1.7^\circ$) groups, with no statistically difference between them (Table 3).

Dentoalveolar changes

Maxillary and mandibular dentoalveolar changes in both groups are shown in Table 3. The Herbst and Pendulum groups showed small changes in the anteroposterior displacement of the upper incisors (0.1 ± 2.6 mm and 0.5 ± 2.7 mm, respectively). The upper incisor inclination was similar in the Pendulum ($0.8 \pm 9.7^\circ$) and Herbst groups ($0.3 \pm 8.7^\circ$). The between-group differences in the incisors sagittal position and inclination were not statistically significant.

The upper first molar presented significantly different anteroposterior, vector, and angulation changes between the two groups. The Herbst group showed upper first molar changes in anterior (1.4 ± 2.1 mm), inferior (-1.1 ± 1.1 mm), and vector (3.8 ± 1.3 mm) directions, and also mesial angulation ($3.7 \pm 8.5^\circ$). The Pendulum group presented upper molar changes in posterior (-0.6 ± 1.7 mm), superior (0.2 ± 3.4 mm) and 3D (3.0 ± 1.0 mm) directions, and also distal angulation ($2.6^\circ \pm 5.8^\circ$).

The lower incisors were protruded and proclined, without significant differences between the groups. The lower incisors displaced in an anterior direction in the Herbst group (2.2 ± 2.5 mm) and Pendulum group (1.7 ± 1.9 mm). The inclination in buccal direction also revealed similar averages in the Herbst ($5.4^\circ \pm 6.1^\circ$) and Pendulum groups ($5.2^\circ \pm 5.2^\circ$). The lower first molars presented significantly greater mesial movement in the Herbst group (3.1 ± 1.6 mm) than in the Pendulum group (1.4 ± 1.1 mm).

DISCUSSION

This clinical investigation of pre- and post-treatment CBCT images compared two different therapeutic approaches that incorporated either a Herbst or Pendulum appliance, both followed by comprehensive fixed appliance treatment of Class II malocclusion. The analysis of starting forms revealed that the 2 groups were comparable at T1. The CVM classification revealed a similar stage of development in both groups, even with higher presence of females in the Pendulum sample. The results of this study show that there are differences between these approaches, highlighted by greater mandibular growth in the Herbst group.

Skeletal Changes

A “headgear effect” on the maxilla and increased mandibular growth increments are desirable outcomes for Class II treatment. The mandibular sagittal changes in the Pendulum appliance resulted in a gain of 3.4 mm in growth of the mandible compared to the maxilla (difference between mandibular length and maxilla length), while in the Herbst group the same parameter showed a gain of 4.7 mm.

The amount of anterior maxillary growth observed in the Pendulum group was significantly smaller than in the Herbst group. The small average difference between the 2 groups of 1.4mm lesser anterior maxillary growth, measured at ANS, may indicate that the Pendulum effects on molar position and subsequent retraction of the upper teeth affected the overall maxillary growth. Previous two-dimensional studies have shown a “headgear effect” with the Herbst appliance due to the posterior and upward force vector imparted to the maxilla.^{20,21} In the present study, this effect was not observed. The displacement of the maxilla in the Herbst group, measured at ANS, showed 2.6 ± 2.0 mm and -1.6 ± 2.6 mm in anterior and inferior directions, respectively. A similar result was observed at point A, presenting 1.9 ± 1.8 mm and -2.7 ± 2.7 mm anterior and inferior direction, respectively.

Interestingly, the inferior displacement of Pogonion, as well as the increase length of the mandible, was significantly greater in the Herbst group, (-2.2 mm and 2.9 mm, respectively) than in the Pendulum group. The 2mm difference in pogonion displacement between the two groups could indicate greater mandibular growth in the Herbst group. This 2mm is in agreement with a previous study that reported 2.2 mm of 3D pogonion

displacement in Class II patients treated without functional appliances.¹² Vertical mandibular skeletal changes, as measured by alterations in the inclination of the mandibular plane, were less than 1°, with no significant differences between the Herbst and Pendulum groups at the end of comprehensive orthodontic treatment. The amount of vertical mandibular growth, even though no rotation of the mandibular plane was observed, reduces the anteroposterior mandibular skeletal effects in both groups, as also observed by Burkhardt et al.¹⁴ The average increase in anterior Pogonion projection for the Herbst group was 3.3 mm ±2.9 mm, 1.6 mm greater than in the Pendulum group, a difference that was not statistically significant.

Dentoalveolar Changes

In this study, a small upward and distal dentoalveolar maxillary effect at the upper first molar (-0.6 ±1.7 mm and 0.2 ±3.4 mm, respectively) was observed in the group treated with Pendulum followed by fixed appliances. Care should be taken, however, when interpreting this finding due to the small average displacement, large standard deviation, and the Phase II treatment using full fixed appliances. In fact, at the end of comprehensive treatment in the group treated with Pendulum, the upper molars did not distalize bodily nor tipped distally but remained fairly upright, corroborating the findings of other studies on patients treated with Pendulum after comprehensive treatment^{5,14} No posterior and upward effects of the maxillary first molar following treatment with the Herbst appliance reported in other studies were seen in the current study.^{4,5,22}

These contradictory results can be attributed to differences in the methodology (3D vs 2D using cephalometric variables) to assess maxillary dental positional changes. Another possible reason is that the headgear effect may have been present following Phase I part of the treatment but was diminished or negated following Phase II treatment with comprehensive fixed appliances.

Interestingly, the lower molar presented significantly greater mesial displacement in the Herbst group than in the Pendulum group (3.1±1.6 mm and 1.4 ±1.1 mm, respectively), probably due to differences in the forces applied by the Herbst appliance on the lower teeth compared to the Pendulum appliance.

The small maxillary incisor (U1) proclination and antero-posterior displacement was not significantly different between the two groups. The Pendulum and Herbst groups showed proclination changes of $0.3^\circ \pm 8.7^\circ$ and $0.8^\circ \pm 9.7^\circ$, and anteroposterior displacement of $0.1 \text{ mm} \pm 2.6 \text{ mm}$ and $0.5 \pm 2.7 \text{ mm}$, respectively. The 2D cephalometry literature also reports similar ranges of variability of upper incisor proclination in patients treated with the Herbst appliance and Pendulum appliances.^{6,14,20,23,24} The small average anterior displacement and proclination of the upper incisors in the Herbst group in the current 3D study differs from previous investigations that reported posterior displacement of the upper incisors between 0.2 mm ²³ and 2.8 mm .²⁵ The lack between-group differences in incisor proclination in the present study could be attributed to the large variability among patients in this study, and to Phase II treatment with full fixed appliances.

Proclination and protrusion of the lower incisors are attributed more frequently to mandibular advancement appliances²⁶, such as the Herbst treatment and less to distalization methods, such as with the Pendulum appliance. Our findings showed no significant between-group differences, with average difference of 0.5 mm and 0.6° in lower incisor protrusion and proclination, respectively. These results are in agreement with those of Burkhardt et al.¹⁴

Overall Treatment Effects

This study evaluated changes after 2 phases of treatment, Phase I Class II correction (Herbst or Pendulum appliances) and Phase II detailing of the occlusion with fixed appliances. The combination of skeletal and dentoalveolar effects at the end of treatment led to a similar overall correction of the maxillo-mandibular discrepancy, although each approach had different influences in the maxilla or mandible (Figures 2 and 3). Herbst treatment followed by fixed appliances corrected the Class II malocclusion, with greater effects in the lower arch, leading to a differential maxillo-mandibular growth of 4.7 mm mandibular gain (CoGn - ANS-PNS), and 2.3 mm greater mesial displacement of the lower first molar than the upper first molar (U6 - L6 AP).

This study is limited in that specific treatment effect of either type of Class II corrector cannot be determined with precision because a CBCT image was not taken at the end of Phase I for ethical reasons and ALARA principle, balancing the risks and benefits,

especially in young populations.²⁷ Another limitation of the present study is its retrospective design, as a prospective study would allow better control of the treatment protocols and monitoring of the clinical variables. The sample size calculation was performed as described, and while 2 mm for statistical significance may be questionable and controversial clinically. Future studies could assess how much, in mm, can prove to be clinically significant and also bring additional information about the skeletal and dentoalveolar effects of the Pendulum and Herbst treatment with orthodontic fixed appliances.

The results of this study provided insights for clinical choice for Class II correction. Dentoalveolar effects combined with skeletal changes contributed to the correction of the Class II malocclusion, with opposite effects on the upper posterior teeth in the Herbst and pendulum groups and similar dentoalveolar effects on the anterior teeth. The 3D changes, and their anteroposterior and supero-inferior components, showed that these Class II treatment approaches in this study both achieve Class II correction by different mechanisms. The large patient variability in response to treatment in both the Herbst and Pendulum groups, however, revealed that within each group there were patients who responded well, and some who did not, to the predicted molar distalization in Pendulum group or anterior mandibular positioning in the Herbst group. Given the study results, the decision between different types of therapies in non-surgical Class II patients can focus on the magnitude of skeletal and dentoalveolar needs and also on the priority regions of desired changes.

CONCLUSIONS

- The differential maxillo-mandibular growth contributed to the correction of the Class II malocclusion in patients treated either with Herbst or Pendulum followed up by fixed appliances with overall downward and forward maxillary and mandibular skeletal displacement relative to the cranial base.
- The growth response was significantly greater in the Herbst group for maxillary and mandibular length.

- The directional changes showed greater inferior displacement of Pogonion and anterior displacement of maxilla (ANS) in Herbst group.
- The upper first molar in the Pendulum group showed slight distal displacement in the opposite direction compared to the Herbst group.
- The lower first molar showed greater mesial movement in the Herbst group.
- Both treatment groups showed similar amount of proclination and protrusion of the lower incisors.

Mandibular Dentoalveolar							
IMPA	92.9	7.3	90.8	4.4	1.8	-2.4;6.0	.385

Fischer's exact test [†], Chi-square [‡] and t tests (P < .05).

TABLE 2. 3D linear distances and angles used in this study.

Craniofacial Relationships	Measures	Abbreviation	Direction
Maxillary Skeletal			
	Point A displacement	A (mm)	AP, SI, 3D
	Point ANS displacement	ANS (mm)	AP, SI, 3D
	Maxillary length change	ANS-PNS (mm)	3D
	Maxillary plane change	ANS-PNS (°)	Pitch
Maxillary Dentoalveolar			
	Central incisor displacement (U1T)	U1 (mm)	AP, SI, 3D
	Maxillary first molar displacement (U6T)	U6 (mm)	AP, SI, 3D
	Incisor inclination change (U1T-U1A)	U1 Inclination (°)	Pitch
	Molar angulation change (U6T-U6A)	U6 Angulation (°)	Pitch
Mandibular Skeletal			
	Point Pogonion displacement	Pog (mm)	AP, SI, 3D
	Mandibular plane change	GoMe (°)	Pitch
	Mandibular length	Co-Gn (mm)	3D
Mandibular Dentoalveolar			
	Central incisor displacement (L1T)	L1(mm)	AP, SI, 3D
	Maxillary first molar displacement (L6T)	L6 (mm)	AP, SI, 3D
	Incisor inclination change L1T-L1A	L1 Inclination (°)	Pitch
	Molar angulation change L6T-L6A	L6 Angulation (°)	Pitch

AP: antero-posterior; SI:supero-inferior; 3D:three-dimensional.

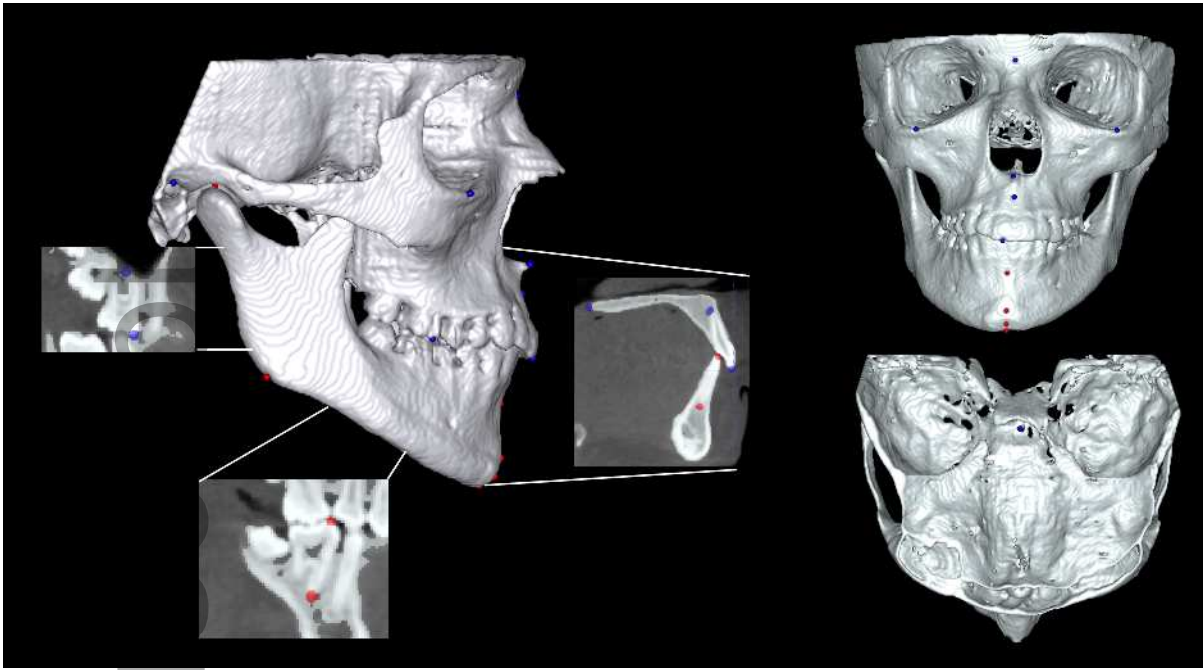

TABLE 3- Intraclass coefficient correlation of intra-rater reliability and comparison of maxillary and mandibular skeletal and dentoalveolar changes T1-T2 relative to cranial base and regional superimpositions.

	ICC		Herbst (n=17)		Pendulum (n=18)		Mean Diff	95% CI of mean diff	P value
