35 ABSTRACT

36       Animals must balance various costs and benefits when deciding when to breed. The costs  
37 and benefits of breeding at different times have received much attention, but most studies have  
38 been limited to investigating short-term season-to-season fitness effects. However, breeding  
39 early, versus late, in a season may influence lifetime fitness over many years, trading off in  
40 complex ways across the breeder's lifespan. In this study, we examined the complete life histories  
41 of 867 female tree swallows (*Tachycineta bicolor*) breeding in Ithaca, New York, between 2002  
42 and 2016. Earlier breeders outperformed later breeders in short-term measures of reproductive  
43 output and offspring quality. Though there were weak indications that females paid long-term  
44 future survival costs for breeding early, lifetime fledgling output was markedly higher overall in  
45 early-breeding birds. Importantly, older females breeding later in the season did not experience  
46 compensating life-history advantages that suggested an alternative equal-fitness breeding  
47 strategy. Rather, most or all of the swallows appear to be breeding as early as they can, and  
48 differences in lay dates appear to be determined primarily by differences in individual quality or  
49 condition. Lay date had a significant repeatability across breeding attempts by the same female,  
50 and the first lay date of females fledged in our population was strongly influenced by the first lay  
51 date of their mothers, indicating the potential for ongoing selection on lay date. By examining  
52 performance over the entire lifespan of a large number of individuals, we were able to clarify the  
53 relationship between timing of breeding and fitness and gain new insight into the sources of  
54 variability in this important life history trait.

55 *Keywords:* lay date, life history, alternative strategies, lifetime fitness, *Tachycineta bicolor*,  
56 timing of breeding, tree swallow

57

58 INTRODUCTION

59           Timing of breeding is one of the most important determinants of organismal fitness.  
60    Across a broad variety of taxa, the decision of when to breed determines what food resources  
61    will be abundant during each stage of reproduction (e.g. mink, Ben-David 1997; sea ducks, Love  
62    et al. 2010), the types and variety of nest sites available for breeding (e.g. house martins, Piersma  
63    2013), the prevalence of parasites and predators that may harm the adult or its offspring (e.g.  
64    squirrels and hares, O'Donoghue and Boutin 1995; cliff swallows, Brown and Brown 1999), and  
65    the energy budget available for investment into other life history traits (e.g. wheatears, Low et al.  
66    2015). Previous researchers have documented the many costs associated with breeding at  
67    suboptimal times (blue tits, Nilsson 1994; sandpipers, McKinnon et al. 2012; owls, Toyama et al.  
68    2015), and the importance of proper timing has become especially clear in circumstances in  
69    which environmental conditions have recently deviated from historical norms (e.g. flycatchers,  
70    Both and Visser 2001; grouse, Ludwig et al. 2006; deer, Plard et al. 2014). Indeed, changes in  
71    reproductive phenology are one of the most pervasive responses observed to global climate  
72    change (squirrels, Reale et al. 2003; wide variety of taxa, Visser and Both 2005; frogs, Benard  
73    2015, red deer, Moyes et al. 2011; wide variety of plants, Cleland et al. 2012).

74           In seasonally breeding birds, individuals that lay their eggs earlier in the season generally  
75    fledge more young than do individuals that lay later (e.g. Hochachka 1990, Goodenough et al.  
76    2009, Öberg et al. 2014). This could be because early breeding offers greater access to food  
77    quantity (e.g. Schoech et al. 2004, Ardia et al. 2006) or quality (Twining et al. 2018), availability  
78    of better nesting sites (e.g. Rosvall 2008), access to better mates (Kirkpatrick et al. 1990) or more  
79    time to assess them (Ferretti and Winkler 2009), additional time for undertaking a greater  
80    number of reproductive attempts (e.g. Monroe et al. 2008, Morrison et al. 2019), or the chance to  
81    breed before high background rates of mortality take one or both of the parents (Goutis and  
82    Winkler 1992).

83           Much past research has attempted to parse two effects that might explain why early  
84    breeders are more successful (reviewed in Verhulst and Nilsson 2008). A quality effect would  
85    appear as a decline in reproductive output over the course of a breeding season because  
86    individuals of higher quality or condition are breeding before birds of lower quality or condition.  
87    (For some of the complexities in different concepts of individual quality see Bergeron et al.  
88    2011). In contrast, a date effect could lead to a seasonal deterioration in environmental

89 conditions such that all individuals have lower success later in the season. These two effects have  
90 traditionally been treated as alternatives, and several studies have attempted to tease them apart  
91 by experimentally manipulating timing of breeding (Wardrop and Ydenberg 2003, Dawson  
92 2008, reviewed in Verhulst and Nilsson 2008, Harriman et al. 2017). However, for the quality  
93 effect to be supported, there must be a reason why high-quality birds should choose to breed  
94 earlier, and, to the extent that advantages of earlier breeding are environmentally derived, as the  
95 date effect suggests, rather than representing true alternatives, these two effects are not really  
96 distinct and may best be seen as causally linked (cf. Verhulst and Nilsson 2008).

97         There is another persistent question about lay dates: if, as long thought (Perrins 1970),  
98 breeding birds are attempting to match their reproductive efforts with an optimal time to breed,  
99 why do some members of the population breed later than would be ideal? The most likely  
100 explanation is that breeding early is difficult – that it imposes challenges that only some  
101 individuals are able to overcome. Such challenges could include enduring harsh early-season  
102 environmental conditions such as inclement weather (e.g. Ramos et al. 2002), low food  
103 availability (e.g. Young 1994, Bowlin and Winkler 2004), high levels of predation (e.g.  
104 Borgmann et al. 2013), or competition for scarce nesting sites or mates (e.g. Smith 2006).  
105 Several studies of timing of breeding have explored the connection between quality and date  
106 experimentally (reviewed in Verhulst and Nilsson 2008) or by examining facets of fitness  
107 beyond reproduction (Brinkof et al. 2002, Brown et al. 2015, Low et al. 2015, Needham et al.  
108 2017, Evans et al. 2019). However, in the latter cases, breeding adults have usually been  
109 followed only to the season just after the focal breeding attempt. All of these environmental costs  
110 of breeding early provide a mechanistic link between quality and date and reinforce the non-  
111 independence of these effects.

112         When multi-trait data are available over the entire lifespans of many individuals, rather  
113 than try to tease apart two effects that are so tightly linked, we decided instead to recast the  
114 research to distinguish between two more fundamental hypotheses about the origins of life  
115 history variation: Is reproductive output highest early in the season because early breeders are of  
116 higher quality and do better across the board, or are early breeders paying a price in the form of  
117 lower performance elsewhere in their lives? These hypotheses pertain to one of the longest-  
118 running questions in evolutionary and behavioral ecology (Maynard Smith 1982, Werner and

119 Sherry 1978, Stamps et al. 2013): are variations in the behavior and reproduction of individuals  
120 within populations the result of different individuals pursuing different strategies or the result of  
121 all or most individuals all essentially pursuing the same strategy with individual variations the  
122 result of the vagaries of chance and circumstance? If there is a life-history trade-off between  
123 allocations to parental effort vs. self-maintenance (e.g. Stearns 1976, Winkler and Wilkinson  
124 1987), birds that seem to underperform in one aspect or stage of their lives may compensate  
125 elsewhere in their life history. We would best be able to detect such a trade-off with full life-  
126 cycle data: the full consequences of a lay date decision may only become apparent over long  
127 timescales.

128 *Hypotheses and predictions:* Here we take a full lifespan approach to testing these two  
129 hypotheses, analyzing fifteen years of life history data from a population of tree swallows  
130 (*Tachycineta bicolor*) in upstate New York. A negative correlation between lay date and single-  
131 season reproductive output is well-documented in this population (Winkler and Allen 1996), but  
132 the full-lifetime perspective on lay date variation has not been explored. We tested the two  
133 fundamental hypotheses mentioned above:

134 *Hypothesis 1: Variation in lay dates of tree swallows is the result of variation in individual*  
135 *quality.* Under this hypothesis, which can include both quality and date effects, we assume that  
136 lay date is constrained by the high costs of breeding early, costs that only high-quality females  
137 are able to bear. If only those females in the best condition are able to surmount the obstacles  
138 that prevent an early reproductive effort, then this could explain why only some females can reap  
139 the benefits of early breeding. Under this integrated „Quality Hypothesis“, lower quality females  
140 would be constrained to breed later in the season when resources are more abundant. Because  
141 this hypothesis posits a difference in individual quality between early and late breeders, it  
142 predicts that early breeders should be superior to late breeders across all components of fitness.  
143 Early breeders should fledge relatively more offspring in better condition over the course of their  
144 longer lives. In contrast, later breeders should fledge relatively fewer offspring in poorer  
145 condition over the course of their shorter lives.

146 *Hypothesis 2: Variation in lay dates of tree swallows is the result of different individuals*  
147 *pursuing alternative, equal-fitness, life history strategies.* Under this hypothesis, early and late  
148 breeders do not necessarily differ from one another in overall quality or fitness. Instead, they

149 make a different trade-off between lay date and other life history components. For example, early  
150 breeders may excel in gathering food at times of year when resources are scarce and subject to  
151 greater uncertainty, but this may come at the cost of greater energetic expenditure and lower  
152 body condition, both of which could contribute to reduced parental survival. In contrast, late  
153 breeders may avoid some of the self-maintenance costs of breeding in colder spring  
154 temperatures, but pass these costs on to their offspring, who would fledge later in the summer  
155 when reduced time to migration may be disadvantageous. This Alternative Strategies Hypothesis  
156 predicts that early and late breeders use different strategies to manage the costs and benefits of  
157 breeding early such that their life histories will differ markedly in kind, but not in overall fitness  
158 (cf. Tarwater and Beissinger 2013). Our sample of breeding years encompassed considerable  
159 diversity in breeding conditions, and the Alternative Strategies Hypothesis predicts that earlier  
160 and later breeders will each excel in different life history components, with earlier breeders  
161 overall exceeding later breeders in some components of fitness and later breeders overall out-  
162 performing earlier breeders in others.

163 The contrasting predictions of the two hypotheses are summarized for each fitness metric  
164 being tested here in Table 1.

165 *Complexities in assessing lay date variation:* One of the chief difficulties in evaluating  
166 the relationship between lay date and its fitness consequences in long-term data is that lay date is  
167 not necessarily stable across a female's lifetime. A female that breeds relatively late in one year  
168 may breed relatively early the following year, and vice versa. Understanding the costs and  
169 constraints that accompany variation in lay date therefore requires that we understand the  
170 relevant timescales over which the effects of lay date are felt. Fitness costs incurred as a result of  
171 breeding at a suboptimal time may be relatively short-lived, affecting each breeding attempt  
172 independently of all others, or they may accumulate across an individual's lifetime, with each set  
173 of costs adding up to greater and greater consequence. It is also possible that some reproductive  
174 events exert a greater impact on an individual's fitness trajectory than do others. This may be  
175 especially likely for an individual's first reproductive attempt. Because young females breeding  
176 for the first time must grapple with all of the typical costs of reproduction as well as their own  
177 inexperience, it is possible that costs incurred then may influence a female's life history for the  
178 rest of her life. In this study, we evaluate each of these possibilities by considering the fitness

179 consequences of each female's current lay date, her previous lay date, and the lay date of her first  
180 reproductive attempt.

181 It has also long been appreciated (von Haartman 1982) that lay dates can affect avian  
182 reproduction both through "absolute" and "relative" timing. If external effects from the  
183 environment are most important, then absolute calendar date is going to be most informative. On  
184 the other hand, if interactions between members of the breeding population dictate optimal  
185 timing of reproduction, when a female lays relative to the others in her local population may  
186 better account for lay date effects on fitness.

187 Finally, any life-history view of lay date variation must be prepared to address potential  
188 selective effects on trait variation, and our long-term data provided us the opportunity to assess  
189 mother-daughter similarities and the potential for heritable variation in this key life-history trait.

## 190 METHODS

191 *Study Species.* Tree swallows are migratory aerial insectivores that breed across much of North  
192 America. Tree swallows are one of the earliest migrants to return to their breeding grounds, and  
193 they must contend with adverse weather up to six weeks before and during early reproductive  
194 attempts, sometimes with disastrous consequences (Hess et al. 2008). They are also one of the  
195 last to migrate to wintering latitudes in the fall, a characteristic that is likely facilitated by their  
196 ability to subsist on *Myrica* sp. berries at times of year when flying insects become unavailable  
197 (Winkler et al. 2011, Piland and Winkler 2015). Tree swallows are secondary cavity nesters, and  
198 intense competition for scarce nesting sites has probably shaped much of their biology. As in  
199 other species, a negative correlation between lay date and clutch size is well documented  
200 (Winkler and Allen 1996), with at least some of the variation in lay date correlated to variation in  
201 female flight performance (Bowlin and Winkler 2004). Earlier laying birds also exhibit higher  
202 immunocompetence when exposed to novel antigens (Hasselquist et al. 2001, Ardia 2005).

203 *Study Sites.* This study relied on data collected from a population of tree swallows breeding near  
204 Ithaca, in Tompkins County, New York (42°28' N, 76° 29' E). The study population was first  
205 established in 1985 at the Cornell University Experimental Ponds Unit 1. Since that time,  
206 additional nest boxes have been variably added and removed at nine other study sites distributed  
207 throughout Tompkins County. For the present study, we used data collected from females

208 breeding at five sites that were well-established and regularly monitored with consistent  
209 protocols from 2002 onward. At each site, between 22 and 260 nest boxes of the same design  
210 (for further details see Winkler and Allen 1996) were placed ~20 m apart on free-standing metal  
211 poles or affixed to existing wooden fence posts in open habitat suitable for tree swallow  
212 breeding.

213 Beginning in April of each year, nest boxes were checked every 2-3 days for nesting  
214 material that might indicate the presence of nest-building swallows. As breeding progressed,  
215 observers noted the presence and number of any eggs or nestlings. Female parents were captured  
216 in the box by hand or using a nest trap during incubation to be banded with a USGS aluminum  
217 band and measured (head + bill length, wing length, and mass). Many male parents were  
218 captured and processed in the same way during the nestling period, but male capture rates were  
219 sufficiently low that our analyses of adult reproductive costs and benefits are here limited to  
220 females only. A small (<100  $\mu$ L) blood sample was also taken by brachial venipuncture at this  
221 time. Nestling swallows were similarly banded, measured, and blood-sampled between days 6  
222 and 12 after hatching. During the course of this study, a number of additional observational  
223 studies and experiments were ongoing. Therefore, in particular years at particular sites, a subset  
224 of birds was subjected to treatments or sampling regimens that fell outside the scope of the long-  
225 term monitoring effort. Depending on the severity of the treatment and its anticipated effects on  
226 tree swallow fitness, we excluded some of these nesting attempts from our final dataset (see  
227 ‘Data Filtering’, next).

228 *Data Filtering.* In this study, we sought to track the fitness of individual females across their  
229 entire adult lives. To accomplish this goal, we needed to know the age of each swallow in our  
230 population. Female tree swallows included in our dataset could be aged in one of two ways: first,  
231 swallows fledged from one of our study sites could be aged based on the year in which they were  
232 first banded as nestlings; second, swallows who first appeared at our sites as unbanded adults  
233 could be aged based on plumage. This was possible because female tree swallows exhibit  
234 delayed plumage maturation, with one-year-old females (henceforth “yearlings”) having  
235 predominantly brown upperparts and females two years old and older (henceforth “older  
236 females”) wearing male-like iridescent blue-green plumage (Cohen 1980, Hussell 1983). Thus,  
237 females who were first banded in brown plumage could be reliably aged as being yearlings, still

238 in their first complete year of life. Approximately 40% of the breeding females in our study  
239 population are first captured and banded in non-brown plumage (i.e., older females), and these  
240 were excluded from our dataset owing to our inability to reliably estimate their age and entire life  
241 history.

242 The second requirement for inclusion in our dataset was that female swallows of known  
243 age must have bred in one of our boxes as yearlings. Of the 494 cases in which a female fledged  
244 from our study population and returned to breed there, 388 (78.5%) bred as yearlings. The  
245 remaining 106 (21.5%) returning females that first bred in our study area as older females were  
246 excluded from our final dataset, as we could not know whether they had been non-breeding  
247 floaters (Stutchbury and Robertson 1987) or bred undetected in unmonitored areas during their  
248 first year of life. In either case, our lack of information concerning their activities would have  
249 made spurious any effort at linking their lay date and fitness.

250 Having assembled this dataset of all reproductive attempts for every female tree swallow  
251 at our sites known to have bred as a yearling, we then evaluated individual reproductive attempts  
252 for inclusion or exclusion from our final analysis. We required that every female's yearling  
253 breeding attempt had complete information regarding its lay date and fate and that the nest had  
254 not been subjected to severe manipulation. If any of these criteria were not met, we excluded the  
255 female from further analysis. We likewise required that all older female attempts had complete  
256 information regarding lay date and fate, but for older female attempts that were manipulated in  
257 the course of a secondary observational study or experiment, we evaluated the severity of  
258 sampling or treatment to determine the best course of action to take. Treatments that involved  
259 non-destructive sampling of adults or nestlings (e.g. collection of a primary feather, additional  
260 blood samples, or immune assays) were allowed to remain in our final dataset (see Orzechowski  
261 et al. 2019 for negligible life history effects of bleeding), as were nests subjected to short-term  
262 treatments designed to measure a behavioral or physiological response over a restricted period of  
263 time (e.g. less than a few hours). Nests subjected to destructive sampling or longer-term  
264 manipulations (e.g. manipulation of nest materials, microbial environment, stress physiology,  
265 energetic expenditure, egg or brood number, or predator exposure) were treated in one of two  
266 ways. For analyses involving single-season reproductive output, such nests were excluded from  
267 the point in the nesting cycle at which the treatment was expected to have had an effect. For

268 example, an experiment that involved transplanting nestlings between nests would have been  
269 included in analyses of clutch size but excluded from analyses of number fledged. For analyses  
270 involving lifetime reproductive output, we adjusted the female's lifetime number fledged to  
271 reflect the expected number of offspring she would have produced in the absence of the  
272 experimental treatment. To arrive at this adjustment, we calculated for each female the mean  
273 deviance in number fledged from the population means for her age class (yearling vs. older  
274 female) in each of her unmanipulated years of breeding, and then applied this deviance to the  
275 population mean for her age class in the year(s) during which she was manipulated. For example,  
276 a female whose unmanipulated reproductive attempts resulted in an average fledge number that  
277 was two nestlings higher than the average fledge number of other members of her age class in  
278 each relevant breeding year would have been assigned a fledge number that was two nestlings  
279 above the population mean in each year for which her reproductive success was unavailable. We  
280 chose to perform this adjustment because longer-lived females were necessarily more likely to  
281 have been subjected to one of these experimental treatments simply because they presented more  
282 opportunities for manipulation. Thus, this adjustment enabled us to eliminate a severe bias in  
283 representation of shorter-lived vs longer-lived females. For those particularly concerned about  
284 any of these sorts of adjustments, we also ran the analyses for lifetime performance leaving out  
285 any female that had had a disqualifying manipulation in any of its seasons. The reduced and  
286 biased sample lent these analyses less statistical power, and one of the analyses produced the  
287 same result as the corrected version (Appendix S1: Table S13 vs. S14), while the other returned  
288 the null model as the most highly supported (Appendix S1: Table S11 vs. S12).

## 289 *Statistical Analyses.*

290 *Life history and fitness metrics.* To evaluate whether early and late breeders vary in lay  
291 date due to differences in overall quality or due to differences in life history strategy, we  
292 examined the relationship between lay date and a variety of short- and long-term fitness  
293 outcomes using a combination of general and generalized linear mixed effects models (*lme4*  
294 package in R v.3.5.1; Bates et al. 2015, R Core Team 2018). Fitness benefits and costs for  
295 breeding females were analyzed in three aspects: reproductive output, offspring quality and  
296 parental survival. Within reproductive output, we analyzed three components that, combined, led  
297 to number fledged: *clutch size* (the number of eggs in the first clutch laid by a female each  
298 season); whether or not any young were produced (0 or 1; henceforth "*fledging success*"); and if

299 successful, *number fledged*. (To recall the distinct definitions used for fitness components, we  
300 henceforth standardize and italicize their names—see Table 1.) Making the distinction between  
301 *fledging success* and *number fledged* allowed us to remain clear about reproductive outcomes  
302 that may have fundamentally different causes and consequences. The former was analyzed as a  
303 binomial response whereas the latter (because all the zeros in the distributions of number fledged  
304 are removed by only considering successful females) was analyzed as a Gaussian response.

305 To assess offspring quality, we measured *nestling mass* prior to fledging and *fledgling*  
306 *recruitment* to the breeding population. Tree swallows are highly dispersive, with only about 4%  
307 of fledged offspring returning to breed at the sites from which they fledged (Winkler et al. 2005).  
308 Thus, *fledgling recruitment* cannot be taken as a precise measure of the percentage of young  
309 surviving to breeding age. Rather, we analyze it here primarily to see if there is any suggestion  
310 that the timing of reproduction may influence the quality of offspring and their probabilities of  
311 recruitment.

312 To assess the effect of lay date on parental survival, we relied on female returns to the  
313 breeding site in the following year. Tree swallows do not necessarily breed at the same site every  
314 year that they survive, and the recapture histories of individuals occasionally include gaps in  
315 which a succession of years of regular recaptures is broken by a year in which the bird was not  
316 captured, followed by a year or years in which the same individual is captured again. For all  
317 analyses of adult *return rate* reported here, we used a corrected return rate which counts the bird  
318 as having been alive in any of the gap years which were bracketed by years before and after  
319 recapture. The dispersal of breeding adults from one site to another in a subsequent year could be  
320 a problem for interpretations of adult female survival rates; however, only about 14% of females  
321 (and of these, mostly younger females) breeding in this population disperse to a new breeding  
322 site (Winkler et al. 2004) after breeding in our study areas. Also, because female tree swallows  
323 are straightforward to capture in the nest with built-in traps once the clutch is complete, our  
324 recapture rate for surviving females is very high. We thus base the analyses of female breeder  
325 survival here on direct recapture rates, but we also provide in Appendix S1 an analysis conducted  
326 with Program MARK (White and Burnham 1999) that produces the same qualitative results.

327 In addition to the single-season fitness metrics outlined above, we examined *lifetime*  
328 *fledging success* and *lifetime number fledged* of successful females as holistic, integrated  
329 measures of reproductive output and survival over each individual's entire life (Table 1).

330 *Testing hypotheses:* Under the Quality Hypothesis being tested, females differ in lay date  
331 due principally to variation in overall quality, and we would expect that earlier breeding would  
332 correlate with better outcomes across all life history metrics. Under the Alternative Strategies  
333 Hypothesis, on the other hand, we would expect early lay dates to be associated with increased  
334 reproductive output, but reductions in offspring quality or adult survival (Table 1).

335 Each life history metric was coded as a response variable, while lay dates from various  
336 seasons in the females' reproductive lifetimes were included as fixed effects in separate models.  
337 In addition to lay date, we included a number of other fixed and random effects that varied by  
338 model type (Table 1), and that were held constant across multiple models for the same response  
339 variable. When lay dates were excluded from a particular model, these other variables in  
340 combination thus represented a null model that incorporated sources of variation outside of lay  
341 date that we believed *a priori* to be important in influencing the response variable under  
342 examination. Because clutch size is very strongly related to lay date in tree swallows (Winkler  
343 and Allen 1996, Winkler et al. 2002) and other *Tachycineta* swallows (Winkler et al. 2014), we  
344 included *clutch size* as a fixed effect in analyses of reproductive output to gauge the direct and  
345 indirect effects of lay date on reproduction. Chick age at measurement was included as a fixed  
346 effect in models of *nestling mass* to account for the expected larger size of nestlings measured  
347 later in the nesting cycle (Winkler and Adler 1996, Winkler et al. 2011), while *number fledged*  
348 was included as a fixed effect to account for variation attributable to increased sibling  
349 competition in larger broods. For models of adult *return rate*, single-season *fledging success* was  
350 included as a fixed effect, since reproductive failure may influence the probability of future  
351 dispersal and apparent death (Winkler et al. 2004), and female age was included as a fixed effect  
352 (in models involving older females, see below) to account for the possibility that females may be  
353 less likely to survive to the following year as they age, irrespective of their lay dates. In models  
354 of *fledgling recruitment* (in which individual fledglings were the focal unit of analysis), we  
355 included maternal age class as a fixed effect, since offspring quality could differ between  
356 yearling and older breeders. We did not code age class as a fixed effect in any other analyses

357 because we analyzed yearling and older female attempts separately (see below). Current year  
358 was coded as a random intercept in all single-season models to account for annual variation in  
359 environmental conditions, and breeding site was coded as a random intercept to account for  
360 spatial variation in breeding conditions. In lifetime models and in single-season models that  
361 included multiple attempts by the same female, we included hatch year as a random intercept to  
362 account for cohort-level variation. We also included female identity as a random intercept in any  
363 models that included multiple attempts by the same female to account for the non-independence  
364 of such reproductive efforts. For models of *fledgling recruitment*, our random error structure  
365 included intercepts for nest identity, natal site, and natal year. For models that examined *clutch*  
366 *size*, *number fledged*, and *nestling mass*, we used a Gaussian distribution with one exception: the  
367 very long right tail of the distribution of *lifetime number fledged* precluded treating it as a  
368 Gaussian variate, and a Poisson distribution was used instead. For models of *fledging success*,  
369 *adult return rate* and *fledgling recruitment* we used a binomial distribution.

370 For each fitness metric under study, we used an information theoretic approach (Burnham  
371 and Anderson 2004) and Akaike's information criterion (AIC) to rank models according to their  
372 relative fit to our data, corrected for the number of parameters. There has been a great deal of  
373 development of methods for model selection in ecology in recent years, especially in Bayesian  
374 methods (reviewed in Hooten and Hobbs 2015), and some of the more sophisticated methods for  
375 hierarchical model structures (e.g., WAIC) might be tempting to apply here (cf. Gelman et al.  
376 2013). We ran each set of candidate models with hierarchical random effects (e.g. site nested  
377 within year), but, after considering the degree of replication we could achieve in the random  
378 effect structures and the fact that we had no research rationale for interpreting the random  
379 effects, we limited ourselves here to simple non-hierarchical random effects. None of these  
380 hierarchical models yielded results for the fixed effects qualitatively different than those  
381 presented here.

382 We compared each set of candidate models against a null model that excluded lay date.  
383 We considered any models that outperformed this null model by at least 2 to be well supported.  
384 Within the resulting group of supported models, we gave preference to models with fewer  
385 parameters and which were more than  $\Delta\text{AIC}$  of 2 from the rest. We fitted each candidate model  
386 using maximum likelihood. For fitness metrics that relied on a Gaussian distribution, we refitted

387 our best-supported models using restricted maximum likelihood (REML), which provides more  
388 precise parameter estimation. Similar REML-based methods are not well-established for models  
389 that utilize a binomial or Poisson distribution. All parameter estimates that we report for best-  
390 supported Gaussian models are taken from those refitted using REML. All parameter estimates  
391 that we report for best-supported binomial and Poisson models are based on estimates derived  
392 from maximum likelihood. In the interests of space, we report in the results only the P-value and  
393 conditional  $R^2$  of mixed model fits. Marginal  $R^2$  values (which assess only the explained  
394 variance of the fixed effects) and coefficient values and their standard errors are reported in the  
395 tables in Appendix S1.

396 *The relevant time scale of lay date effects.* For all analyses of lay date, each season's lay  
397 date for a given female was taken to be the date that she started her first clutch in that season. In  
398 full life-cycle data, there are lay dates from at least three important seasons to be considered  
399 (Table 2). To estimate short-term effects of lay date variation on fitness, we used lay date in the  
400 current season. To estimate the longer-term effects of lay date variation on fitness, we used lay  
401 date from the previous season. Finally, we used lay date from the female's yearling season to  
402 account for fitness consequences of lay date variation arising from each female's first  
403 reproductive experience. For each of the season's lay dates that we tested, we tested both  
404 absolute (1 = 1 May) and relative (1 = day of the earliest clutch in our dataset each year) lay  
405 dates. Finally, we tested each lay date variant as both a linear and a quadratic predictor of fitness  
406 to account for the possibility that females laying too early, as well as too late, might suffer  
407 greater costs.

408 Because yearling and previous lay dates could only be examined for females breeding for  
409 at least the second time, we subsetted our data to ensure that different lay dates from the different  
410 seasons were being compared using the same dataset. For models investigating single-season  
411 fitness metrics, we compared the effects of yearling, current, and previous lay dates on  
412 reproductive output, *nestling mass*, and *return rate* among those females breeding for at least the  
413 second time (i.e. all older female attempts). A second analysis compared the effects of current  
414 lay date on reproductive output, *nestling mass*, and *return rate* among females breeding for the  
415 first time (i.e. all yearling attempts).

416 For models of *offspring recruitment*, which were carried out from the perspective of  
417 individual nestlings, we ran a single analysis that examined the effect of current lay date (i.e. of  
418 the nest from which the nestling fledged) on the probability that the fledgling would return to our  
419 study area as an adult. For models of lifetime fitness, we compared the effects on long-term  
420 fitness outcomes of both each female's yearling lay date and her average lay date over all  
421 reproductive attempts she undertook.

422 *Mother-daughter comparisons of lay dates and repeatabilities.* Within our existing  
423 dataset of 867 female swallows, we identified 113 instances in which a female's daughter had  
424 recruited into our study population and bred in her first year of life, and of these, a further 32  
425 instances in which both mother and daughter survived and bred as two-year olds. This pairing of  
426 mothers and daughters enabled us to examine the relative influence of maternal lay date, natal  
427 environment, and contemporary environment in determining each daughter's timing of breeding.  
428 We constructed a linear mixed effects model in which each daughter's absolute yearling lay date  
429 was coded as the response variable, and her mother's absolute yearling lay date, average  
430 maximum temperature (a determinant of food availability; Winkler et al. 2013) during her natal  
431 period, and average maximum temperature immediately prior to her yearling breeding attempt  
432 were coded as fixed effects (Table 3). Maternal identity was included as a random intercept to  
433 account for the potential non-independence of data arising from sisters raised by the same  
434 mother, while breeding year and site were included as random intercepts to account for temporal  
435 and spatial variation not captured by our temperature metrics. For two-year-old females, we  
436 constructed a similar linear mixed effects model in which each daughter's absolute two-year lay  
437 date was coded as the response variable, and her mother's two-year lay date, daily maximum  
438 temperatures during her natal period, and daily maximum temperatures immediately prior to her  
439 second breeding attempt were coded as fixed effects. Again, we coded maternal identity,  
440 breeding year, and site as random intercepts. Temperature data used in these analyses were  
441 collected from a nearby weather station monitored by the Northeast Regional Climate Center  
442 (<http://www.nrcc.cornell.edu/wxstation/ithaca/ithaca.html>).

443 To further examine lay date variability within individual females, we estimated intra-  
444 individual repeatability of lay dates using the *rpt* function in the *rptR* package in R v.3.5.1  
445 (Stoffel et al. 2017, R Core Team 2018). We carried out one repeatability analysis on all

446 breeding attempts and a second repeatability analysis on all breeding attempts undertaken by  
447 older females.

## 448 RESULTS

449 Our final dataset included 1576 nesting attempts (1479 first nesting attempts and 97  
450 second or re-nesting attempts) carried out by 867 females between 2002 and 2016. The average  
451 lifespan of a breeding female swallow in our population was 1.7 years (range: 1-10 years). The  
452 average number of fledglings produced during a female's lifetime was 4.9 (range: 0-39).  
453 Initiation of breeding for yearlings was later on average than for older females (yearlings: 20  
454 May vs older females: 14 May), though variation for both age classes was substantial (yearlings:  
455 range 4 May – 24 June, older females: range 2 May – 20 June). In general, a female's first nest in  
456 a season was most often initiated between 10 and 20 May (Figure 1).

457 *Relationship between lay date and older female fitness metrics.* Our best supported model  
458 explaining variation in older female *clutch size* included the absolute lay date of each female's  
459 current attempt ( $R^2 = 0.48$ ), and revealed that females laying earlier in the year laid larger  
460 clutches than did females who laid eggs later ( $P < 0.0001$ ; Table 4, Appendix S1: Table S1).  
461 *Clutch size*, in turn, strongly influenced variation in *number fledged* ( $P < 0.0001$ , Table 4,  
462 Appendix S1: Table S3). In contrast, variation in lay date did not significantly influence directly  
463 either *fledging success* (null model:  $R^2 = 0.07$ ; Table 4, Appendix S1: Table S2) or *number*  
464 *fledged* (null model:  $R^2 = 0.20$ ; Table 4, Appendix S1: Table S3). However, lay date did strongly  
465 influence *nestling mass*: earlier-reared nestlings were heavier than nestlings fledged from nests  
466 initiated later in the season (current absolute date:  $R^2 = 0.46$ ,  $P = 0.02$ ; Table 4, Appendix S1:  
467 Table S4). Our best-supported models explaining variation in older female *return rate* indicated  
468 that a female's lay date in the previous year was associated with her likelihood of returning to the  
469 study area in the following season (previous relative date:  $R^2 = 0.16$ ; previous absolute date:  $R^2 =$   
470  $0.15$ ; Table 4, Appendix S1: Table S5). In this analysis, models fitted with a quadratic predictor  
471 outperformed models fitted with only a linear effect of previous lay date, indicating that the  
472 relationship between previous lay date and future return was curvilinear in nature – that is, that  
473 the likelihood of future return for older females increased more than linearly with later lay dates  
474 in the previous season (for previous relative date, quadratic  $P = 0.002$  and linear  $P = 0.009$ ; for  
475 previous absolute date quadratic  $P = 0.005$  and linear  $P = 0.02$ ; Figure 2). Note that the effect

476 being detected here manifests across three years: older females breeding early in 2010 would be  
477 expected to have a lower return rate not in 2011 but in 2012. Thus, these effects of laying date on  
478 return are not simple direct effects on death or dispersal but delayed until after the following  
479 breeding season. The very same effect appears in the MARK analyses (Appendix S1: Table  
480 S16).

481 *Relationship between lay date and yearling fitness metrics.* As for older females, *clutch*  
482 *sizes* for yearling females were strongly influenced by the absolute lay date of the current attempt  
483 ( $R^2 = 0.12$ ; Table 4, Appendix S1: Table S6). Interestingly, a model that included a quadratic  
484 term outperformed one that included only a linear fixed effect of lay date, and indicated that  
485 *clutch sizes* were greatest for females laying at intermediate times (for current absolute date,  
486 quadratic  $P = 0.009$  and linear  $P = 0.83$ ; Figure 3). Lay date had no effect on either yearling  
487 *fledging success* (null model:  $R^2 = 0.06$ ; Table 4, Appendix S1: Table S7) or *number fledged*  
488 (null model:  $R^2 = 0.12$ ; Table 4, Appendix S1: Table S8). However, *clutch size* once again  
489 exerted a strong positive effect on *number fledged* ( $P < 0.0001$ , Table 4, Appendix S1: Table  
490 S8). In contrast to chicks fledged by older females, *nestling mass* in yearling nests did not  
491 depend on lay date (null model  $R^2 = 0.28$ ; Table 4, Appendix S1: Table S9). Lay date also had no  
492 effect on yearling female *return rate* (null model:  $R^2 = 0.10$ ; Table 4, Appendix S1: Table S10).

493 *Relationship between lay date and lifetime reproductive output.* There was a weak but  
494 statistically significant positive effect of yearling lay date on a female's *lifetime fledging success*  
495 (for yearling absolute date,  $P = 0.01$ ,  $R^2 = 0.06$ ; Table 4, Appendix S1: Table S11; for yearling  
496 relative date,  $P = 0.02$ ,  $R^2 = 0.07$ , Table 4, Appendix S1: Table S11). Although this indicates that  
497 yearlings laying later may be more likely to be successful at least once in their life, another  
498 indicator of reproductive strategy, *average clutch size*, had a much stronger effect ( $P < 0.0001$ ,  
499 Appendix S1: Table S11). Among females that fledged at least one nestling in their life, any  
500 advantage of later yearling lay dates is overshadowed by the advantages of earlier laying  
501 otherwise, as our best-supported model revealed that females whose average absolute lay date  
502 was earlier produced a greater number of fledglings overall (for average absolute date,  $R^2 = 0.40$ ,  
503  $P < 0.0001$ ; Figure 4; Table 4, Appendix S1: Table S13). In this model, as for per-season *number*  
504 *fledged*, *average clutch size* was again positively related to *lifetime number fledged* (*clutch size*:  
505  $P < 0.0001$ ).

506 *Relationship between lay date and offspring recruitment.* Our best-supported models  
507 indicated a significant effect of lay date, such that nestlings fledged from earlier nests were more  
508 likely to return to the study population as adults (for absolute date,  $R^2 = 0.05$ ,  $P = 0.04$ ; and for  
509 relative date,  $R^2 = 0.05$ ,  $P = 0.02$ ; Figure 5; Table 4, Appendix S1: Table S15).

510 *Mother-daughter comparisons and repeatabilities.* Our model for absolute lay date  
511 variation in 113 pairs of mothers and daughters revealed a significant positive effect of the  
512 mother's yearling lay date on that of her daughter (full model  $R^2 = 0.36$ ; mother yearling lay date  
513  $P = 0.009$ ; Figure 6). In contrast, neither temperature during development nor temperature  
514 immediately prior to the yearling breeding attempt had any effect on the daughter's yearling lay  
515 date (natal temperature  $P = 0.97$ ; breeding temperature  $P = 0.35$ ). A similar analysis carried out  
516 on the lay dates of 32 mother-daughter pairs for which we had information on lay dates of  
517 mother-daughter pairs in their second breeding year failed to find any significant predictors of  
518 second-season lay date among these same factors (full model  $R^2 = 0.33$ ; maternal lay date  $P =$   
519  $0.67$ ; natal temperature  $P = 0.70$ ; breeding temperature  $P = 0.36$ ). Intra-individual repeatability  
520 of absolute lay date among all females represented in our study was 0.15 (CI: 0.08-0.22,  $P <$   
521  $0.0001$ ). Intra-individual repeatability of absolute lay date among all older females represented in  
522 our study was 0.34 (CI: 0.23-0.44,  $P < 0.0001$ ). We performed all the same analyses for relative  
523 lay date, and the results are consistent with those for absolute lay date, though the patterns are  
524 weaker (Appendix S1: Tables S17, S18 and associated text).

## 525 DISCUSSION

526 One limitation of past studies that have investigated the relationship between lay date and  
527 fitness is that this relationship has often been considered solely in the context of a single  
528 breeding season. That work has taught us a great deal about the seasonal decline in reproductive  
529 output and the linkage between clutch size and lay date (Verhulst and Nilsson 2008), but little  
530 about how it relates to longer-term breeding performance and survival of individuals. Our study  
531 looked beyond a single breeding season and followed individual female tree swallows  
532 throughout their lives, monitoring all measurable fitness components throughout. By taking such  
533 an approach, we were able to discern between two fundamental hypotheses about the nature of  
534 life history differences among individuals. Before proceeding to those hypotheses, we emphasize  
535 that the fitness effects of lay date variation are strongly intertwined with the effects of *clutch*

536 *size*. Given all that has been done on the clutch size - lay date connection in tree swallows (e.g.,  
537 Winkler and Allen 1996, Wardrop and Ydenberg 2003, Dawson 2008, Winkler et al. 2002,  
538 2014), it came as no surprise that some of the effect of lay date on *number fledged*, both per-  
539 season and over the lifetime, was indirect: *clutch size* was strongly influenced by lay date  
540 throughout (Appendix S1: Tables S1, S6), but, though *clutch size* remained a strong predictor of  
541 number fledged in all relevant models (Appendix S1: Tables S3, S8, S13), in two of these  
542 (Appendix S1: Tables S3, S8), lay date did not add significantly to the explanatory power of  
543 *clutch size*, alone. Still, in the remaining model, lay date retained a strong direct connection to  
544 *lifetime number fledged*, and its variation was shown to have effects on many other aspects of the  
545 life history. We now review these other effects and discuss future research directions as they  
546 relate to understanding the costs and benefits of early breeding in tree swallows and the sources  
547 of individual variation in this key life history trait.

548 *Quality vs. Alternative Strategies, yearlings vs. older females*. Our results strongly suggest that  
549 earlier breeding tree swallows are of higher phenotypic quality than their late-breeding  
550 counterparts: in general, the relationships between reproductive performance and lay date were  
551 those predicted by an over-riding importance of individual quality, not the expression of  
552 alternative life history strategies (Table 4). In our population, earlier breeding was associated  
553 with larger *clutch size* and thus higher per-season *number fledged*, and in the nests of older  
554 females, broods from earlier in the season produced higher average *nestling mass* than did later  
555 nests. When we examined *lifetime number fledged*, earlier-breeding females fledged significantly  
556 more offspring, and the offspring fledged from such nests were more likely to recruit into their  
557 natal population as adults. Taken together, these results provide strong evidence that earlier  
558 breeding has higher fitness.

559 Interestingly, the associations between lay date and fitness that we observed were  
560 universally more pronounced among experienced breeders. This may indicate that inexperienced  
561 yearlings in our population are less savvy in successfully navigating the costs and benefits of  
562 breeding at a particular time. In a population of breeding tree swallows in Wisconsin, there was  
563 evidence that yearlings were less adroit in managing their mating choices: experienced females  
564 mated with more extra-pair sires when paired with a genetically similar mate, and broods that  
565 had more sires exhibited greater hatching success. In contrast, inexperienced females did not

566 adjust their mating behavior according to their genetic similarity to their mate and thus missed  
567 out on a potential benefit of polyandry (Whittingham and Dunn 2010). Wearing a distinctive  
568 brown plumage, yearlings may also be less attractive to prospective mates, delaying their  
569 formation of a pair bond (cf. Bitton et al. 2008, Coady and Dawson 2013, Taff et al. 2019). Both  
570 of these factors could help explain why reproductive output is consistently lower among  
571 yearlings in our population.

572 Of all of the fitness metrics that we examined in yearlings, the two that were most  
573 affected by lay date variation were also the only two metrics in our entire study that exhibited a  
574 negative quadratic relationship with lay date. Both *clutch size* and, indirectly, *number fledged*  
575 tended to be highest among yearlings breeding at intermediate times – both were reduced in the  
576 earliest and the latest breeders. This strengthens the indication that yearlings are more sensitive  
577 to costs of early breeding while being unable to take advantage of some of its benefits. Indeed,  
578 all of these indications of the advantage of yearling delay may have exerted selective pressures  
579 toward less attractive brown yearling plumage. In any event, it appears that females are likely  
580 subject to selection on lay date that varies in direction and mode across their lifespans (see also  
581 Tarwater and Arcese 2017).

582 This difference between yearlings and older females in the effects of lay date may be  
583 behind the one result for older females that runs counter to the Quality Hypothesis: among older  
584 females, the likelihood of returning one year later was higher among those individuals whose  
585 previous breeding attempt had taken place *later* in the season (Figure 2, Table 4, Table S5). In  
586 this result, we see evidence that later breeding may confer a survival advantage, consistent with  
587 the idea that some females may forgo reproductive benefits of early breeding to invest more  
588 heavily in self-maintenance and future survival. This result is one of the weakest significant  
589 results in this study ( $R^2 = 0.16$ ), and, though current female age was included in the two best  
590 supported models, the coefficient for current age was not significant in either one ( $P > 0.18$ ). The  
591 average lifespan of female tree swallows included in this study was 1.7 years. Thus, the typical  
592 female did not make it past a single breeding season, and the sample of older females in Table S5  
593 is dominated by older females in their first post-yearling breeding season. In this case, we cannot  
594 suggest other biological mechanisms that might explain a delayed trade-off in costs, and we  
595 tentatively ascribe most of this effect to the difference between yearlings and older females in

596 their breeding life histories. The strong ( $R^2 = 0.40$ ) overall prediction of total *lifetime number*  
597 *fledged* in our study came from a simple linear relationship with mean absolute lay date of the  
598 female (Appendix S1: Table S13).

599 *The relevant time scale of lay date effects.* In every instance in which we observed a positive  
600 association between early breeding and female performance, that association indicated an effect  
601 of the lay date on the female's current attempt. In contrast, we only observed two negative  
602 associations between early breeding and female performance: the one just discussed indicating  
603 an effect of current lay date on a female's return rate two years hence and the finding that later-  
604 laying yearlings had higher *lifetime fledging success* (Appendix S1: Table S11). These two  
605 negative effects are both quite weak ( $R^2 < 0.15$ ), and the large number of positive associations  
606 between earlier lay date and reproductive performance indicate that its benefits are generally  
607 short-lived and limited to the current breeding season. Previous research has concluded that tree  
608 swallows are income breeders – that they acquire the resources necessary for breeding in the  
609 days immediately before breeding begins (Winkler and Allen 1995, Nooker et al. 2005). The  
610 results of this study indicate that, in the same time horizon that resources are acquired and  
611 invested, most of the costs of those allocations are being paid.

612 *Mother-daughter similarity and repeatability.* Lay date had a significant repeatability coefficient  
613 in female tree swallows, a result that would be expected under the Quality Hypothesis. But the  
614 finding that a female's yearling lay date was significantly influenced by the yearling lay date of  
615 her mother suggests that an important aspect of individual quality differences may stem from  
616 genetic or maternal effects. Surprisingly, we found no evidence that temperatures during  
617 development or immediately prior to breeding influenced a female's yearling lay date. Past  
618 research in tree swallows has documented population-level advancements in laying date in  
619 concert with warmer spring temperatures, suggesting that environmental conditions immediately  
620 prior to breeding are important determinants of lay date at the population level (Dunn and  
621 Winkler 1999, Hussell 2003, Shipley et al. & Winkler et al. in prep.). However, our results  
622 suggest that individual-level determinants of lay date may involve a more complex suite of  
623 factors. In fact, when we examined determinants of older female lay date among the 32 mother-  
624 daughter pairs for which we had information on lay dates from attempts in their second breeding  
625 seasons, we found no significant determinants of lay date among those factors that we  
626 investigated. At the same time, lay date repeatability was greater among older females than

627 among all females, suggesting that the individual signature of lay date becomes stronger as  
628 females age. It is also interesting that individual repeatabilities in absolute lay dates were higher  
629 than those for relative lay dates. Of the 13 models in Appendix 1 with a significant effect of lay  
630 dates, 3 included both absolute and relative lay date measures in the best supported models, 5  
631 had only absolute lay dates as predictors in the best supported models, and none had relative lay  
632 dates alone. This suggests, as in another study of tree swallows (Bourret et al. 2015), that social  
633 factors are not as important as we suspected in determining lay dates. Surprisingly, the majority  
634 of the response to environmental factors appears to come from individual responses to  
635 photoperiodic and other year-invariant factors. In the future, it will be important to understand  
636 exactly what factors cause a female swallow to breed at a particular time (cf. Bourret et al. 2015),  
637 as well as how the potential decline in maternal influence across the lifespan influences  
638 opportunities for a response to selection on lay date to occur.

639 *Potential for response to selection.* Tree swallows continent-wide have been shifting their lay  
640 date earlier (Dunn and Winkler 1999); however, evidence for a comparable advance in lay dates  
641 in single sites with long records of monitoring is much weaker or non-existent (i.e., Hussell  
642 2003, cf. Shipley et al. in prep.). If earlier breeding generally results in better fitness outcomes,  
643 why then do we not see ever-advancing lay dates in response to strong directional selection?  
644 Price et al. (1988) modeled such a lack of selective advance in lay date in the face of directional  
645 selection as resulting from constraining correlations between physiological condition and lay  
646 date. However, Winkler and Allen (1995, 1996) showed that, though female tree swallows  
647 achieve good condition before they lay, they are not laying eggs on somatic stores of resources  
648 that they brought with them on migration, and thus, the condition of early spring birds is not  
649 determining their lay dates.

650 Our data suggest that older females are under strong directional selection for earlier  
651 laying and that yearlings are under balancing selection to breed early, but not *too* early. At the  
652 same time, lay dates among yearlings were determined at least partly by that of their mothers,  
653 while lay dates among older females were not. Thus, yearling lay date may be partially heritable  
654 and able to respond to the balancing selection that such females face, while older female lay date  
655 appears to be responsive to more varying environmental factors and thus less heritable and less  
656 likely to respond to any form of selection, however strong. At a population level, these patterns

657 may result in a continuous stream of young birds suffering reproductive deficits for breeding too  
658 early, leading to the production of offspring which are primed to breed later as yearlings. As such  
659 females age, they may breed earlier to great advantage, but this early breeding is unlikely to  
660 transfer into the next generation of swallows.

661 *Generalizing to other members of the population, “invisible fractions” and beyond.* Our goal  
662 was to examine the relationships between lay date and various fitness components over the  
663 course of a swallow’s entire life, thus limiting our analyses to including swallows for whom we  
664 had complete information regarding their reproductive histories. In limiting our analyses in this  
665 way, we excluded members of the population whose relationship to lay date could be markedly  
666 different.

667 First, we excluded from analysis any females that did not breed in our population as  
668 yearlings. Approximately 40% of the females that enter our population do so in older female  
669 plumage. Although we do not know what, if any, breeding activities they engaged in prior to  
670 their initial breeding effort in our study area, their numerical abundance means that it is  
671 important to consider whether they are likely to differ in behavior from females who bred in our  
672 study area for the first time as yearlings. This seems most likely to be the case if these unbanded  
673 older females spent their adult life prior to their first breeding effort at our sites as non-  
674 reproductive floaters. The alternative is that such females might have bred elsewhere before  
675 moving into our study area. While we cannot definitively account for the behavior of unbanded  
676 older females prior to their entry into our population, their *clutch size*, brood size, and *number*  
677 *fledged* in their first year in our study area are indistinguishable from those of older females that  
678 first bred in our study area as yearlings. In fact, the only point of dissimilarity is that older  
679 females breeding in our population for the first time lay earlier than yearlings but later than older  
680 females with prior breeding experience on our study sites (D.W. Winkler, unpublished data).  
681 Taken together, these results suggest that most females entering our study area in older female  
682 plumage have bred elsewhere in the past, and their later-than-expected lay dates perhaps reflect  
683 additional costs involved in adjusting to an unfamiliar site and a new mate or adjusting a  
684 response mechanism that may have been tuned to a previous breeding site. In the future, it will  
685 be important to consider whether such costs materially shift the intricate balance of benefits and  
686 costs associated with variable lay date and, if so, how this might affect the population’s ability to

687 adapt to changing environmental conditions. Additionally, several other populations of tree  
688 swallows exhibit different compositions of yearlings and older females. For example, a long-  
689 term study area in Wisconsin encounters nearly 90% of its females for the first time in older  
690 female plumage (Whittingham and Dunn 2010). Understanding how lay date affects fitness in  
691 populations that exhibit different demographic structure should become a priority for future  
692 research.

693 Our finding that earlier-breeding females were less likely to return to our study area two  
694 years hence lends support to the idea that early breeding can impair future survival in the subset  
695 of individuals that already are living longer than most. However, as in any discussion of a  
696 segment of a bird population that disappears between seasons, these results could also indicate  
697 that earlier-breeding birds may have been more likely to disperse to a new breeding site two  
698 years later. Tree swallow females in this population are site-faithful 86% of the time, and  
699 breeding females are more likely to disperse following a reproductive failure (Winkler et al.  
700 2004). It is possible that early-breeding yearlings, more likely to fail, are also more likely to  
701 disperse away. Not being able to follow this “invisible fraction” (cf. Grafen 1998) may thus give  
702 us a biased interpretation of the importance of lay date.

703 Our study also did not consider the relationship between lay date and performance in  
704 male tree swallows. Male reproductive output is inherently more challenging to measure because  
705 of the high rates of extra-pair paternity in this species (reviewed in Winkler et al. 2011). Not only  
706 does accurate assessment of male siring success require complete genotyping of the population,  
707 but the gregarious nocturnal roosting behavior of this species early in the season may create the  
708 opportunity for males to routinely sire offspring in nests that are located well outside of the focal  
709 study area (see Dunn and Whittingham 2005, Stapleton and Robertson 2006). Nevertheless, the  
710 relationship between timing of breeding and male performance is worthy of future attention, both  
711 in its own right and because males may materially affect when females choose to breed and how  
712 successful they are when they do.

713 If we extend the scope of generalization to other populations of the same species (e.g.,  
714 Wardrop and Ydenberg 2003, Dawson 2008, Harriman et al. 2017), the results we report here  
715 can be seen to depend on the environments to which the same bird species is exposed. Wardrop  
716 and Ydenberg (2003) reported support for both quality and date effects in a hatch-date

717 manipulation in British Columbia. Dawson (2008) conducted a similar experiment and reported  
718 that, despite complicating effects of inclement weather, the date effects was better supported at  
719 another site in the same province. Harriman et al. (2017) conducted paired experiments in both  
720 British Columbia and Sakatchewan over two seasons, and concluded that declines in food  
721 availability with date were most important in affecting seasonal reproductive declines. Such  
722 declines in seasonal food availability contrast with those elsewhere in the species' range,  
723 including the Ithaca field sites (Dunn et al. 2011). Tree swallows clearly have a life history that  
724 is able to flexibly respond to variable conditions in both space and time.

725 The lifetime perspective developed here has allowed us to extend the scope of fitness  
726 consequences beyond single breeding seasons, and the lay date effects we have seen on *offspring*  
727 *recruitment* and *lifetime number fledged* mirror those detected in another well-studied swallow  
728 (Saino et al. 2012, Raja-Aho et al. 2017, cf. Evans et al. 2019).

729 *Conclusions and perspective.* In the context of the hypotheses laid out in the beginning of  
730 this paper, it appears that most of the variation in breeding phenology and its consequences are  
731 due to variation in the overall phenotypic quality of females and not alternative life history  
732 strategies being traded off differently among individuals. In many ways, these results reinforce  
733 much of what has been known or suspected about tree swallows for decades – that they are  
734 income breeders whose performance is tied to contemporary environmental factors that must be  
735 'just right' in order for successful reproduction to occur, that earlier breeders are of superior  
736 quality to their later-breeding counterparts, and that timing of breeding is one of the most  
737 important determinants of tree swallow reproductive output. But in other ways, this study yields  
738 new insight that provokes a whole host of unanswered questions. Are there combinations of  
739 ecological factors that might make later breeding the more favorable strategy, and if so, what  
740 would they be? The contrast in the life histories of yearling vs. older females, and the presence of  
741 maternal effects on yearling lay dates, suggest many interesting research challenges for better  
742 understanding the lives of yearling breeders and how the reproductive challenge changes for  
743 those that survive to breed as older females. And finally, given that lay date seems so  
744 fundamental to tree swallow fitness, what are the actual mechanisms by which a female swallow  
745 decides to start laying on a given date? Answering these questions and others will help future

746 researchers better understand this important and often enigmatic life history trait in a well-  
747 studied bird.

748         This study's results are interesting from much broader perspectives as well. The timing of  
749 breeding is probably the life history trait that has borne the clearest signal of climate change  
750 impact across the broadest range of taxa, and the fact that, in this relatively short-lived  
751 vertebrate, non-genetic quality differences are the prevailing influence on this critical life history  
752 trait might engender some hope for the future of this and other vertebrate populations. Even  
753 though there may be some heritable basis for lay date variation, it is clear that these small birds  
754 have ample means for adjusting their timing of breeding throughout their lives and this life-long  
755 flexibility suggests an on-going responsive adjustment to the rapidly changing anthropogenic  
756 environments around them. The Ithaca tree swallow population can most accurately be seen as  
757 being made up of individuals, each with a similar tool kit for meeting environmental and  
758 developmental challenges, varying in their fitness because of chance variations in the conditions  
759 that each individual encounters in their ontogeny and ecology through each of their lives.

#### ACKNOWLEDGMENTS

Kelly Hallinger and David Winkler contributed equally to this work and served as co-principal authors. We thank the many dozens of undergrads and visitors who helped us monitor and amass the data in this paper. This research was supported by NSF IBN-0131437, DEB-0717021, and DEB 1242573 to DW Winkler, by NSF IOS-1457251 to MV, and by undergraduate support from Cornell University. All work reported here was conducted under Protocol number 2001-0051 approved by Cornell University's IACUC.

 14 TABLE 1. Fitness metrics under examination, along with an explanation of fixed and random  
 15 effects included in each model. Plus and minus signs under H1 and H2 refer to the predicted  
 16 relationship between lay date and each fitness metric if timing of breeding reflects variation in  
 17 individual quality (H1) or if it reflects the expression of alternative life-history strategies (H2).

|                    | Fitness metric          | Definition                                                                        | Fixed effects                | Random effects                                          | H1 | H2 |
|--------------------|-------------------------|-----------------------------------------------------------------------------------|------------------------------|---------------------------------------------------------|----|----|
| Offspring quantity | <i>clutch size</i>      | maximum number of eggs observed in first nest each season                         | lay date                     | female identity, hatch year, current year, current site | -  | -  |
|                    | <i>fledging success</i> | binary 0-1 indicator of whether a female fledged any young in a given season      | lay date, <i>clutch size</i> | female identity, hatch year, current year, current site | -  | -  |
|                    | <i>number fledged</i>   | number of nestlings fledged from a female's successful nest(s) over entire season | lay date, <i>clutch size</i> | female identity, hatch year, current year, current site | -  | -  |

|                   |                                  |                                                                                                   |                                                                  |                                                         |   |     |
|-------------------|----------------------------------|---------------------------------------------------------------------------------------------------|------------------------------------------------------------------|---------------------------------------------------------|---|-----|
| Offspring quality | <i>nestling mass</i>             | average mass of all nestlings in brood that would later go on to fledge                           | lay date, age of nestlings at measurement, <i>number fledged</i> | female identity, hatch year, current year, current site | - | +   |
|                   | <i>fledgling recruitment</i>     | binary 0-1 indicator of whether fledgling ever reappeared in study area as adult                  | maternal lay date, maternal age class                            | nest identity, natal year, natal site                   | - | +   |
| Adult survival    | <i>return rate</i>               | binary 0-1 indicator of whether adult was detected in study area in any subsequent year           | lay date, <i>fledging success</i>                                | female identity, hatch year, current year, current site | - | +   |
| Lifetime fitness  | <i>lifetime fledging success</i> | binary 0-1 indicator of whether a female fledged any young over the course of her life            | lay date, average <i>clutch size</i>                             | hatch year                                              | - | +/- |
|                   | <i>lifetime number fledged</i>   | number of fledglings believed to have been fledged by a successful female's nests in her lifetime | lay date, average <i>clutch size</i>                             | hatch year                                              | - | +/- |

1 TABLE 2. Explanation of lay date variants tested in alternative candidate models.

|                                                         | Lay date variant | Definition                                           | Interpretation                                 |
|---------------------------------------------------------|------------------|------------------------------------------------------|------------------------------------------------|
| Time scale over which timing of breeding exerts effects | yearling         | earliest clutch initiation date during yearling year | organizational effect of first breeding effort |
|                                                         | current          | earliest clutch initiation date during current year  | short-term effect                              |

|                                                                      | previous  | earliest clutch initiation date during previous year                        | long-term effect                            |
|----------------------------------------------------------------------|-----------|-----------------------------------------------------------------------------|---------------------------------------------|
| Importance of social context in mediating timing of breeding effects | absolute  | date defined as 1 = 1 May                                                   | effects independent of social context       |
|                                                                      | relative  | date defined as 1 = earliest clutch initiation during current season        | effects dependent on social context         |
| Potential for timing of breeding to respond to selection             | linear    | performance exhibits monotonic increase or decrease with advancing lay date | directional selection on timing of breeding |
|                                                                      | quadratic | performance exhibits parabolic relationship with advancing lay date         | stabilizing selection on timing of breeding |

3 FIGURE LEGENDS

4 FIGURE 1. Distribution of tree swallow absolute lay dates (n = 1479 breeding attempts).

5 FIGURE 2. Relationship between absolute lay date in previous year and likelihood of future return  
 6 (n = 493 breeding attempts). Solid line indicates average *return rate* for females predicted by  
 7 linear model of female return on lay date in previous year. Dashed line indicates average female  
 8 *return rate* predicted by model including a quadratic effect of lay date in previous year. Sample  
 9 sizes are displayed above each point. For interpretation see text.

10 FIGURE 3. Relationship between absolute lay date in current year and *clutch size* for older female  
 11 and yearling female attempts (n = 612 older female attempts and n = 867 yearling attempts).  
 12 Points represent mean *clutch size* produced by females whose absolute lay date fell within each  
 13 of eight one-week intervals. Bars represent standard errors, and sample sizes are above each  
 14 point.

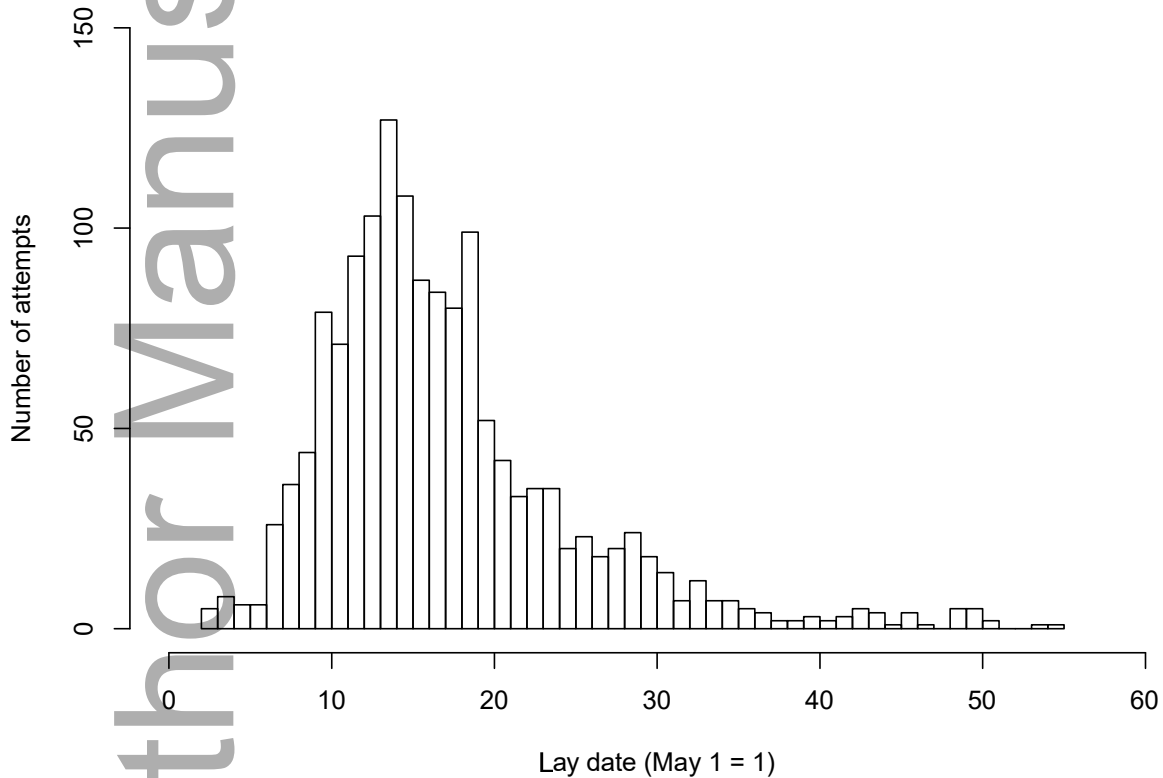

15 FIGURE 4. Relationship between average absolute lay date and *lifetime number fledged* for  
 16 females that fledged at least one nestling (n = 616 females). Points represent mean number of  
 17 fledglings produced by females whose average absolute lay date fell within each of seven one-  
 18 week intervals. Bars represent standard errors, and sample sizes are above each point.

1 FIGURE 5. Relationship between a fledgling's absolute lay date and its likelihood of recruiting as  
2 a breeder in the Ithaca study population ( $n = 3205$  fledglings). Sample sizes appear above each  
3 data point.

4 FIGURE 6. Relationship between absolute lay dates of mothers and daughters breeding in their  
5 yearling years. Solid line indicates the expectation if a daughter's lay date was completely  
6 determined by her mother's lay date ( $n = 113$  mother-daughter pairs). For further details see text.
