Abbreviations: PUFA, polyunsaturated fatty acids; IDA, iron deficiency anemia; FA, fatty acids; INTA, University of Chile Institute of Nutrition and Food Technology; DXA, dual energy X-ray absorptiometry; ALA, alpha-linolenic acid; EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid; LA, linoleic acid; GLA, gamma-linolenic acid; DGLA, dihomogamma-linolenic acid; AA, arachidonic acid; D6D,  $\Delta$ 6-desaturase; D5D,  $\Delta$ 5-desaturase; BMI, body mass index; ToFM, total fat mass; TrFM, truncal fat mass; TLM, total lean mass; %ToFM, percent total fat mass; %TrFM, percent truncal fat mass; SES, socioeconomic status; CI, confidence interval; BMIZ, BMI-for-age Z score

**ABSTRACT**

**Background:** Polyunsaturated fatty acids (PUFA) have been related to the development of adiposity. N-3 PUFA appear to be protective against obesity risk, while n-6 PUFA may be associated with greater adiposity. However, most studies have been conducted among adults. The role of PUFA in infancy is unknown.

**Objective:** To examine associations of serum PUFA at age 1 y with age- and sex-adjusted body mass index Z score (BMIZ) change through age 16 y and body composition at 16 y.

**Methods:** We quantified serum PUFA in 636 Chilean infants aged 1 y. We measured BMIZ at ages 1, 5, 10, and 16 y, and body composition by dual energy X-ray absorptiometry at 16 y. We estimated differences in 1- to 16-y BMIZ change between PUFA quartiles from multivariable linear mixed models with restricted cubic splines. At 16 y, we estimated differences in total fat mass (ToFM), truncal fat mass (TrFM), total lean mass (TLM), percent total fat mass (%ToFM), and percent truncal fat mass (%TrFM) between PUFA quartiles using linear regression.

**Results:** PUFA were not associated with BMIZ change. Alpha-linolenic acid (ALA) was positively associated with TrFM ( $P=0.03$ ) and %TrFM ( $P<0.0001$ ) at 16 y while eicosapentaenoic acid (EPA) was inversely associated with %TrFM ( $P=0.001$ ). Docosapentaenoic acid (DPA) was positively associated with ToFM ( $P=0.01$ ), TrFM ( $P=0.009$ ), %ToFM ( $P=0.02$ ), and %TrFM ( $P=0.02$ ). Gamma-linolenic acid (GLA) and the  $\Delta 6$ -desaturase (D6D) activity index were each positively, linearly associated with ToFM, TrFM,

and %ToFM. The  $\Delta$ 5-desaturase (D5D) activity index was inversely associated with %TrFM ( $P=0.04$ ).

**Conclusions:** ALA, DPA, GLA, and the D6D index at 1 y of age were positively associated with adiposity at age 16 y, while EPA and the D5D index were inversely associated with central adiposity. Our results related to EPA and desaturase indices are in agreement with limited prior studies.

## INTRODUCTION

Childhood obesity is the most prevalent early life risk factor for the development of chronic diseases, including type 2 diabetes, hypertension, and coronary heart disease.<sup>1</sup> Childhood obesity has increased globally throughout recent decades<sup>2</sup> and represents a significant public health concern. Identifying potentially modifiable nutritional exposures that influence the early development of adiposity is crucial in order to address this epidemic.

Polyunsaturated fatty acids (PUFA) are nutrients that may be related to the etiology of obesity. These fatty acids (FA), primarily classified into the n-3 and n-6 families, are necessary for a variety of physiologic processes. In particular, long-chain PUFA are precursors for eicosanoids, signaling molecules that regulate cardiovascular and immune function. In animal and *in vitro* studies, both plant- and marine-derived n-3 PUFA reduce or prevent adiposity, through reduction of fat deposition in adipose tissue and appetite suppression.<sup>3,4</sup> Conversely, n-6 PUFA upregulate adipocyte size and number.<sup>5</sup> Studies of PUFA and adiposity among adult humans have yielded mixed results. Some, but not all, trials of n-3 PUFA supplementation have found an inverse effect on adiposity.<sup>6</sup> While several observational studies (reviewed by Naughton et al<sup>7</sup>) report a positive association between the n-6 PUFA linoleic acid (18:2 n-6; LA) and body weight, a meta-analysis of n-6 PUFA supplementation trials did not find strong evidence for an effect of these PUFA on adiposity.<sup>8</sup>

PUFA status in infancy may be particularly influential on future adiposity. The precursor PUFA alpha-linolenic acid (18:3 n-3; ALA) and LA cannot be synthesized endogenously, and

their conversion into long-chain PUFA is inefficient in humans.<sup>9</sup> Thus infants must largely obtain these FA through diet, initially from breast milk or formula<sup>10</sup> and later through complementary feeding. Nutrition during infancy can have long-term effects on cardiovascular health.<sup>11</sup> Adipose tissue in childhood may be especially sensitive to the effects of PUFA, since this is the time during which the number of adipocytes in the body is determined.<sup>12</sup> Most previous investigations of early-life PUFA and adiposity have focused on exposure *in utero*.<sup>13</sup> The potential effects of PUFA in infancy may differ from those *in utero*, but results from previous studies have been inconclusive, and little research exists on measures of long-term adiposity. In a recent review of both observational studies and trials of n-3 PUFA supplementation in infancy, results were a mix of positive, inverse, and null associations of specific PUFA with measures of adiposity through middle childhood.<sup>13</sup> In addition to these inconclusive findings, the outcomes in these studies were assessed at ages 6-8 y, and thus it is still unclear whether PUFA might have longer-reaching effects on adiposity throughout development. Moreover, very few studies have been conducted in low- and middle-income countries,<sup>14-16</sup> despite the rapidly growing burden of childhood obesity<sup>2</sup> and low availability of dietary PUFA<sup>17</sup> affecting many of these regions.

We aimed to investigate the relations between serum PUFA biomarkers at 1 y of age and measures of adiposity at age 16 y in a cohort of children from Santiago, Chile.

## METHODS

**Study design and population.** We conducted a longitudinal investigation among Chilean children who were enrolled as infants in studies on iron status and were followed through adolescence. Details of the study design have been published previously.<sup>18,19</sup> Briefly, participants were recruited at ages 4-6-months from low- and middle-income communities in Santiago, Chile between 1991 and 1996. Eligible infants were singleton, born at term weighing at least 3 kg through uncomplicated, vaginal births, and did not have major health complications. Infants without iron deficiency anemia (IDA) at baseline were enrolled in a trial of iron supplementation. These participants were randomly assigned to high- or low-dose iron supplementation or usual nutrition until 12 months of age. Infants with IDA were treated with iron and enrolled in an observational study of neurodevelopment, along with a group of non-anemic controls. There were 1798 infants enrolled; of these, 1657 completed the trial and 135 were in the neurodevelopment study at 6 months. The cohort was followed during middle childhood and adolescence: 888 children were assessed at 5 y of age, 1127 at 10 y of age, and a subset of 679 were assessed at a mean age of 16.8 y of age as part of a study on cardiometabolic risk.<sup>20</sup> The study of FA was conducted among participants who had a stored serum sample available from age 1 y plus at least one more sample from ages 5 or 10 y. For analyses of BMIZ change between 1 and 16 y of age, we included 636 children in the FA study who had BMIZ data available at 1 y of age and at  $\geq 1$  subsequent assessment (5, 10, or 16 y of age). For the analysis of PUFA at 1 y of age and DXA measures of body composition at 16 y of age, there were 382

children with available information. A flowchart of the sample size at each inclusion step is provided in **Figure S1**.

The study procedures were approved by institutional review boards at the University of Chile Institute of Nutrition and Food Technology (INTA), the University of Michigan, and the University of California, San Diego. Parents provided written informed consent to participate for their children, and children provided written assent beginning at 10 y of age.

**Data collection.** Birth weight in g, length in cm, and gestational age in weeks were determined via hospital records. The date of the mother's last menstrual period was used to determine gestational age. Study personnel collected information from parents on household socioeconomic indicators at enrollment. Information on breastfeeding habits, including the date of the first bottle feeding and last breastfeeding, were collected from mothers at weekly study visits that took place from enrollment until the infant was 12 months old. For infants who had already been bottle fed at enrollment, mothers were asked to recall the date of the first bottle feeding. Because feeding breast milk by bottle was nonexistent in this population, bottle feeding was equivalent to giving infant formula or cow milk.

Anthropometric measurements were collected at INTA by trained study personnel using standardized techniques. At 1 y of age, weight was measured unclothed to the nearest 10 g and length was measured to the nearest millimeter using a recumbent length board. Weight at 5, 10 and 16 y was measured to the nearest 100 g using a Seca scale (Seca, Hamburg, Germany) and height was measured to the nearest millimeter using a Holtain stadiometer (Holtain, Crymych,

UK). All measures were obtained in duplicate and a third measurement was taken if the difference between the first two was greater than 0.3 kg or 0.5 cm; the mean of the two closest values was used. At the 16.8 y assessment, total fat mass, truncal fat mass, and total lean mass were measured with a dual energy X-ray absorptiometry (DXA) instrument (Lunar Prodigy Corp., Madison, WI, USA). These measures were conducted in the subset of children who participated in the study of cardiometabolic risk.

A blood sample was collected by venipuncture at 1, 5 and 10 y of age. The median (25<sup>th</sup>, 75<sup>th</sup> percentile) age at the 1 y blood draw was 1.00 y (0.99, 1.02). Blood components were separated and serum samples from 1 y of age were stored at -80°C before transportation as a single batch to the University of Michigan where they were cryostored at -80°C and analyzed after approximately 20 y from collection. Serum PUFA stored at -80°C are highly stable. A previous study found virtually no degradation of PUFA in samples stored at -80°C for up to 10 years.<sup>21</sup>

**Fatty acid analyses.** FA in serum were quantified at the University of Michigan Regional Comprehensive Metabolomics Resource Core. Total lipids were extracted from 200 µL of serum according to the method described by Bligh and Dyer.<sup>22</sup> 10 µL of 4 mM nonadecanoic acid (C19:0) was used as the internal standard. The FA fraction of the total lipids was derivatized into methyl esters using BF<sub>3</sub>-methanol as previously described.<sup>23</sup> These were extracted with a 2:1 hexane-water, dried, and resuspended in hexane. FA were measured using gas chromatography. 1-2 µL of sample was injected via autosampler onto an Agilent 6890N chromatograph (Agilent,

Santa Clara, CA, USA) with a flame ionization detector, a 100 m x 0.25 mm x 0.2  $\mu$ m SP-2560 column (Sigma-Aldrich, Bellefonte, PA, USA) and Chemstation software. C19:0 and other authentic methyl esters were used to create a calibration curve for FA quantification. The authentic methyl esters were also used to identify FA in samples based on retention times. The coefficients of variation for quantification of specific FA ranged between 2.5-3.6%.

**Statistical Analyses.** *Definition of exposures.* The main exposures were serum PUFA biomarkers measured at 1 y of age, expressed as percentage relative to the total FA concentration (FA %) quantified in a sample. The n-3 PUFA we considered were ALA, eicosapentaenoic acid (20:5 n-3; EPA), docosapentaenoic acid (22:5 n-3; DPA), and docosahexaenoic acid (22:6 n-3; DHA). N-6 PUFA included LA, gamma-linolenic acid (18:3 n-6; GLA), dihomo-gamma-linolenic acid (20:3 n-6; DGLA), and arachidonic acid (20:4 n-6; AA). We also considered the ratio of total n-6:n-3 PUFA, which may be important for adiposity development.<sup>24</sup> Additionally, we considered activity indices of the  $\Delta$ 6-desaturase (D6D) and  $\Delta$ 5-desaturase (D5D) enzymes, using the GLA/LA and AA/DGLA ratios, respectively. We categorized all exposures into quartiles to allow for possible non-linear associations with the outcomes.

*Definition of outcomes.* The primary outcomes were change in age- and sex-adjusted body mass index (BMI) Z scores (BMIZ) between 1 and 16 y of age and DXA measures of body composition at 16 y of age. BMI was calculated as  $\text{kg/m}^2$  and BMIZ were calculated according to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup> DXA measures

included the total fat mass (ToFM), truncal fat mass (TrFM), total lean mass (TLM), percent total fat mass (%ToFM), and percent truncal fat mass (%TrFM).

*Covariates.* All covariates were measured in infancy and included sociodemographic and anthropometric characteristics as well as serum FA. We categorized birth length and weight as average or large for gestational age according to the INTERGROWTH 21<sup>st</sup> standards for newborn size.<sup>26</sup> We defined large for gestational age as  $\geq 90^{\text{th}}$  percentile. We did not consider a category of small for gestational age because birth weight  $\geq 3$  kg was an eligibility criterion for recruitment and there were no children  $\leq 10^{\text{th}}$  percentile for birth weight. Seven children with birth length  $\leq 10^{\text{th}}$  percentile were classified in the average for gestational age group. We categorized breastfeeding as  $< 6$  months,  $\geq 6$  months mixed bottle/breastfeeding, or  $\geq 6$  months exclusive breastfeeding. Iron supplementation was categorized as any (combining low- and high-dose groups) vs. none. We measured socioeconomic status (SES) using a modified Graffar index.<sup>27</sup> The index consists of 13 items related to family structure, education and employment, crowding and housing condition, and ownership of assets. The index ranges from 0 to 65; higher values indicate lower SES. The serum FA that we considered as covariates were total *trans* FA, which have been associated with weight gain in adults.<sup>28</sup>

*Correlates of serum PUFA at 1 y of age.* We compared distributions of serum PUFA biomarkers by categories of covariates using means  $\pm$  SD. We tested the significance of associations using linear regression models with each PUFA biomarker as the outcome. For dichotomous covariates, we obtained P values from Wald tests. For ordinal variables, we tested

for linear trends using Wald tests of a variable representing category-specific medians introduced as a continuous variable. For categorical covariates, we used a  $\chi^2$  score statistic. We specified robust estimates of variance in all models.

*Serum PUFA at 1 y of age and change in BMIZ from ages 1 to 16 y.* In bivariate analysis, we estimated means  $\pm$  SE of BMIZ at 1 and 16 y of age and change in BMIZ between 1 and 16 y by quartiles of the PUFA exposures at age 1 y. These were from BMIZ growth curves estimated using mixed effects linear regression models.<sup>29</sup> The outcome was BMIZ and age was represented as a predictor using restricted cubic splines.<sup>30</sup> These piecewise cubic polynomials are smoothly joined at each knot and linear in the tails. They allow for modeling of smoothed, non-linear trajectories of BMIZ across different ages. These methods do not require that all children have the same number of measurements or that the measurements be obtained at the same ages. Thus, we fitted the models with data from all assessments (1, 5, 10, and 16 y) and placed knots at the median ages of children measured at each assessment. Other predictors in the model included indicator variables for each PUFA quartile, interaction terms between the PUFA indicators and all age terms, and random intercepts and age slopes for each child. We estimated adjusted mean differences and 95% confidence intervals (CI) in 1 to 16 y BMIZ change between quartiles of serum PUFA from these models. We included covariates that were associated with the PUFA biomarkers or that have been related to BMIZ change. The final model included sex, birth weight, breastfeeding, Graffar index, and total serum *trans* FA at 1 y of age. Each long-chain PUFA was adjusted for its immediate metabolic precursor: EPA was adjusted for ALA, DPA for

EPA, DHA for DPA, GLA for LA, DGLA for GLA, and AA for DGLA. In order to adjust for potential confounding by common dietary sources of n-3 and n-6 PUFA, which co-occur as LA and ALA in foods such as plant oils,<sup>31</sup> we adjusted estimates for each n-3 PUFA for LA and total long-chain n-6 PUFA, while estimates for each n-6 PUFA were adjusted for ALA and total long-chain n-3 PUFA. All covariate FA were entered in the model as restricted cubic splines in order to account for possible residual confounding due to non-linear associations with the outcome. When the association between PUFA quartiles and BMIZ change seemed linear, we estimated the difference in change per 1 SD of the PUFA distribution.

*Serum PUFA at 1 y of age and body composition at 16 y.* In bivariate analysis, we compared distributions of ToFM, TrFM, TLM, %ToFM, and %TrFM by quartiles of serum PUFA using means  $\pm$  SD. We conducted tests for linear trend using linear regression models with each body composition measure as the outcome and a variable representing median values of each PUFA quartile introduced as a continuous variable. In multivariable analysis we obtained adjusted mean differences and 95% CI in the body composition measures by quartiles of serum PUFA. These models included indicators for PUFA quartiles and were also adjusted for sex, birth weight, breastfeeding, Graffar index, BMI at 1 y of age, and total serum *trans* FA. We also included other PUFA as covariates following the strategy described for the analyses of BMIZ change. Because body composition may differ by sex in adolescence, we conducted supplemental analyses stratified by sex by including interaction terms between sex and all other model predictors and testing for their statistical significance.

We fitted all models with empirical variance estimates, which are robust to heteroskedasticity and deviations from normality.<sup>32</sup> All analyses were conducted using Statistical Analysis Software version 9.4 (SAS Institute, Cary, NC, USA).

## RESULTS

The number of children with 2, 3, or 4 measurements was 78, 183, and 375, respectively. Mean  $\pm$  SD BMIZ at 1, 5, 10, and 16 y of age was  $0.81 \pm 0.94$ ,  $0.98 \pm 1.18$ ,  $1.02 \pm 1.16$ , and  $0.71 \pm 1.13$ , respectively. At age 16 y, mean  $\pm$  SD ToFM, TrFM, and LM was  $19.8 \pm 10.1$ ,  $10.0 \pm 5.7$ , and  $44.0 \pm 8.9$  kg, respectively. Mean  $\pm$  SD %ToFM and %TrFM was  $29.1 \pm 10.9$  and  $49.3 \pm 5.9$ .

### N-3 PUFA

*Correlates of n-3 PUFA at 1 y.* Serum ALA was positively associated with iron supplementation (**Table S1**). EPA was positively related to exclusive breastfeeding duration and total *trans* FA. DPA was inversely associated with iron supplementation. DHA was related to female sex and exclusive breastfeeding duration, and inversely associated with total serum *trans* FA.

*BMIZ change between ages 1 and 16 y.* N-3 PUFA at 1 y of age were not significantly associated with BMIZ change from 1 to 16 y (**Table 1 and Table S2**).

*Body composition at age 16 y.* ALA was positively associated with TrFM and %TrFM in non-linear fashions (**Table 2 and Table S2**). Adjusted mean differences (95% CI) between children with ALA in quartile (Q) 4 vs. <Q4 were 1.5 kg (0.2, 2.8;  $P=0.03$ ) for TrFM and 3.3 percentage points (95% CI: 2.0%, 4.6%;  $P<0.0001$ ) for %TrFM. EPA was inversely associated with %TrFM (adjusted mean difference >Q1 vs. Q1: -2.1%; 95% CI: -3.5%, -0.9%;  $P=0.001$ ). DPA was positively associated with fat mass indices in non-linear manners. Adjusted mean

differences (95% CI) between DPA >Q1 vs. Q1 for ToFM, TrFM, %ToFM, and %TrFM were, respectively, 2.7 kg (95% CI: 0.7, 4.8;  $P=0.01$ ), 1.6 kg (95% CI: 0.4, 2.8;  $P=0.009$ ), 2.3% (95% CI: 0.4, 4.2;  $P=0.02$ ), and 1.8% (95% CI: 0.3, 3.2;  $P=0.02$ ). Most associations did not differ by sex (**Table S3 and Table S4**). However, the positive association of ALA with %TrFM was stronger among boys ( $P$ , interaction=0.02), as was the inverse association of EPA with %TrFM ( $P$ , interaction=0.004).

### **N-6 PUFA**

*Correlates of n-6 PUFA at 1 y.* LA was positively associated with exclusive breastfeeding  $\geq 6$  months and with iron supplementation (**Table S5**). It was inversely associated with total *trans* FA. Serum GLA was inversely related to length-for-gestational age and socioeconomic status. DGLA was positively associated with length- and weight-for-gestational age and inversely related to iron supplementation. AA was positively associated with length- and weight-for-gestational age, and exclusive breastfeeding  $\geq 6$  months, and inversely related to iron supplementation and total *trans* FA. The n-6:n-3 ratio was inversely associated with total *trans* FA. The D6D index was inversely associated with length-for-gestational age and socioeconomic status.

*BMIZ change between ages 1 and 16 y.* Neither n-6 PUFA, the n-6:n-3 ratio, nor desaturase indices at 1 y of age was significantly associated with change in BMIZ (**Table 3 and Table S6**).

*Body composition at 16 y of age.* Without adjustment for n-3 PUFA, GLA ( $P$ , trend=0.02) and the D6D index ( $P$ , trend=0.01) were each positively associated with %ToFM (**Table S6**). In fully adjusted models, GLA and the D6D index were each positively, linearly associated with ToFM, TrFM, and %ToFM (**Table 4**). Every 1 SD (0.36) difference in GLA was associated with an adjusted higher mean ToFM (1.0 kg per SD; 95% CI: 0.1, 1.9;  $P=0.03$ ), TrFM (0.6 kg per SD; 95% CI: 0.1, 1.1;  $P=0.03$ ), and %ToFM (1.0 percentage points per SD; 95% CI: 0.2%, 1.7%;  $P=0.01$ ). A 1 SD difference (0.02) in the D6D index was related to a higher mean ToFM (1.2 kg per SD; 95% CI: 0.0, 2.3;  $P=0.04$ ), TrFM (0.7 kg per SD; 95% CI: 0.0, 1.4;  $P=0.05$ ), and %ToFM (1.1 percentage points per SD; 95% CI: 0.2%, 2.1%;  $P=0.02$ ). The D5D index was inversely associated with %TrFM. Children in the highest quartile had a mean %TrFM 1.9 percentage points lower than did children in the lowest quartile (95% CI: -3.8%, -0.1%;  $P=0.04$ ). A slight inverse association between DGLA and %TrFM was present only among girls ( $P$ , interaction=0.02); no other associations differed by sex (**Table S7 and Table S8**).

## DISCUSSION

In this longitudinal study of Chilean children, PUFA at 1 y of age were not associated with BMIZ changes through childhood and adolescence. Nevertheless, they were related to body composition at age 16 y. Serum ALA at 1 y of age was positively associated with TrFM and %TrFM at 16 y. EPA was inversely associated with %TrFM, while DPA was positively associated with ToFM, TrFM, %ToFM, and %TrFM. GLA and the D6D index were each positively associated with ToFM, TrFM, and %ToFM. The D5D index was inversely associated with %TrFM.

Serum ALA was positively associated with truncal fat. This is in contrast to a previous study in which maternal plasma ALA during pregnancy was inversely associated with the android/gynoid fat mass ratio and pre-peritoneal fat mass area in offspring at 6 y of age.<sup>33</sup> One potential explanation for this discrepancy is the difference in ages at which body composition was measured in the two studies. Body composition may not track completely between childhood and adolescence. Thus, the relation between early-life ALA and body composition at 6 y of age may be different than its relation with body composition at 16 y. Other possible explanations include the differences in timing of exposure assessment, measures of central adiposity, or ALA intake between the study populations. Four other studies of early-life ALA exposure and measures of adiposity have used BMI as an outcome, which does not distinguish between fat compartments. None of these found associations between ALA in cord blood<sup>34,35</sup> or breastmilk<sup>15,36</sup> with BMI during infancy or childhood, consistent with our finding of no

association with BMI change. The mechanism underlying a potential effect of ALA on central adiposity is unclear. One possibility is that much of the serum ALA measured in these children could have been *trans* ALA. In areas where hydrogenated oils are present in the food supply, *trans* ALA represents a large proportion of total dietary ALA.<sup>37</sup> Chile had not banned *trans* FA from its food supply at the time of FA measurement in this study.<sup>38</sup> Although few studies have investigated the health effects of *trans* ALA, other *trans* FA have been positively associated with central adiposity.<sup>39</sup> We did not measure *trans* isomers of ALA and could not differentiate its effects from those of *cis* ALA. The association could also be due to confounding by unmeasured aspects of diet.

We found that EPA was inversely associated with %TrFM. In a randomized trial, supplementation with EPA+DHA from birth to 6 months resulted in lower waist circumference at 5 y of age.<sup>40</sup> In another study, maternal plasma EPA during pregnancy was inversely associated with the android/gynoid fat mass ratio and pre-peritoneal fat mass area at 6 y.<sup>33</sup> Previous studies of EPA during pregnancy, in cord blood, or in breastmilk have not consistently found protective associations with measures of overall adiposity such as BMI and %ToFM.<sup>13</sup> However, our results and others suggest that EPA may be specifically protective against central adiposity, which is related to development of the metabolic syndrome<sup>41</sup> and cardiovascular disease.<sup>42</sup> Whether early-life EPA decreases risk of future chronic disease remains to be investigated.

DPA at age 1 y was positively associated with ToFM, TrFM, %ToFM, and %TrFM at 16 y. In a pooled analysis of two large cohorts, cord blood DPA was not associated with childhood BMI.<sup>43</sup> Maternal DPA during pregnancy was inversely associated with %ToFM and the android/gynoid fat mass ratio at 6 y in a Dutch study.<sup>33</sup> Compared with EPA, DPA is found at lower levels in the diet<sup>44</sup> and may be less bioavailable.<sup>45</sup> Thus, DPA in serum could more closely reflect endogenous activity of D6D than it does DPA intake. Associations between DPA and fat mass might reflect associations with D6D activity rather than an effect of DPA itself.

GLA was positively associated with ToFM, TrFM, and %ToFM. This is in agreement with an investigation that reported a positive association between maternal plasma GLA during pregnancy and %ToFM and pre-peritoneal fat mass area in offspring at age 6 y.<sup>33</sup> However, two other studies found no association between cord blood GLA and BMI or %ToFM in childhood.<sup>43,46</sup> A trial of formula supplemented with GLA+DHA until 9 months of age found no effect on BMI or %ToFM at age 10 y.<sup>47</sup> Differences among studies may be the result of differences in GLA levels between populations, or effect modification by desaturase gene variations.<sup>48</sup>

Estimated D6D enzyme activity was positively associated with ToFM, TrFM, and %ToFM, while the D5D index was inversely associated with %TrFM. Our results are consistent with two longitudinal studies conducted among children aged 2-10 y<sup>49</sup> and 10 y,<sup>50</sup> and evidence that cardiometabolic risk factors are positively related to D6D activity and inversely associated with D5D activity among adults.<sup>51</sup>

Although PUFA in infancy were related to body composition in adolescence, they were not associated with BMIZ trajectories. These results are unexpected since BMI and BMIZ correlate with fat mass throughout childhood. One possible explanation is that the differences in body composition at 16 y by PUFA concentrations may already have been present at 1 y. We tried to overcome this possibility by adjusting the analyses of body composition measures at age 16 y for BMI at 1 y, but BMI in infancy is an imperfect proxy for fat mass. Another possibility is that the outcomes measured by DXA are more precise measures of adiposity than BMIZ, which reflects both fat and lean mass, or that the effects of PUFA differ between body fat compartments, which are not separated by using BMIZ.

One of the primary strengths of this study is its longitudinal design, which limits the possibility of reverse causation. We had an opportunity to examine associations of early-life exposures with outcomes at older ages, which provides evidence for the relevance of PUFA status in infancy for long-term health. PUFA biomarkers are not subject to errors in recall or food composition tables, as opposed to dietary assessment data. Furthermore, we assessed body composition using DXA, which provides reliable and valid measures of fat and lean mass.<sup>52</sup>

One of the limitations of this study is that serum PUFA biomarkers reflect status over a period of weeks and may misclassify participants with respect to long-term intake.<sup>53</sup> Analyses of multiple exposures could have increased type I error. Body composition measures differ by sex in adolescence<sup>54</sup>; although interactions by sex were not statistically significant, effect modification by sex cannot be completely ruled out. The lack of available body composition

Author Manuscript

measurements in infancy prevented us from analyzing change in these outcomes or adjusting for their baseline values. Adiposity at 1 y of age could have influenced serum PUFA levels at 1 y of age, and this reverse causation may have influenced the results related to BMIZ trajectories. However, we chose not to adjust for baseline BMIZ in these analyses because this adjustment can cause bias.<sup>55</sup> Measured baseline BMIZ is the result of both true baseline BMIZ and its measurement error, which in turn contributes to measured BMIZ change from baseline to 16 y, the outcome of interest. As a common effect of two variables (a “collider”), baseline BMIZ naturally blocks the flow of a non-causal statistical association between the exposure (PUFA) and the outcome. Adjusted for baseline BMIZ could unblock such a non-causal path and induce a spurious association between PUFA and BMIZ change from baseline to later ages. Finally, because we only had relative measures of serum PUFA expressed as a percentage of total FA, we were unable to determine the extent to which differences in PUFA FA percentage reflect differences in absolute serum PUFA content or serum levels of saturated, monounsaturated, and *trans* FA.

In conclusion, serum ALA and DPA at 1 y of age were positively associated with measures of fat mass at age 16 y, whereas EPA was inversely associated with %TrFM. GLA and the D6D index were also positively associated with adiposity in adolescence, while D5D activity was inversely related to this outcome. PUFA status in infancy might affect long-term body composition and adiposity. Our results could be generalizable to other populations with similar dietary intake and behavior, which in this Chilean population have been characterized as low in

fruits and vegetables, high in snack foods with saturated fat and refined carbohydrates, and low in physical activity levels.<sup>56</sup> Our results may also be applicable to populations undergoing a similar nutrition transition. In Chile, economic growth in the 1990s resulted in one of the most rapid transitions in Latin America, including a shift toward Western diets and sedentary lifestyles.<sup>57</sup> By the time of the 16 y follow-up in our study, the transition was advanced with a very low prevalence of stunting and high prevalence of obesity.<sup>58</sup> Intervention studies are warranted to elucidate the potential protective effect of EPA against the development of central adiposity in children and adolescents.

**CONFLICT OF INTEREST STATEMENT**

The authors report no conflicts of interest.

**Footnotes to Table 1**

- <sup>a</sup> According to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup>
- <sup>b</sup> From growth curves estimated using mixed effects linear regression models with BMIZ as the outcome, and predictors that included indicator variables for each PUFA quartile, linear and cubic spline terms for age, and interaction terms between the quartiles and age terms. All models included random intercepts and age slopes to account for within-child correlations of repeated BMI measurements.
- <sup>c</sup> Adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), and total serum trans fatty acids (FA). All n-3 PUFA are adjusted for LA and total long-chain n-6 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate FA are represented with linear and restricted cubic spline terms.
- <sup>d</sup> From mixed effects linear regression models with BMI as the outcome and a variable representing medians of PUFA quartiles introduced as continuous.

**Footnotes to Table 2**

- <sup>a</sup> Measured by dual-energy X-ray absorptiometry.
- <sup>b</sup> From linear regression models with a given body composition measure as the outcome and indicator variables for PUFA quartiles as predictors. In addition, all models were adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), BMI at 1 y (continuous), and total serum trans fatty acids. All n-3 PUFA are adjusted for LA and total long-chain n-6 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.
- <sup>c</sup> From linear regression models with a variable representing medians of PUFA quartiles introduced as continuous.

**Table 3. Changes in BMI-for-age Z scores (BMIZ)<sup>a</sup> from 1 to 16 years of age by serum n-6 polyunsaturated fatty acid biomarkers and desaturase activity indices at 1 year of age among children from Santiago, Chile**

**Footnotes to Table 3**

- <sup>a</sup> According to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup>
- <sup>b</sup> From growth curves estimated using mixed effects linear regression models with BMI as the outcome, and predictors that included indicator variables for each PUFA quartile, linear and cubic spline terms for age, and interaction terms between the quartiles and age terms. All models included random intercepts and age slopes to account for within-child correlations of repeated BMI measurements.
- <sup>c</sup> Adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥ 6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), and total serum trans fatty acids. All n-6 PUFA are adjusted for ALA and total long-chain n-3 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.
- <sup>d</sup> From mixed effects linear regression models with BMI as the outcome and a variable representing medians of PUFA quartiles introduced as continuous.

Abbreviations: PUFA, polyunsaturated fatty acids; IDA, iron deficiency anemia; FA, fatty acids; INTA, University of Chile Institute of Nutrition and Food Technology; DXA, dual energy X-ray absorptiometry; ALA, alpha-linolenic acid; EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid; LA, linoleic acid; GLA, gamma-linolenic acid; DGLA, dihomo-gamma-linolenic acid; AA, arachidonic acid; D6D,  $\Delta$ 6-desaturase; D5D,  $\Delta$ 5-desaturase; BMI, body mass index; ToFM, total fat mass; TrFM, truncal fat mass; TLM, total lean mass; %ToFM, percent total fat mass; %TrFM, percent truncal fat mass; SES, socioeconomic status; CI, confidence interval; BMIZ, BMI-for-age Z score

## ABSTRACT

**Background:** Polyunsaturated fatty acids (PUFA) have been related to the development of adiposity. N-3 PUFA appear to be protective against obesity risk, while n-6 PUFA may be associated with greater adiposity. However, most studies have been conducted among adults. The role of PUFA in infancy is unknown.

**Objective:** To examine associations of serum PUFA at age 1 y with age- and sex-adjusted body mass index Z score (BMIZ) change through age 16 y and body composition at 16 y.

**Methods:** We quantified serum PUFA in 636 Chilean infants aged 1 y. We measured BMIZ at ages 1, 5, 10, and 16 y, and body composition by dual energy X-ray absorptiometry at 16 y. We estimated differences in 1- to 16-y BMIZ change between PUFA quartiles from multivariable linear mixed models with restricted cubic splines. At 16 y, we estimated differences in total fat mass (ToFM), truncal fat mass (TrFM), total lean mass (TLM), percent total fat mass (%ToFM), and percent truncal fat mass (%TrFM) between PUFA quartiles using linear regression.

**Results:** PUFA were not associated with BMIZ change. Alpha-linolenic acid (ALA) was positively associated with TrFM ( $P=0.03$ ) and %TrFM ( $P<0.0001$ ) at 16 y while eicosapentaenoic acid (EPA) was inversely associated with %TrFM ( $P=0.001$ ).

Docosapentaenoic acid (DPA) was positively associated with ToFM ( $P=0.01$ ), TrFM ( $P=0.009$ ), %ToFM ( $P=0.02$ ), and %TrFM ( $P=0.02$ ). Gamma-linolenic acid (GLA) and the  $\Delta 6$ -desaturase (D6D) activity index were each positively, linearly associated with ToFM, TrFM, and %ToFM. The  $\Delta 5$ -desaturase (D5D) activity index was inversely associated with %TrFM ( $P=0.04$ ).

**Conclusions:** ALA, DPA, GLA, and the D6D index at 1 y of age were positively associated with adiposity at age 16 y, while EPA and the D5D index were inversely associated with central

adiposity. Our results related to EPA and desaturase indices are in agreement with limited prior studies.

## INTRODUCTION

Childhood obesity is the most prevalent early life risk factor for the development of chronic diseases, including type 2 diabetes, hypertension, and coronary heart disease.<sup>1</sup> Childhood obesity has increased globally throughout recent decades<sup>2</sup> and represents a significant public health concern. Identifying potentially modifiable nutritional exposures that influence the early development of adiposity is crucial in order to address this epidemic.

Polyunsaturated fatty acids (PUFA) are nutrients that may be related to the etiology of obesity. These fatty acids (FA), primarily classified into the n-3 and n-6 families, are necessary for a variety of physiologic processes. In particular, long-chain PUFA are precursors for eicosanoids, signaling molecules that regulate cardiovascular and immune function. In animal and *in vitro* studies, both plant- and marine-derived n-3 PUFA reduce or prevent adiposity, through reduction of fat deposition in adipose tissue and appetite suppression.<sup>3,4</sup> Conversely, n-6 PUFA upregulate adipocyte size and number.<sup>5</sup> Studies of PUFA and adiposity among adult humans have yielded mixed results. Some, but not all, trials of n-3 PUFA supplementation have found an inverse effect on adiposity.<sup>6</sup> While several observational studies (reviewed by Naughton et al<sup>7</sup>) report a positive association between the n-6 PUFA linoleic acid (18:2 n-6; LA) and body weight, a meta-analysis of n-6 PUFA supplementation trials did not find strong evidence for an effect of these PUFA on adiposity.<sup>8</sup>

PUFA status in infancy may be particularly influential on future adiposity. The precursor PUFA alpha-linolenic acid (18:3 n-3; ALA) and LA cannot be synthesized endogenously, and their conversion into long-chain PUFA is inefficient in humans.<sup>9</sup> Thus infants must largely obtain these FA through diet, initially from breast milk or formula<sup>10</sup> and later through complementary feeding. Nutrition during infancy can have long-term effects on cardiovascular

health.<sup>11</sup> Adipose tissue in childhood may be especially sensitive to the effects of PUFA, since this is the time during which the number of adipocytes in the body is determined.<sup>12</sup> Most previous investigations of early-life PUFA and adiposity have focused on exposure *in utero*.<sup>13</sup> The potential effects of PUFA in infancy may differ from those *in utero*, but results from previous studies have been inconclusive, and little research exists on measures of long-term adiposity. In a recent review of both observational studies and trials of n-3 PUFA supplementation in infancy, results were a mix of positive, inverse, and null associations of specific PUFA with measures of adiposity through middle childhood.<sup>13</sup> In addition to these inconclusive findings, the outcomes in these studies were assessed at ages 6-8 y, and thus it is still unclear whether PUFA might have longer-reaching effects on adiposity throughout development. Moreover, very few studies have been conducted in low- and middle-income countries,<sup>14-16</sup> despite the rapidly growing burden of childhood obesity<sup>2</sup> and low availability of dietary PUFA<sup>17</sup> affecting many of these regions.

We aimed to investigate the relations between serum PUFA biomarkers at 1 y of age and measures of adiposity at age 16 y in a cohort of children from Santiago, Chile.

## METHODS

**Study design and population.** We conducted a longitudinal investigation among Chilean children who were enrolled as infants in studies on iron status and were followed through adolescence. Details of the study design have been published previously.<sup>18,19</sup> Briefly, participants were recruited at ages 4-6-months from low- and middle-income communities in Santiago, Chile between 1991 and 1996. Eligible infants were singleton, born at term weighing at least 3 kg through uncomplicated, vaginal births, and did not have major health complications. Infants without iron deficiency anemia (IDA) at baseline were enrolled in a trial of iron supplementation. These participants were randomly assigned to high- or low-dose iron supplementation or usual nutrition until 12 months of age. Infants with IDA were treated with iron and enrolled in an observational study of neurodevelopment, along with a group of non-anemic controls. There were 1798 infants enrolled; of these, 1657 completed the trial and 135 were in the neurodevelopment study at 6 months. The cohort was followed during middle childhood and adolescence: 888 children were assessed at 5 y of age, 1127 at 10 y of age, and a subset of 679 were assessed at a mean age of 16.8 y of age as part of a study on cardiometabolic risk.<sup>20</sup> The study of FA was conducted among participants who had a stored serum sample available from age 1 y plus at least one more sample from ages 5 or 10 y. For analyses of BMIZ change between 1 and 16 y of age, we included 636 children in the FA study who had BMIZ data available at 1 y of age and at  $\geq 1$  subsequent assessment (5, 10, or 16 y of age). For the analysis of PUFA at 1 y of age and DXA measures of body composition at 16 y of age, there were 382 children with available information. A flowchart of the sample size at each inclusion step is provided in **Figure S1**.

The study procedures were approved by institutional review boards at the University of Chile Institute of Nutrition and Food Technology (INTA), the University of Michigan, and the University of California, San Diego. Parents provided written informed consent to participate for their children, and children provided written assent beginning at 10 y of age.

**Data collection.** Birth weight in g, length in cm, and gestational age in weeks were determined via hospital records. The date of the mother's last menstrual period was used to determine gestational age. Study personnel collected information from parents on household socioeconomic indicators at enrollment. Information on breastfeeding habits, including the date of the first bottle feeding and last breastfeeding, were collected from mothers at weekly study visits that took place from enrollment until the infant was 12 months old. For infants who had already been bottle fed at enrollment, mothers were asked to recall the date of the first bottle feeding. Because feeding breast milk by bottle was nonexistent in this population, bottle feeding was equivalent to giving infant formula or cow milk.

Anthropometric measurements were collected at INTA by trained study personnel using standardized techniques. At 1 y of age, weight was measured unclothed to the nearest 10 g and length was measured to the nearest millimeter using a recumbent length board. Weight at 5, 10 and 16 y was measured to the nearest 100 g using a Seca scale (Seca, Hamburg, Germany) and height was measured to the nearest millimeter using a Holtain stadiometer (Holtain, Crymych, UK). All measures were obtained in duplicate and a third measurement was taken if the difference between the first two was greater than 0.3 kg or 0.5 cm; the mean of the two closest values was used. At the 16.8 y assessment, total fat mass, truncal fat mass, and total lean mass were measured with a dual energy X-ray absorptiometry (DXA) instrument (Lunar Prodigy

Corp., Madison, WI, USA). These measures were conducted in the subset of children who participated in the study of cardiometabolic risk.

A blood sample was collected by venipuncture at 1, 5 and 10 y of age. The median (25<sup>th</sup>, 75<sup>th</sup> percentile) age at the 1 y blood draw was 1.00 y (0.99, 1.02). Blood components were separated and serum samples from 1 y of age were stored at -80°C before transportation as a single batch to the University of Michigan where they were cryostored at -80°C and analyzed after approximately 20 y from collection. Serum PUFA stored at -80°C are highly stable. A previous study found virtually no degradation of PUFA in samples stored at -80°C for up to 10 years.<sup>21</sup>

**Fatty acid analyses.** FA in serum were quantified at the University of Michigan Regional Comprehensive Metabolomics Resource Core. Total lipids were extracted from 200 µl of serum according to the method described by Bligh and Dyer.<sup>22</sup> 10 µL of 4 mM nonadecanoic acid (C19:0) was used as the internal standard. The FA fraction of the total lipids was derivatized into methyl esters using BF<sub>3</sub>-methanol as previously described.<sup>23</sup> These were extracted with a 2:1 hexane-water, dried, and resuspended in hexane. FA were measured using gas chromatography. 1-2 µL of sample was injected via autosampler onto an Agilent 6890N chromatograph (Agilent, Santa Clara, CA, USA) with a flame ionization detector, a 100 m x 0.25 mm x 0.2 µm SP-2560 column (Sigma-Aldrich, Bellefonte, PA, USA) and Chemstation software. C19:0 and other authentic methyl esters were used to create a calibration curve for FA quantification. The authentic methyl esters were also used to identify FA in samples based on retention times. The coefficients of variation for quantification of specific FA ranged between 2.5-3.6%.

**Statistical Analyses.** *Definition of exposures.* The main exposures were serum PUFA biomarkers measured at 1 y of age, expressed as percentage relative to the total FA concentration

(FA %) quantified in a sample. The n-3 PUFA we considered were ALA, eicosapentaenoic acid (20:5 n-3; EPA), docosapentaenoic acid (22:5 n-3; DPA), and docosahexaenoic acid (22:6 n-3; DHA). N-6 PUFA included LA, gamma-linolenic acid (18:3 n-6; GLA), dihomo-gamma-linolenic acid (20:3 n-6; DGLA), and arachidonic acid (20:4 n-6; AA). We also considered the ratio of total n-6:n-3 PUFA, which may be important for adiposity development.<sup>24</sup> Additionally, we considered activity indices of the  $\Delta$ 6-desaturase (D6D) and  $\Delta$ 5-desaturase (D5D) enzymes, using the GLA/LA and AA/DGLA ratios, respectively. We categorized all exposures into quartiles to allow for possible non-linear associations with the outcomes.

*Definition of outcomes.* The primary outcomes were change in age- and sex-adjusted body mass index (BMI) Z scores (BMIZ) between 1 and 16 y of age and DXA measures of body composition at 16 y of age. BMI was calculated as kg/m<sup>2</sup> and BMIZ were calculated according to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup> DXA measures included the total fat mass (ToFM), truncal fat mass (TrFM), total lean mass (TLM), percent total fat mass (%ToFM), and percent truncal fat mass (%TrFM).

*Covariates.* All covariates were measured in infancy and included sociodemographic and anthropometric characteristics as well as serum FA. We categorized birth length and weight as average or large for gestational age according to the INTERGROWTH 21<sup>st</sup> standards for newborn size.<sup>26</sup> We defined large for gestational age as  $\geq 90^{\text{th}}$  percentile. We did not consider a category of small for gestational age because birth weight  $\geq 3$  kg was an eligibility criterion for recruitment and there were no children  $\leq 10^{\text{th}}$  percentile for birth weight. Seven children with birth length  $\leq 10^{\text{th}}$  percentile were classified in the average for gestational age group. We categorized breastfeeding as <6 months,  $\geq 6$  months mixed bottle/breastfeeding, or  $\geq 6$  months exclusive breastfeeding. Iron supplementation was categorized as any (combining low- and high-

dose groups) vs. none. We measured socioeconomic status (SES) using a modified Graffar index.<sup>27</sup> The index consists of 13 items related to family structure, education and employment, crowding and housing condition, and ownership of assets. The index ranges from 0 to 65; higher values indicate lower SES. The serum FA that we considered as covariates were total *trans* FA, which have been associated with weight gain in adults.<sup>28</sup>

*Correlates of serum PUFA at 1 y of age.* We compared distributions of serum PUFA biomarkers by categories of covariates using means  $\pm$  SD. We tested the significance of associations using linear regression models with each PUFA biomarker as the outcome. For dichotomous covariates, we obtained P values from Wald tests. For ordinal variables, we tested for linear trends using Wald tests of a variable representing category-specific medians introduced as a continuous variable. For categorical covariates, we used a  $\chi^2$  score statistic. We specified robust estimates of variance in all models.

*Serum PUFA at 1 y of age and change in BMIZ from ages 1 to 16 y.* In bivariate analysis, we estimated means  $\pm$  SE of BMIZ at 1 and 16 y of age and change in BMIZ between 1 and 16 y by quartiles of the PUFA exposures at age 1 y. These were from BMIZ growth curves estimated using mixed effects linear regression models.<sup>29</sup> The outcome was BMIZ and age was represented as a predictor using restricted cubic splines.<sup>30</sup> These piecewise cubic polynomials are smoothly joined at each knot and linear in the tails. They allow for modeling of smoothed, non-linear trajectories of BMIZ across different ages. These methods do not require that all children have the same number of measurements or that the measurements be obtained at the same ages. Thus, we fitted the models with data from all assessments (1, 5, 10, and 16 y) and placed knots at the median ages of children measured at each assessment. Other predictors in the model included indicator variables for each PUFA quartile, interaction terms between the PUFA indicators and

all age terms, and random intercepts and age slopes for each child. We estimated adjusted mean differences and 95% confidence intervals (CI) in 1 to 16 y BMIZ change between quartiles of serum PUFA from these models. We included covariates that were associated with the PUFA biomarkers or that have been related to BMIZ change. The final model included sex, birth weight, breastfeeding, Graffar index, and total serum *trans* FA at 1 y of age. Each long-chain PUFA was adjusted for its immediate metabolic precursor: EPA was adjusted for ALA, DPA for EPA, DHA for DPA, GLA for LA, DGLA for GLA, and AA for DGLA. In order to adjust for potential confounding by common dietary sources of n-3 and n-6 PUFA, which co-occur as LA and ALA in foods such as plant oils,<sup>31</sup> we adjusted estimates for each n-3 PUFA for LA and total long-chain n-6 PUFA, while estimates for each n-6 PUFA were adjusted for ALA and total long-chain n-3 PUFA. All covariate FA were entered in the model as restricted cubic splines in order to account for possible residual confounding due to non-linear associations with the outcome. When the association between PUFA quartiles and BMIZ change seemed linear, we estimated the difference in change per 1 SD of the PUFA distribution.

*Serum PUFA at 1 y of age and body composition at 16 y.* In bivariate analysis, we compared distributions of ToFM, TrFM, TLM, %ToFM, and %TrFM by quartiles of serum PUFA using means  $\pm$  SD. We conducted tests for linear trend using linear regression models with each body composition measure as the outcome and a variable representing median values of each PUFA quartile introduced as a continuous variable. In multivariable analysis we obtained adjusted mean differences and 95% CI in the body composition measures by quartiles of serum PUFA. These models included indicators for PUFA quartiles and were also adjusted for sex, birth weight, breastfeeding, Graffar index, BMI at 1 y of age, and total serum *trans* FA. We also included other PUFA as covariates following the strategy described for the analyses of BMIZ

change. Because body composition may differ by sex in adolescence, we conducted supplemental analyses stratified by sex by including interaction terms between sex and all other model predictors and testing for their statistical significance.

We fitted all models with empirical variance estimates, which are robust to heteroskedasticity and deviations from normality.<sup>32</sup> All analyses were conducted using Statistical Analysis Software version 9.4 (SAS Institute, Cary, NC, USA).

## RESULTS

The number of children with 2, 3, or 4 measurements was 78, 183, and 375, respectively. Mean  $\pm$  SD BMIZ at 1, 5, 10, and 16 y of age was  $0.81 \pm 0.94$ ,  $0.98 \pm 1.18$ ,  $1.02 \pm 1.16$ , and  $0.71 \pm 1.13$ , respectively. At age 16 y, mean  $\pm$  SD ToFM, TrFM, and LM was  $19.8 \pm 10.1$ ,  $10.0 \pm 5.7$ , and  $44.0 \pm 8.9$  kg, respectively. Mean  $\pm$  SD %ToFM and %TrFM was  $29.1 \pm 10.9$  and  $49.3 \pm 5.9$ .

### N-3 PUFA

*Correlates of n-3 PUFA at 1 y.* Serum ALA was positively associated with iron supplementation (**Table S1**). EPA was positively related to exclusive breastfeeding duration and total *trans* FA. DPA was inversely associated with iron supplementation. DHA was related to female sex and exclusive breastfeeding duration, and inversely associated with total serum *trans* FA.

*BMIZ change between ages 1 and 16 y.* N-3 PUFA at 1 y of age were not significantly associated with BMIZ change from 1 to 16 y (**Table 1 and Table S2**).

*Body composition at age 16 y.* ALA was positively associated with TrFM and %TrFM in non-linear fashions (**Table 2 and Table S2**). Adjusted mean differences (95% CI) between children with ALA in quartile (Q) 4 vs. <Q4 were 1.5 kg (0.2, 2.8;  $P=0.03$ ) for TrFM and 3.3 percentage points (95% CI: 2.0%, 4.6%;  $P<0.0001$ ) for %TrFM. EPA was inversely associated with %TrFM (adjusted mean difference >Q1 vs. Q1: -2.1%; 95% CI: -3.5%, -0.9%;  $P=0.001$ ). DPA was positively associated with fat mass indices in non-linear manners. Adjusted mean differences (95% CI) between DPA >Q1 vs. Q1 for ToFM, TrFM, %ToFM, and %TrFM were, respectively, 2.7 kg (95% CI: 0.7, 4.8;  $P=0.01$ ), 1.6 kg (95% CI: 0.4, 2.8;  $P=0.009$ ), 2.3% (95% CI: 0.4, 4.2;  $P=0.02$ ), and 1.8% (95% CI: 0.3, 3.2;  $P=0.02$ ). Most associations did not differ by

sex (**Table S3 and Table S4**). However, the positive association of ALA with %TrFM was stronger among boys ( $P$ , interaction=0.02), as was the inverse association of EPA with %TrFM ( $P$ , interaction=0.004).

## **N-6 PUFA**

*Correlates of n-6 PUFA at 1 y.* LA was positively associated with exclusive breastfeeding  $\geq 6$  months and with iron supplementation (**Table S5**). It was inversely associated with total *trans* FA. Serum GLA was inversely related to length-for-gestational age and socioeconomic status. DGLA was positively associated with length- and weight-for-gestational age and inversely related to iron supplementation. AA was positively associated with length- and weight-for-gestational age, and exclusive breastfeeding  $\geq 6$  months, and inversely related to iron supplementation and total *trans* FA. The n-6:n-3 ratio was inversely associated with total *trans* FA. The D6D index was inversely associated with length-for-gestational age and socioeconomic status.

*BMIZ change between ages 1 and 16 y.* Neither n-6 PUFA, the n-6:n-3 ratio, nor desaturase indices at 1 y of age was significantly associated with change in BMIZ (**Table 3 and Table S6**).

*Body composition at 16 y of age.* Without adjustment for n-3 PUFA, GLA ( $P$ , trend=0.02) and the D6D index ( $P$ , trend=0.01) were each positively associated with %ToFM (**Table S6**). In fully adjusted models, GLA and the D6D index were each positively, linearly associated with ToFM, TrFM, and %ToFM (**Table 4**). Every 1 SD (0.36) difference in GLA was associated with an adjusted higher mean ToFM (1.0 kg per SD; 95% CI: 0.1, 1.9;  $P=0.03$ ), TrFM (0.6 kg per SD; 95% CI: 0.1, 1.1;  $P=0.03$ ), and %ToFM (1.0 percentage points per SD; 95% CI: 0.2%, 1.7%;  $P=0.01$ ). A 1 SD difference (0.02) in the D6D index was related to a higher mean

ToFM (1.2 kg per SD; 95% CI: 0.0, 2.3;  $P=0.04$ ), TrFM (0.7 kg per SD; 95% CI: 0.0, 1.4;  $P=0.05$ ), and %ToFM (1.1 percentage points per SD; 95% CI: 0.2%, 2.1%;  $P=0.02$ ). The D5D index was inversely associated with %TrFM. Children in the highest quartile had a mean %TrFM 1.9 percentage points lower than did children in the lowest quartile (95% CI: -3.8%, -0.1%;  $P=0.04$ ). A slight inverse association between DGLA and %TrFM was present only among girls ( $P$ , interaction=0.02); no other associations differed by sex (**Table S7 and Table S8**).

## DISCUSSION

In this longitudinal study of Chilean children, PUFA at 1 y of age were not associated with BMIZ changes through childhood and adolescence. Nevertheless, they were related to body composition at age 16 y. Serum ALA at 1 y of age was positively associated with TrFM and %TrFM at 16 y. EPA was inversely associated with %TrFM, while DPA was positively associated with ToFM, TrFM, %ToFM, and %TrFM. GLA and the D6D index were each positively associated with ToFM, TrFM, and %ToFM. The D5D index was inversely associated with %TrFM.

Serum ALA was positively associated with truncal fat. This is in contrast to a previous study in which maternal plasma ALA during pregnancy was inversely associated with the android/gynoid fat mass ratio and pre-peritoneal fat mass area in offspring at 6 y of age.<sup>33</sup> One potential explanation for this discrepancy is the difference in ages at which body composition was measured in the two studies. Body composition may not track completely between childhood and adolescence. Thus, the relation between early-life ALA and body composition at 6 y of age may be different than its relation with body composition at 16 y. Other possible explanations include the differences in timing of exposure assessment, measures of central adiposity, or ALA intake between the study populations. Four other studies of early-life ALA exposure and measures of adiposity have used BMI as an outcome, which does not distinguish between fat compartments. None of these found associations between ALA in cord blood<sup>34,35</sup> or breastmilk<sup>15,36</sup> with BMI during infancy or childhood, consistent with our finding of no association with BMI change. The mechanism underlying a potential effect of ALA on central adiposity is unclear. One possibility is that much of the serum ALA measured in these children could have been *trans* ALA. In areas where hydrogenated oils are present in the food supply,

*trans* ALA represents a large proportion of total dietary ALA.<sup>37</sup> Chile had not banned *trans* FA from its food supply at the time of FA measurement in this study.<sup>38</sup> Although few studies have investigated the health effects of *trans* ALA, other *trans* FA have been positively associated with central adiposity.<sup>39</sup> We did not measure *trans* isomers of ALA and could not differentiate its effects from those of *cis* ALA. The association could also be due to confounding by unmeasured aspects of diet.

We found that EPA was inversely associated with %TrFM. In a randomized trial, supplementation with EPA+DHA from birth to 6 months resulted in lower waist circumference at 5 y of age.<sup>40</sup> In another study, maternal plasma EPA during pregnancy was inversely associated with the android/gynoid fat mass ratio and pre-peritoneal fat mass area at 6 y.<sup>33</sup> Previous studies of EPA during pregnancy, in cord blood, or in breastmilk have not consistently found protective associations with measures of overall adiposity such as BMI and %ToFM.<sup>13</sup> However, our results and others suggest that EPA may be specifically protective against central adiposity, which is related to development of the metabolic syndrome<sup>41</sup> and cardiovascular disease.<sup>42</sup> Whether early-life EPA decreases risk of future chronic disease remains to be investigated.

DPA at age 1 y was positively associated with ToFM, TrFM, %ToFM, and %TrFM at 16 y. In a pooled analysis of two large cohorts, cord blood DPA was not associated with childhood BMI.<sup>43</sup> Maternal DPA during pregnancy was inversely associated with %ToFM and the android/gynoid fat mass ratio at 6 y in a Dutch study.<sup>33</sup> Compared with EPA, DPA is found at lower levels in the diet<sup>44</sup> and may be less bioavailable.<sup>45</sup> Thus, DPA in serum could more closely reflect endogenous activity of D6D than it does DPA intake. Associations between DPA and fat mass might reflect associations with D6D activity rather than an effect of DPA itself.

GLA was positively associated with ToFM, TrFM, and %ToFM. This is in agreement with an investigation that reported a positive association between maternal plasma GLA during pregnancy and %ToFM and pre-peritoneal fat mass area in offspring at age 6 y.<sup>33</sup> However, two other studies found no association between cord blood GLA and BMI or %ToFM in childhood.<sup>43,46</sup> A trial of formula supplemented with GLA+DHA until 9 months of age found no effect on BMI or %ToFM at age 10 y.<sup>47</sup> Differences among studies may be the result of differences in GLA levels between populations, or effect modification by desaturase gene variations.<sup>48</sup>

Estimated D6D enzyme activity was positively associated with ToFM, TrFM, and %ToFM, while the D5D index was inversely associated with %TrFM. Our results are consistent with two longitudinal studies conducted among children aged 2-10 y<sup>49</sup> and 10 y,<sup>50</sup> and evidence that cardiometabolic risk factors are positively related to D6D activity and inversely associated with D5D activity among adults.<sup>51</sup>

Although PUFA in infancy were related to body composition in adolescence, they were not associated with BMIZ trajectories. These results are unexpected since BMI and BMIZ correlate with fat mass throughout childhood. One possible explanation is that the differences in body composition at 16 y by PUFA concentrations may already have been present at 1 y. We tried to overcome this possibility by adjusting the analyses of body composition measures at age 16 y for BMI at 1 y, but BMI in infancy is an imperfect proxy for fat mass. Another possibility is that the outcomes measured by DXA are more precise measures of adiposity than BMIZ, which reflects both fat and lean mass, or that the effects of PUFA differ between body fat compartments, which are not separated by using BMIZ.

One of the primary strengths of this study is its longitudinal design, which limits the possibility of reverse causation. We had an opportunity to examine associations of early-life exposures with outcomes at older ages, which provides evidence for the relevance of PUFA status in infancy for long-term health. PUFA biomarkers are not subject to errors in recall or food composition tables, as opposed to dietary assessment data. Furthermore, we assessed body composition using DXA, which provides reliable and valid measures of fat and lean mass.<sup>52</sup>

One of the limitations of this study is that serum PUFA biomarkers reflect status over a period of weeks and may misclassify participants with respect to long-term intake.<sup>53</sup> Analyses of multiple exposures could have increased type I error. Body composition measures differ by sex in adolescence<sup>54</sup>; although interactions by sex were not statistically significant, effect modification by sex cannot be completely ruled out. The lack of available body composition measurements in infancy prevented us from analyzing change in these outcomes or adjusting for their baseline values. Adiposity at 1 y of age could have influenced serum PUFA levels at 1 y of age, and this reverse causation may have influenced the results related to BMIZ trajectories. However, we chose not to adjust for baseline BMIZ in these analyses because this adjustment can cause bias.<sup>55</sup> Measured baseline BMIZ is the result of both true baseline BMIZ and its measurement error, which in turn contributes to measured BMIZ change from baseline to 16 y, the outcome of interest. As a common effect of two variables (a “collider”), baseline BMIZ naturally blocks the flow of a non-causal statistical association between the exposure (PUFA) and the outcome. Adjusted for baseline BMIZ could unblock such a non-causal path and induce a spurious association between PUFA and BMIZ change from baseline to later ages. Finally, because we only had relative measures of serum PUFA expressed as a percentage of total FA, we were unable to determine the extent to which differences in PUFA FA percentage reflect

differences in absolute serum PUFA content or serum levels of saturated, monounsaturated, and *trans* FA.

In conclusion, serum ALA and DPA at 1 y of age were positively associated with measures of fat mass at age 16 y, whereas EPA was inversely associated with %TrFM. GLA and the D6D index were also positively associated with adiposity in adolescence, while D5D activity was inversely related to this outcome. PUFA status in infancy might affect long-term body composition and adiposity. Our results could be generalizable to other populations with similar dietary intake and behavior, which in this Chilean population have been characterized as low in fruits and vegetables, high in snack foods with saturated fat and refined carbohydrates, and low in physical activity levels.<sup>56</sup> Our results may also be applicable to populations undergoing a similar nutrition transition. In Chile, economic growth in the 1990s resulted in one of the most rapid transitions in Latin America, including a shift toward Western diets and sedentary lifestyles.<sup>57</sup> By the time of the 16 y follow-up in our study, the transition was advanced with a very low prevalence of stunting and high prevalence of obesity.<sup>58</sup> Intervention studies are warranted to elucidate the potential protective effect of EPA against the development of central adiposity in children and adolescents.

**CONFLICT OF INTEREST STATEMENT**

The authors report no conflicts of interest.

Author Manuscript

## ACKNOWLEDGMENTS

EV, SG, and BL designed the research. SG, BL, and AD conducted the research. KF performed the data analysis. KF and EV wrote the paper and had primary responsibility for the final content. All authors read and approved the final manuscript.

The study was funded by grants HL117860, HD033487, and HL088530 from the National Institutes of Health. Fatty acids were quantified using Core Services supported by grant DK097153 from the National Institutes of Health to the University of Michigan.

**Footnotes to Table 1**

- <sup>a</sup> According to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup>
- <sup>b</sup> From growth curves estimated using mixed effects linear regression models with BMIZ as the outcome, and predictors that included indicator variables for each PUFA quartile, linear and cubic spline terms for age, and interaction terms between the quartiles and age terms. All models included random intercepts and age slopes to account for within-child correlations of repeated BMI measurements.
- <sup>c</sup> Adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), and total serum trans fatty acids (FA). All n-3 PUFA are adjusted for LA and total long-chain n-6 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate FA are represented with linear and restricted cubic spline terms.
- <sup>d</sup> From mixed effects linear regression models with BMI as the outcome and a variable representing medians of PUFA quartiles introduced as continuous.

**Footnotes to Table 2**

- <sup>a</sup> Measured by dual-energy X-ray absorptiometry.
- <sup>b</sup> From linear regression models with a given body composition measure as the outcome and indicator variables for PUFA quartiles as predictors. In addition, all models were adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), BMI at 1 y (continuous), and total serum trans fatty acids. All n-3 PUFA are adjusted for LA and total long-chain n-6 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.
- <sup>c</sup> From linear regression models with a variable representing medians of PUFA quartiles introduced as continuous.

**Table 3. Changes in BMI-for-age Z scores (BMIZ)<sup>a</sup> from 1 to 16 years of age by serum n-6 polyunsaturated fatty acid biomarkers and desaturase activity indices at 1 year of age among children from Santiago, Chile**

Fatty acid quartile (median, weight % of total FA)	N	1 y BMIZ (mean ± SE) <sup>b</sup>	16 y BMIZ (mean ± SE)	Change in BMIZ 1 - 16 y (mean ± SE) <sup>b</sup>	Adjusted difference in change (95% CI) <sup>c</sup>

**Footnotes to Table 3**

- <sup>a</sup> According to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup>
- <sup>b</sup> From growth curves estimated using mixed effects linear regression models with BMI as the outcome, and predictors that included indicator variables for each PUFA quartile, linear and cubic spline terms for age, and interaction terms between the quartiles and age terms. All models included random intercepts and age slopes to account for within-child correlations of repeated BMI measurements.
- <sup>c</sup> Adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥ 6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), and total serum trans fatty acids. All n-6 PUFA are adjusted for ALA and total long-chain n-3 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.
- <sup>d</sup> From mixed effects linear regression models with BMI as the outcome and a variable representing medians of PUFA quartiles introduced as continuous.

## Footnotes to Table S2

- <sup>a</sup> Adjustment strategy is similar to main analyses, but without PUFA of the opposite family as covariates. In total, all models were adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), BMI at 1 y (continuous), and total serum trans fatty acids. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.
- <sup>b</sup> According to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup>
- <sup>c</sup> Measured by dual-energy X-ray absorptiometry.
- <sup>d</sup> Estimates are from growth curves created using mixed effects linear regression models with BMI as the outcome, and predictors that included indicator variables for each PUFA quartile, linear and cubic spline terms for age, and interaction terms between the quartiles and age terms. All models included random intercepts and age slopes to account for within-child correlations of repeated BMI measurements.
- <sup>e</sup> From linear regression models with a given body composition measure as the outcome and indicator variables for PUFA quartiles as predictors.
- <sup>f</sup> From linear regression models with a variable representing medians of PUFA quartiles introduced as a continuous predictor.

<sup>a</sup> Measured by dual-energy X-ray absorptiometry.

<sup>b</sup> From linear regression models with a given body composition measure as the outcome and indicator variables for PUFA quartiles as predictors. In addition, all models were adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), BMI at 1 y (continuous), and total serum trans fatty acids. All n-3 PUFA are adjusted for LA and total long-chain n-6 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.

<sup>c</sup> From linear regression models with a variable representing medians of PUFA quartiles introduced as a continuous predictor.

<sup>d</sup> From linear regression models with an indicator for male sex as a predictor and cross-product terms between the indicator and all other predictors in the model.

**Table S5. Cross-sectional unadjusted analyses of serum n-6 polyunsaturated fatty acid biomarkers<sup>a</sup> by categories of sociodemographic and other characteristics among infants from Santiago, Chile**

<sup>a</sup> Adjustment strategy is similar to main analyses, but without PUFA of the opposite family as covariates. In total, all models were adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), BMI at 1 y (continuous), and total serum trans fatty acids. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.

<sup>b</sup> According to the World Health Organization Growth Reference for children ages 5-19 y.<sup>25</sup>

<sup>c</sup> Measured by dual-energy X-ray absorptiometry.

<sup>d</sup> Estimates are from growth curves created using mixed effects linear regression models with BMI as the outcome, and predictors that included indicator variables for each PUFA quartile, linear and cubic spline terms for age, and interaction terms between the quartiles and age terms. All models included random intercepts and age slopes to account for within-child correlations of repeated BMI measurements.

<sup>e</sup> From linear regression models with a given body composition measure as the outcome and indicator variables for PUFA quartiles as predictors.

<sup>f</sup> From linear regression models with a variable representing medians of PUFA quartiles introduced as a continuous predictor.

**Table S7. Body mass measured in kg<sup>a</sup> at 16 y by serum n-6 polyunsaturated fatty acid biomarkers at 1 years of age among children from Santiago, Chile, stratified by sex**

**Footnotes to Table S7**

<sup>a</sup> Measured by dual-energy X-ray absorptiometry.

<sup>b</sup> From linear regression models with a given body composition measure as the outcome and indicator variables for PUFA quartiles as predictors. In addition, all models were adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), BMI at 1 y (continuous), and total serum trans fatty acids. All n-6 PUFA are adjusted for ALA and total long-chain n-3 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.

<sup>c</sup> From linear regression models with a variable representing medians of PUFA quartiles introduced as a continuous predictor.

<sup>d</sup> From linear regression models with an indicator for male sex as a predictor and cross-product terms between the indicator and all other predictors in the model.

**Table S8. Percent total and truncal fat<sup>a</sup> at 16 y by serum n-6 polyunsaturated fatty acid biomarkers at 1 years of age among children from Santiago, Chile, stratified by sex**

Fatty acid quartile (median, girls/boys, weight % of total FA)	% Total fat						% Truncal fat			
	Mean ± SD		Adjusted mean difference (95% CI) <sup>b</sup>		Mean ± SD		Adjusted mean difference (95% CI)

**Footnotes to Table S8**

<sup>a</sup> Measured by dual-energy X-ray absorptiometry.

<sup>b</sup> From linear regression models with a given body composition measure as the outcome and indicator variables for PUFA quartiles as predictors. In addition, all models were adjusted for sex, birth weight (large vs. average for gestational age), breastfeeding (<6 mo, ≥6 mo w/ bottle feeding, ≥6 mo exclusive), Graffar index (indicator variables for quintiles), BMI at 1 y (continuous), and total serum trans fatty acids. All n-6 PUFA are adjusted for ALA and total long-chain n-3 PUFA. All long chain PUFA are adjusted for their precursor PUFA. Covariate fatty acids are represented with linear and restricted cubic spline terms.

<sup>c</sup> From linear regression models with a variable representing medians of PUFA quartiles introduced as a continuous predictor.

<sup>d</sup> From linear regression models with an indicator for male sex as a predictor and cross-product terms between the indicator and all other predictors in the model.
