1 **Abstract**

2 **Background and Aims:** Binge eating disorder (BED) is correlated with substance use. This
3 study aimed to estimate the lifetime prevalence of alcohol use disorder (AUD) among
4 individuals with non-compensatory binge eating and determine whether their lifetime
5 prevalence of AUD is higher than in non-bingeing controls.

6 **Design:** A systematic search of databases (PubMed, Embase, and Web of Science) for
7 studies of adults diagnosed with BED or a related behavior that also reported the lifetime
8 prevalence of AUD was conducted. The PRISMA protocol was followed. The protocol was
9 registered on PROSPERO.

10 **Setting:** Studies originating in Canada, Sweden, the United Kingdom, and the United States.

11 **Participants:** 18 studies meeting the inclusion criteria were found, representing 69,233
12 individuals.

13 **Measurements:** Lifetime prevalence of AUD among individuals with binge eating disorder
14 and their lifetime relative risk of AUD compared with individuals without this disorder.

15 **Findings:** The pooled lifetime prevalence of AUD in individuals with binge eating disorder
16 was 19.9% (95% CI 13.7-27.9). The risk of lifetime AUD incidence among individuals with
17 binge eating disorder was over 1.5 times higher than controls (RR 1.59, 95% CI 1.41-1.79).
18 Lifetime AUD prevalence was higher in community samples than in clinical samples (27.45%
19 vs. 14.45%, $p = 0.041$) and in studies with a lower proportion of women ($\beta = -2.27$, $p =$
20 0.044).

21 **Conclusions:** Lifetime alcohol use disorder appears to be more prevalent with binge eating
22 disorder than among those without.

23
24 **Keywords:** Binge eating disorder, alcohol use disorder, alcohol abuse, alcohol dependence,
25 meta-analysis, systematic review

Introduction

Binge eating disorder (BED) was introduced into the 5th edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM) in 2013(1). It is characterized by recurrent (≥ 1 per week for 3 months), periodic, and uncontrolled episodes of consuming large quantities of food, which are accompanied by psychological and social distress. In contrast with bulimia nervosa, the episodes are not followed by inappropriate compensatory behaviors. According to epidemiological studies, it is the most common eating disorder in the world(2), with a lifetime prevalence of 2.6% in the United States and a 3:2 female to male ratio(3).

Binge eating (uncontrolled episodes of consuming large quantities of food) was recognized as a clinical condition as early as 1959(4). Since then, clinical evidence suggested the existence of individuals with marked distress over binge eating that could not be diagnosed with bulimia nervosa because they did not engage in compensatory behaviors(5). Such individuals were referred to as “obese binge eaters” or “nonpurging bulimia nervosa patients”(5,6). BED first appeared as a diagnostic entity in 1994 in an appendix to the 4th edition of the DSM; it was a provisional diagnosis that required further research(7). Even after its establishment as a distinct diagnosis, BED remained a heterogeneous and complex disorder(8). Moreover, in addition to BED, the DSM-5 now recognizes a lower-threshold form of BED(1); research suggests that subthreshold BED does not differ significantly from full-syndrome BED regarding outcomes such as body weight, eating disorder symptoms, and associated psychiatric symptoms(9). Thus, BED may be regarded as existing on a spectrum of non-compensatory binge-eating(10).

Emotional dysregulation has been noted as a predictor of binge eating(11) and is regarded as an etiological factor of BED(12). In addition to established theories of addiction, such as the opponent process theory(13) or incentive sensitization theory(14), research also supports the role of emotion dysregulation in the development of alcohol use disorder (AUD)(15,16). Inefficient utilization of emotion regulation strategies may increase arousal, negative affect, and craving, thus fueling a vicious cycle of dependence(17). Both binge

1 eating and AUD may represent a maladaptive way of coping with intolerable affective
2 states(18) and the development of one disorder may be linked with the development of the
3 other(19). Studies confirm higher rates of lifetime AUD among individuals with BED(20) and
4 binge eating behavior not meeting the DSM criteria(21) compared with non-bingeing
5 controls.

6 Aside from deficits in emotion regulation, neuroimaging studies conducted on
7 individuals with BED showed impairment in impulse-control-related areas (e.g.,
8 ventromedial-prefrontal, inferior-frontal, and insular cortex)(22); similar changes were found
9 among individuals with AUD(23). Lee and colleagues(24) observed that individuals with BED
10 showed stronger activation of the ventral striatum in response to food pictures than healthy
11 controls in a cue-reactivity paradigm. These changes might indicate specific changes in
12 reward response and difficulties with decision-making and motivation(25). The same
13 mechanisms contribute to the development of AUD(26).

14 There have been a few meta-analyses conducted on substance use among patients
15 with various eating disorders(20,27,28). One previous meta-analysis investigated the co-
16 occurrence of binge eating and AUD(20); however, the association was not the main focus
17 of the article as it reported only one effect size. Prior meta-analyses have several
18 methodological limitations, such as not conforming to reporting guidelines, not pre-
19 registering their protocols, or including only a small number of studies with data on
20 participants who binge eat. Thus, the extent of comorbidity between binge eating and AUD
21 remains unclear as there is a lack of systematic empirical support on this topic. Patients with
22 co-occurring AUD and binge eating behavior also pose unique challenges for diagnosis and
23 treatment, including differential diagnosis and greater symptom severity(29). Broader
24 awareness regarding the link between AUD and binge eating behavior could be informative
25 of the importance of assessing past or current alcohol use and related psychopathology, as
26 well as treating co-occurring psychopathology.

27 In order to address the current gap in the literature, a systematic review and meta-
28 analysis was performed on data pertaining to the lifetime prevalence of AUD in studies

1 investigating BED and related disorders. The primary aim of this systematic review and
2 meta-analysis was to assess the lifetime prevalence of AUD among individuals who binge
3 eat. The secondary aim of this study was to determine if the lifetime prevalence of AUD
4 among individuals who binge eat is higher than in non-bingeing controls.

5 6 **Materials and Methods**

7 This systematic review and meta-analysis was registered with PROSPERO
8 (CRD42019140622) and conducted using an a priori protocol. It was carried out in
9 accordance with the guidelines for Meta-analysis of Observational Studies in Epidemiology
10 (MOOSE)(30) and the Preferred Reporting Items for Systematic Reviews and Meta-
11 Analyses (PRISMA)(31).

12 13 ***Search strategy***

14 The search strategy was developed by two researchers with experience in eating
15 disorders and substance use (MK, AJ). Three electronic databases (PubMed, Embase, and
16 Web of Science) were searched for articles published from January 1, 1966 until June 1,
17 2019 for adequate and efficient coverage(32). Additionally, per prior recommendations(32),
18 the first 200 relevant references from Google Scholar were screened using a shortened
19 search strategy. There were no restrictions on language or geographic location. The search
20 was limited to studies performed in humans. The following search terms were used: "binge
21 eating", "binge eating disorder", "alcohol", "alcoholism", "alcohol use", "alcohol use disorder",
22 "alcohol consumption", "alcohol abuse", "alcohol drinking", "substance abuse", "substance
23 use", "correlate", "co-occurrence", and "association." Medical Subject Headings and
24 "explode" commands were used. The complete search strategy is provided in Supporting
25 information, Table S1. Reference lists of all relevant articles were screened to identify any
26 studies missed in the initial search. References were managed using Mendeley Desktop
27 1.19.4.

1 Study selection

2 Two reviewers (KB, MK) independently screened titles and abstracts. Criteria were
3 broad to include all potentially relevant studies. Studies had to report on associated
4 psychopathology in adult patients with disordered eating for full text review. Articles that
5 focused on binge eating comorbidity in a subgroup of patients with another specific mental
6 disorder (e.g., major depressive disorder, bipolar disorder) were excluded as their inclusion
7 could bias the outcome. References that consisted only of abstracts, case reports, or case
8 series were also excluded. Titles and abstracts in languages other than English, such as
9 German, French or Spanish, were either translated or available in English online.

10 Next, full text of any study selected by either reviewer was obtained. Articles were
11 eligible if they: (1) consisted of original research; (2) were epidemiological, case-controlled or
12 longitudinal studies; (3) included individuals diagnosed with BED using DSM-IV or DSM-5
13 criteria; (4) included individuals diagnosed with subthreshold BED or binge eating behavior
14 (BEB) using other defined criteria (e.g. Composite International Diagnostic Interview,
15 Questionnaire on Eating and Weight Patterns-Revised), or those meeting partial DSM
16 criteria; and (5) reported the lifetime prevalence of AUD among those individuals. Articles
17 were excluded if they: (1) were performed using an underage (<18 years old) sample; (2)
18 used a sample that was chosen using selective sampling (i.e., subjective criteria or personal
19 judgement); (3) measured BED comorbidity only in a subgroup of individuals with a specific
20 mental disorder; or (4) did not include a description of the criteria used for establishing an
21 AUD diagnosis.

23 Data extraction and quality assessment

24 Data extraction was performed by two reviewers (KB, AJ) according to a predefined
25 coding protocol (Table S2). Disagreement was resolved by discussion. The following data
26 were recorded in a Google Sheets spreadsheet: bibliographic data, design details, sample
27 characteristics, and measures of outcomes. If a study reported more than one outcome,

1 each was recorded as a separate group. If necessary, one reviewer (KB) contacted the
2 corresponding author to ask for additional data.

3 Two reviewers (KB, AJ) independently assessed the methodological quality of the
4 articles using a modified version of the Newcastle-Ottawa Scale, a scale used to evaluate
5 the quality of non-randomized studies(Fig. S1)(33). It includes seven items grouped in three
6 categories: selection, comparability, and outcome. The scale is scored from zero to eight
7 stars. Studies were identified as having an overall low risk of bias (≥ 6 stars) or a high risk of
8 bias (< 6 stars).

9 10 ***Data synthesis and analysis***

11 The primary outcome measure was the prevalence of lifetime AUD among individuals
12 engaging in binge eating. The secondary outcome measure was the relative risk (RR) of
13 AUD among patients engaging in binge eating compared to a non-bingeing control group. To
14 avoid excluding individuals diagnosed prior to the publication of the DSM diagnostic criteria
15 for BED, we decided to include studies on individuals who engaged in all non-compensatory
16 binge eating, with a later sub-analysis of individuals diagnosed according to DSM-IV and
17 DSM-5. For studies using DSM-III and DSM-IV diagnostic criteria, the number of individuals
18 with alcohol abuse and alcohol dependence was summed to represent the number of
19 individuals with AUD. In this way, older diagnoses are comparable with the DSM-5 AUD
20 diagnosis with substantial to almost perfect agreement(34).

21 To perform the meta-analyses, we used the “meta” and “metafor” packages(35)
22 within the R software environment, version 3.6.0(36). Meta-analyses of prevalence produce
23 the weighted average proportion, which is an average of the results of multiple studies
24 weighted by the inverse of their sampling variances(37). As design parameters and sample
25 characteristics would likely vary, a random-effects model was chosen(38). The proportions
26 among included studies could be less than 0.2 or greater than 0.8, therefore we used the
27 logit transformation, which handles small samples and extreme proportions more precisely
28 than the direct proportions method(39).

1 We used the DerSimonian-Laird method to estimate between-study variance as it is
2 better equipped to handle non-normally distributed study effects than the Restricted
3 Maximum Likelihood(40). The between-study variance was measured via the tau-squared
4 statistic and the presence of heterogeneity was identified by using the Q-test. Heterogeneity
5 can be described as genuine differences underlying the results of the studies; meta-analyses
6 are less generalizable with increased heterogeneity among included studies(41).
7 Heterogeneity was quantified via the I-squared statistic, which estimates the amount of the
8 observed heterogeneity that constitutes the true variation between studies rather than
9 chance. The Cochrane Handbook proposes a classification where I-squared of 30% to 60%
10 indicates moderate heterogeneity, 50% to 90% indicates substantial heterogeneity, and I-
11 squared greater than 75% indicates considerable heterogeneity(42).

12 We performed subgroup analyses investigating the difference in the outcome
13 measures between studies conducted in community settings (individuals from a given area
14 regardless of treatment status) vs. clinical settings (individuals treated for BED at a hospital
15 or clinic); studies assessing the AUD diagnosis using different DSM versions; and between
16 studies with low and high risk of bias. To help explain residual heterogeneity and to assess
17 the potential effect of factors on the outcome, we ran meta-regression analyses for the
18 proportion of females and publication year. The R-squared statistic was assessed, regarding
19 the amount of true heterogeneity that could be explained by tested moderators.

20 We evaluated the sensitivity of our analyses by comparing fitted models with and
21 without samples that we assumed to be influential outliers and by excluding samples without
22 a confirmed BED diagnosis. Influential outliers were identified using the “influence” function.
23 Publication bias and small study effects were assessed with the “funnel” function, which
24 funnel plots for the visual detection of asymmetries. In addition, the Egger test for the
25 detection of asymmetry in the funnel plot was performed; we considered analyses to be
26 statistically significant if the p -value was <0.10 (43). For other outcomes, the p -value <0.05
27 was considered statistically significant.

28

Results

Literature search

We identified 6469 entries through database searches. After removing duplicates, we screened a total of 4044 unique records and excluded 3867 that were determined to not be relevant (Fig. 1). Next, the full text of 177 articles was reviewed. Of these, 18 studies describing 69,233 individuals met the inclusion criteria(21,29,52–59,44–51). Ten of those studies included a comparison group(21,48–50,52–55,57,59). Two studies(21,47) included two samples each, which were recorded as separate groups for the meta-analyses. The most relevant characteristics of included studies are summarized in Table 1 (e.g., country of origin, DSM version, sample type).

Lifetime prevalence of AUD among binge eating individuals

A total of 20 samples including data from 69,233 participants reported lifetime prevalence of AUD among individuals who binge eat. Their findings are summarized in Fig. 1.

The overall pooled lifetime prevalence of AUD was 19.9% (95% CI 13.7-27.9, p -value = <0.0001). There was considerable heterogeneity present (I-squared = 96.6%; Q-test p -value = <0.0001).

Relative risk of lifetime AUD between binge eating individuals and non-bingeing controls

A total of 11 samples, including data from 67,652 participants, reported lifetime prevalence of AUD among individuals who binge eat compared with a non-bingeing control group. The results are presented in Fig. 2.

Results indicate that the incidence of lifetime AUD among individuals engaging in binge eating was over 1.5 times higher in comparison to non-bingeing controls (RR 1.59, 95% CI 1.41-1.79). The heterogeneity was not statistically significant (I-squared = 26.4%; Q-test p -value = 0.19).

26
27**Sensitivity analysis, moderator analysis, and sources of heterogeneity***Prevalence*

There was a significant amount of heterogeneity among the included studies reporting prevalence: the I-squared statistic was 96.6% (95% CI 93.5-98.2); the Q-test p -value was <0.0001 and τ -squared was equal to 0.970 (95% CI 0.483-1.891). Sensitivity analysis did not reveal any significant outliers and excluding samples without a BED diagnosis did not influence the result (19.6%, 95% CI 13.0-28.5).

The results of subgroup analyses are detailed in Table 2. Among subgroups tested, only one significant effect was found. Namely, findings indicate that AUD prevalence is higher among studies performed in a community setting compared to a clinical setting (27.45% vs. 14.45%, p -value = 0.0412; Fig. S2). The amount of heterogeneity explained by this difference was 27.21% (the R-squared statistic).

The slope (β), 95% CIs, and p -values for meta-regression models investigating the proportion of women and publication year are detailed in Table 4. A significant effect was found whereby the prevalence of AUD was lower in studies with a larger proportion of women ($\beta = -2.2773$, p -value = 0.0441; Fig. S4). This moderator explained 14.56% of the heterogeneity. Publication year did not significantly influence the results.

Relative risk

Statistically significant heterogeneity was not detected among studies reporting the relative risk of AUD between binge eating individuals and non-bingeing controls; the I-squared statistic was 26.4% (95% CI=0.00-74.9), the Q-test p -value was 0.19, and τ -squared was equal to 0.009 (95% CI=0.00-0.072). Sensitivity analyses revealed two influential outliers. However, removing them from the analysis did not affect the final outcome (RR 1.59, 95% CI 1.41-1.79 vs RR 1.57, 95% CI 1.35-1.83). Moreover, excluding samples without a BED diagnosis did not influence the result (1.61, 95% CI 1.42-1.82).

1 The results of subgroup analyses are detailed in Table 3. Among subgroups, only
2 one difference was found. Namely, the rate of AUD among individuals who engaged in binge
3 eating did not differ significantly from non-bingeing controls in studies that used the DSM-III
4 diagnostic criteria. The amount of heterogeneity explained by this difference was 100%.

5 The slope (β), 95% CIs, and p -values for meta-regression models are detailed in
6 Table 4. The two meta-regressions indicated that neither gender nor publication year were
7 statistically significant.

8 9 **Assessment of quality**

10 Among all studies, 16 achieved scores of at least 6 stars, indicating low risk of bias
11 (Table S3.). Four studies failed to reach this threshold and were judged to be at high risk of
12 bias(48,50,52,54). They were the only studies with a high risk of bias among those reporting
13 relative risk.

14 Excluding studies with a high risk of bias from the analysis did not significantly
15 influence the results. Namely, the result for prevalence was 22.38% (95% CI 14.95–32.11)
16 and 1.57 (95% CI 1.34–1.83) for relative risk.

17 The item with the largest amount of bias was the assessment of participants that
18 dropped out of the study. Only six studies included any information regarding participants
19 who dropped out of the study early.

20 21 **Publication bias**

22 The number of studies included was sufficient to perform publication bias testing(60).
23 Among studies reporting prevalence, as well as in studies reporting relative risk, there did
24 not appear to be publication bias upon visual inspection of the funnel plot. There was no
25 evidence of small study effects in either group as indicated by the Egger regression test (Fig.
26 S5, S6); tests for funnel plot asymmetry were not significant (p -values = 0.335 and 0.806,
27 respectively). Based on these results, the risk of publication bias in this study was
28 determined to be low.

Discussion

This study investigated the lifetime prevalence of AUD among individuals who binge eat and their relative risk of lifetime AUD compared to non-bingeing controls. There are two main findings. First, the overall lifetime prevalence of AUD among individuals who binge eat is 19.9% or just under one in five patients (Fig. 2). Second, individuals who binge eat are over 1.5 times more likely to be diagnosed with AUD in their lifetime when compared to non-bingeing controls (Fig. 3). These results are consistent with previous reports and extend prior findings. For example, a previous meta-analysis by Gadalla and colleagues (20) used a technique where the effect size in each study was compared to the variability observed in that study; it reported the outcome as a standardized mean difference (SMD). Although it was not its main focus, it included five studies on individuals with BED and found that this disorder was moderately positively associated with AUD (SMD = 0.39).

There are a number of explanations for this outcome. Both food and alcohol activate the reward systems (61), which may reflect a common neurobiological mechanism underlying both AUD and BED. In general, both food and alcohol may be used by individuals seeking relief and/or craving reward, which are thought to be important mechanisms involved in excessive substance consumption(26). Individuals who act impulsively when experiencing negative emotional states were shown to be more likely to develop addictive eating patterns(62) and at greater risk for other addictive behaviors, including AUD(63). Additionally, increased negative urgency and impulsivity have been demonstrated in both BED(64) and AUD(65).

Sources of variation

Differences in effects of continuous moderators and between subgroups were present among studies reporting prevalence rates. A diagnosis of AUD was more common in studies with a higher proportion of men; in studies which only included women, the prevalence of AUD was nearly two times lower in comparison to studies where men

1 accounted for half of the sample. This is consistent with reported biological sex ratios of
2 alcohol abuse and alcohol dependence in the general population, where these disorders are
3 twice as common in men than in women(66,67). AUD prevalence was also two times higher
4 in community samples as opposed to samples from a clinical setting. This difference may
5 exist for a number of reasons. Despite being the most common eating disorder, BED is still
6 underdiagnosed and many patients may go untreated(68,69); half of those who were being
7 treated learned about their disorder on their own(70). Thus, the treated population may
8 represent the group most motivated to seek help. There are a number of barriers to AUD
9 treatment as well, especially among people with a serious comorbidity(71); the difference
10 between the general population and those in treatment may represent a selection bias.
11 Additionally, in a study comparing individuals diagnosed with BED and those meeting the
12 DSM-5 BED diagnostic criteria, but who were previously undiagnosed(70), it was found that
13 the diagnosed group had a higher socioeconomic status, a trait linked to reduced risk of
14 alcohol-attributable harms(72).

15 In studies reporting relative risk of AUD, the rate of AUD among individuals who
16 engaged in binge eating did not differ significantly from a comparison group in studies using
17 DSM-III diagnostic criteria. Even though the three studies using DSM-III criteria had an
18 earlier year of publication, publication year was not found to influence either prevalence or
19 relative risk of diagnosis. This result may simply stem from a small number of participants
20 included in this subgroup (283 vs 30,372 in DSM-IV, and 36,027 in DSM-5) and resulting
21 insufficient statistical power(73), or it may represent discrepancies between versions of the
22 DSM(74).

23 Not all individuals who binge eat meet full DSM-IV or DSM-5 criteria for BED. For
24 example, they may present with binge eating behavior (i.e., consume amounts of food larger
25 than what most people would eat in a similar period), but without a sense of lack of control,
26 or engage in binge eating less often than once a week. Studies on individuals who did not
27 meet DSM criteria for BED, but engaged in non-compensatory binge eating behavior, were
28 included. There were three samples included in this analysis which did not meet DSM

1 criteria; excluding them did not significantly influence either prevalence or relative risk
2 results.

3

4 ***Strengths and limitations***

5 This study's strengths include a strict and comprehensive analytic approach using an
6 a priori protocol, which was pre-registered with PROSPERO and conducted in accordance
7 with PRISMA and MOOSE guidelines. Pre-registration helps minimize bias by outlining
8 analyses a priori and compels the researchers to formulate a study rationale for a specific
9 research question(75). We did not exclude studies based on their geographic location or
10 language to make the results more generalizable. Data extraction and quality assessment
11 were performed using predefined protocols across two independent researchers to further
12 reduce possible bias resulting from arbitrary decision-making. The overall quality of included
13 studies was high and there was no evidence of publication bias.

14 This study has several limitations. First, despite intentionally employing broad search
15 criteria and comprehensive methods, some eligible studies may not have been identified.
16 Second, all included studies came from developed countries, mainly from the US, so their
17 pooled findings may not be applicable to other populations. Third, because the included
18 studies spanned across 25 years, there are marked differences in how AUD was classified in
19 different versions of the DSM. This may result in variability among studies using different
20 criteria. On the other hand, publication year was not found to be a significant moderator;
21 studies have also found that there is substantial to almost perfect agreement between DSM-
22 5 classifications of AUDs and those based on the DSM-IV and DSM-III(34).

23 Fourth, among studies reporting prevalence rates, there was considerable between-
24 study heterogeneity, suggesting either significant differences in study design, study
25 population, or the presence of moderating factors. Reasons behind this variability were
26 explored in a subgroup analysis and meta-regression. There were no outliers that could
27 singularly influence the amount of heterogeneity. Additional moderator analyses revealed
28 that setting and proportion of women were likely moderators; however, these factors could

1 only explain less than half of this heterogeneity. Despite our efforts to only include similar
2 studies by setting eligibility and exclusion criteria, there were considerable discrepancies
3 both in their design and the populations examined.

4 Lastly, the results of this study are limited by the quality of included studies and their
5 methodology. Three samples included less than 100 participants and half of all included
6 studies reported data on less than 500 participants. Moreover, only ten studies, specified the
7 race and/or ethnicity of study participants. Therefore, it is unclear whether these findings are
8 generalizable to diverse populations. In conjunction with a relatively low prevalence of
9 disorders analyzed here, this may indicate that some studies were statistically
10 underpowered.

11 12 **Conclusions**

13 To our knowledge this is the first systematic review and meta-analysis to investigate
14 the lifetime prevalence of AUD among individuals who binge eat. Findings indicate that
15 lifetime AUD is commonly comorbid with binge eating, as one in five individuals who binge
16 eat also meet AUD criteria. When compared with non-bingeing controls, individuals who
17 binge eat are 1.5 times more likely to have a lifetime diagnosis of AUD. AUD's prevalence is
18 higher among men than women and in community samples compared to clinical samples.
19 The relative risk in the incidence of AUD did not significantly differ between individuals who
20 binge eat and controls in studies using DSM-III to derive AUD criteria.

21 In general, our findings indicate that specialists should consider assessing for past or
22 current presence of alcohol use and associated psychopathology among clients who present
23 with binge eating. Future research is warranted that employs similar analyses with studies
24 that include larger sample sizes, represent demographically diverse individuals, focus on the
25 new DSM-5 criteria, investigate the impact of setting, and explore the link between BED and
26 AUD among males. Longitudinal studies investigating whether BED influences the
27 development of AUD or vice versa are also needed.

Table Legend

Table 1. Characteristics of included studies. CLIN – Clinical; COMM – Community; NA – not applicable; NR – not reported.

Table 2. Subgroup analysis of categorical moderators for samples describing prevalence. CI – confidence interval; NA – not applicable; Own criteria – AUD criteria used by study authors that did not use the DSM (e.g. Alcohol Use Disorders Identification Test).

Table 3. Subgroup analysis of categorical moderators for samples describing relative risk. CI – confidence interval; NA – not applicable; Own criteria – AUD criteria used by study authors that did not use the DSM (e.g. Alcohol Use Disorders Identification Test).

Table 4. Meta-regression of continuous moderators. CI – confidence interval; NA – not applicable.

1 Table 2. Prevalence subgroup analysis

2

Moderator	Prevalence [%]	95% CI [%]	I-squared statistic	Test of moderator's p -value	R-squared statistic
Sample characteristics				0.0412	27.21%
Community setting	27.45	17.8, 39.81	91%		
Clinical setting	14.45	8.98, 22.42	97%		
AUD criteria				0.3763	9.30%
Own criteria	12.29	2.12, 47.5	NA		
DSM-III	14.9	4.97, 36.96	0%		
DSM-IV	19.77	13.13, 28.67	97%		
DSM-5	51.89	14.48, 87.29	NA		
Study quality				0.1487	5.46%
Low risk of bias	22.39	15.11, 31.86	97%		
High risk of bias	11.13	4.30, 25.86	61%		

3

1 Table 3. Relative risk subgroup analysis

Moderator	Relative risk	95% CI	I-squared statistic	Test of moderator's <i>p</i> -value	R-squared statistic
Sample characteristics				0.2499	55.83%
Community setting	1.68	1.46, 1.93	13.3%		
Clinical setting	1.49	1.28, 1.73	6.0%		
AUD criteria				0.0331	100.00%
Own criteria	1.84	1.33, 2.56	0%		
DSM-III	1.31	0.71, 2.42	0%		
DSM-IV	1.43	1.27, 1.62	0%		
DSM-5	1.81	1.62, 2.01	0%		
Study quality				0.7668	0.00%
Low risk of bias	1.68	1.46, 1.93	13.3%		
High risk of bias	1.49	1.41, 1.73	6.0%		

2

1 Table 4. Meta-regression

Prevalence				
Moderator	Slope (β)	95% CI	Test of moderators p -value	R-squared statistic
Proportion of women	-2.2773	-4.4940, -0.0607	0.0441	14.56%
Publication year	0.0075	-0.0570, 0.0719	0.8207	0.00%
Relative Risk				
Moderator	Slope (β)	95% CI	Test of moderators p -value	R-squared statistic
Proportion of women	0.2075	-0.5892, 1.0042	0.6098	0.00%
Publication year	0.0097	-0.0088, 0.0281	0.3039	20.68%
