Key Points:

- We calculate the full self-attraction and loading (SAL) term inline, in a barotropic configuration of MPAS-Ocean.
- Inclusion of the inline SAL and higher resolution meshes yield improved tidal accuracy in stand-alone barotropic MPAS-Ocean configurations.
- A 45-km to 5-km variable-resolution mesh provides reduced tidal errors with better computational performance than a quasi-uniform 8-km mesh.

Abstract

We examine ocean tides in the barotropic version of the Model for Prediction Across Scales (MPAS-Ocean), the ocean component of the Department of Energy Earth system model. We focus on four factors that affect tidal accuracy: self-attraction and loading (SAL), model resolution, details of the underlying bathymetry, and parameterized topographic wave drag. The SAL term accounts for the tidal loading of Earth’s crust and the self-gravitation of the ocean and the load-deformed Earth. A common method for calculating SAL is to decompose mass anomalies into their spherical harmonic constituents. Here, we compare a scalar SAL approximation versus an inline SAL using a fast spherical harmonic transform package. Wave drag accounts for energy lost by breaking internal tides that are produced by barotropic tidal flow over topographic features. We compare a series of successively finer quasi-uniform resolution meshes (62.9 km, 31.5 km, 15.7 km, and 7.87 km) to a variable resolution (45 to 5 km) configuration. We ran MPAS-Ocean in a single-layer barotropic mode forced by five tidal constituents. The 45 to 5 km variable resolution mesh obtained the best total root-mean-square error (5.4 cm) for the deep ocean (>1000m) M_2 tide compared to TPXO8 and ran twice as fast as the quasi-uniform 8 km mesh, which had an error of 5.8 cm. This error is comparable to those found in other forward (non-assimilative) ocean tide models. In future work, we plan to use MPAS-Ocean to study tidal interactions with other Earth system components, and the tidal response to climate change.

Plain Language Summary

Over the next century, climate change impacts on coastal regions will include floods, droughts, erosion, and severe weather events. The Department of Energy (DoE) is funding the Integrated Coastal Modeling Project to understand these potential risks better. In this paper, we implement tides in the DoE ocean model. Tides themselves respond to climate change, altering coastal flooding risk assessments. We explore the sensitivity of tides to model resolution (the spacing of model gridpoints), ocean-floor topography, and the so-called “self-attraction and loading” (SAL) effect. Self-attraction and loading occurs as the mass of water in a location fluctuates, causing a deformation of the Earth’s crust and changes in the gravitational potential, which must be accounted for when modeling tides. We present a computationally efficient method of calculating the SAL effects and show that it is more accurate than other commonly used approximations. In future work we will examine interactions of tides with other components of the climate system, including sea ice, floating ice shelves, rivers, and current systems.

1 Introduction

Tides are an integral and dynamic component of the Earth system. According to the IPCC Special Report for Oceans and Cryosphere in a Changing Climate, “it is *very likely* that the majority of coastal regions will experience statistically significant changes in tidal amplitudes over the course of the 21st century” (Bindoff et al., 2019). Additionally, the report concluded with “*high confidence*” that tides are one of several local processes essential to predicting future extreme sea level events (Oppenheimer et al., 2019). Coastal tide gauge records point to changes in tidal amplitudes by as much as 1–2% per decade (Flick et al., 2003; Ray, 2006; Müller et al., 2011). In some locations, the secular changes in tidal amplitudes are of comparable magnitude to changes in mean sea level (Jay, 2009). There are a number of processes that affect observed tides in a particular region, from long-term Earth system processes (such as tectonic motion) to shorter-term processes which could have impacts over the next century (Haigh et al., 2020). For example, mean sea-level rise, shoreline position, or the depth of estuaries can influence the geometry of the local region such that tidal resonance is altered and amphidromic points shift spatially. Meanwhile, seabed roughness, river flow, sea ice coverage, or ocean strat-

70 ification, can lead to changes in the frictional dissipation and energy exchange of the tides
71 (Haigh et al., 2020). These non-astronomical effects are the reason for efforts now to in-
72 clude changes in tides as a factor in assessing flood risks in a changing climate (Jay, 2009;
73 Haigh et al., 2020). In order to model and predict tidal changes and their impacts in a
74 changing climate, it is desirable to simulate tides within an Earth system model.

75 Historically, tide modeling and climate modeling have been performed separately.
76 In relatively recent efforts, the two types of modeling have been performed concurrently
77 (Arbic et al., 2018). Tide gauges have been used for centuries to determine tidal ampli-
78 tudes and phases at specific locations, but as computational methods became more fea-
79 sible, work began on developing tide models that would allow tidal amplitude and phases
80 to be estimated at any point in the ocean (Pekeris & Accad, 1969). The resolution and
81 accuracy of these early barotropic tide models increased throughout the late 20th centu-
82 ry with the help of increased computational power and assimilation from satellite al-
83 timeter data (Hendershott, 1972; Schwiderski, 1979; Parke & Hendershott, 1980; Ray,
84 1993; Le Provost et al., 1994; Shum et al., 1997; Dushaw et al., 1997). Conversely, baro-
85 clinic climate models have historically excluded explicit tide calculations due to compu-
86 tational constraints and the use of large time steps for long-term simulations. Early 3-
87 D ocean models used a “rigid-lid” assumption to remove barotropic gravity waves, thus
88 not permitting tides at all (Bryan, 1969; Griffies et al., 2000). The first studies to include
89 tides in a baroclinic model were performed at regional scales (Cummins & Oey, 1997;
90 Kang et al., 2000; Merrifield et al., 2001). The first global simulations of baroclinic tides
91 (Arbic et al., 2004; Simmons et al., 2004) included only tidal forcing. Over the past decade,
92 several ocean general circulation models have begun incorporating tides (Arbic et al.,
93 2010; Müller et al., 2012; Waterhouse et al., 2014; Rocha et al., 2016; Arbic et al., 2018),
94 allowing for investigations into interactions of barotropic and internal tides with mesoscale
95 eddies and other components of the Earth system.

96 Several factors must be examined and accounted for in global tide models, includ-
97 ing self-attraction and loading (SAL), model resolution, the underlying bathymetric dataset,
98 and parameterized topographic wave drag. SAL accounts for a combination of effects:
99 the deformation of the Earth’s crust due to mass loading and the self-gravitation of the
100 load-deformed Earth as well as of the ocean tide itself (Hendershott, 1972). Self-attraction
101 and loading can change tidal amplitudes to first-order, up to 20% in some regions, and
102 also significantly impacts tidal phases and amphidromic points (Gordeev et al., 1977).
103 Full calculation of SAL calls for convolution of tidal elevation with a proper Green’s func-
104 tion or a multiplication with load Love numbers in the spectral—i.e., spherical harmonic—
105 domain (Ray, 1998). Early attempts to calculate SAL using spherical harmonics proved
106 expensive (Stepanov & Hughes, 2004), so ocean tide models have often employed cheaper
107 methods, such as a scalar approximation (in which the SAL is approximated locally by
108 a constant factor multiplied by the tidal elevation), an iterative method, or the use of
109 SAL fields drawn from other sources. The scalar approximation fails to preserve the scale-
110 dependent, spatially smoothing behavior of the SAL and can be particularly unreliable
111 in shelf areas where tidal length scales are much smaller than in the open ocean (Ray,
112 1998). The iterative method is tedious to employ and relies on intermediate harmonic
113 analysis, meaning that non-periodic self-attraction and loading effects, such as those as-
114 sociated with storm surges, cannot be easily accounted for. Reading in a dataset for SAL
115 can improve the accuracy of modeled tides in the present-day, but is not appropriate for
116 the prediction of tides in a future world where tides and other climate system compo-
117 nents will be different. Motivated by these points and by recent works incorporating SAL
118 in various hydrodynamic frameworks (Schindelegger et al., 2018; Shihora et al., 2022; Vino-
119 gradova et al., 2015), we choose to implement a full inline calculation of SAL for tides.
120 The model we use is the oceanic component of the Department of Energy (DOE) En-
121 ergy Exascale Earth System Model (E3SM) — namely, the ocean Model for Prediction
122 Across Scales (MPAS-Ocean).

This paper represents a first step toward embedding tides within MPAS-Ocean. We evaluate MPAS-Ocean as a barotropic tide model in preparation for including tides in full baroclinic simulations. We demonstrate the feasibility of implementing a full inline calculation of SAL using the barotropic configuration. Furthermore, we compare tidal sensitivity to different bathymetric products, different resolutions, and parameterized topographic wave drag. Sensitivity to bathymetry in tidal simulations has been demonstrated previously and can be improved with high-quality regional patching (Lyard et al., 2021; Blakely et al., 2022). Convergence of tidal errors with increasing model grid resolution has been explored in, e.g., Egbert et al. (2004), Arbic et al. (2008) and Pringle et al. (2021). A parameterized topographic wave drag accounts for the energy dissipation that occurs when internal tides are generated from the tidal flow over rough topography in the presence of stratification. The importance of including this term in barotropic tidal simulations has been discussed in many papers (Jayne & St. Laurent, 2001; Arbic et al., 2004, 2008; Egbert et al., 2004; Blakely et al., 2022). Finally, we expect the inclusion of a full SAL calculation to increase the computational time of the simulations, as has been shown in previous implementations (Schindelegger et al., 2018; Shihora et al., 2022). We end with an examination of the computational cost incurred by our SAL calculation and compare performance on the various resolution meshes used in the study.

2 Methods and Implementation

2.1 Model Description

The Model for Prediction Across Scales, or MPAS, integrates a variety of geophysical fluid dynamics models on unstructured meshes (Ringler et al., 2013; Petersen et al., 2019; Golaz et al., 2019). MPAS contains various dynamical cores, each of which contains a specific implementation of a physical system (e.g. atmosphere, sea ice, etc.). We implement tides in the ocean core, MPAS-Ocean. The model is based on unstructured, Voronoi-type tessellations supporting variable resolution, allowing for a range of spatial length scales to be captured in a single simulation. A variable resolution unstructured mesh allows for a detailed representation of some regions (e.g., coastlines) while reducing overall computational cost through the use of lower resolutions in regions with larger length scales.

For the purpose of evaluating tides in MPAS-Ocean, we have modified the model to run in a two-dimensional (2-D) barotropic mode. The governing equations include a momentum equation in a vector-invariant form and a layer thickness equation,

$$\frac{\partial \mathbf{u}}{\partial t} + (\nabla \times \mathbf{u} + f\mathbf{k}) \times \mathbf{u} = -\nabla K - g\nabla(\eta - \eta_{EQ} - \eta_{SAL}) - \chi \frac{\mathcal{C}\mathbf{u}}{H} - \frac{\mathcal{C}_D|\mathbf{u}|\mathbf{u}}{H}, \quad (1)$$

$$\frac{\partial h}{\partial t} + \nabla \cdot (h\mathbf{u}) = 0, \quad (2)$$

where \mathbf{u} represents the depth-averaged horizontal velocity, t is the time coordinate, f is the Coriolis parameter, \mathbf{k} is the vertical unit vector, $K = |\mathbf{u}|^2/2$ is the kinetic energy, g is the gravitational acceleration constant, η is the sea-surface height relative to the moving bed, henceforth called SSH, η_{EQ} is the equilibrium tide, η_{SAL} is the perturbation of tidal elevations due to SAL, χ is a tunable scalar dimensionless wave drag coefficient, $\frac{\mathcal{C}}{h}$ is a topographic wave drag time scale, H is the resting depth of the ocean, and h is the total ocean thickness such that $H + \eta = h$. The full form of the drag terms in (1) would use the total thickness h , but our implementation uses the linearized version with the resting depth H . In addition, $\frac{H}{\mathcal{C}}$ is read in from the variable `rinv` from the HyCOM file `js1_lim24_inv_hrs.nc`, where the original calculation is described in Buijsman et al. (2016). \mathcal{C}_D is a log-law based drag model, evaluated according to Eq. 3 where $\kappa = 0.4$ is the von Karman constant (Von Kármán, 1931), $z_0 = 0.001$ is the roughness parameter and H is the ocean resting thickness. The minimum and maximum functions constrain \mathcal{C}_D to the range $[0.0025, 0.1]$.

$$C_D = \max \left[0.0025, \min \left[0.1, \left(\frac{\kappa}{\ln \left(\frac{H}{2z_0} \right)} \right)^2 \right] \right] \quad (3)$$

MPAS-Ocean retains the capability to be run with multiple layers with tides and SAL for future investigations, but only the single-layer barotropic model is used in this study. The multi-layer baroclinic model would additionally include three-dimensional tracer equations for temperature and salinity, vertical advection and diffusion terms on all equations, and the computation of density from the equation of state for seawater and pressure at each layer from the hydrostatic equation.

Tidal forcing is implemented by adding a SSH perturbation, η_{EQ} , into the pressure gradient operator.

$$\eta_{EQsd,c} = A_c f_c(t_{ref}) L \cos^2(\phi) \cos[\omega_c(t - t_{ref}) + \chi_c(t_{ref}) + \nu_c(t_{ref}) + 2\lambda] \quad (4)$$

$$\eta_{EQd,c} = A_c f_c(t_{ref}) L \sin(2\phi) \cos[\omega_c(t - t_{ref}) + \chi_c(t_{ref}) + \nu_c(t_{ref}) + \lambda], \quad (5)$$

These terms are valid for semidiurnal (*sd*) and diurnal (*d*) tidal constituents (Arbic et al., 2018). The total forcing comes from summing over each of the constituents, *c*. Here *A* and ω are the forcing amplitude and frequency, respectively, dependent on the tidal constituent, t_{ref} is a specified reference time, *t* is time, ϕ is latitude, λ is longitude, $\chi(t_{ref})$ is an astronomical argument accounting for the constituent's phase due to astronomical positions of the Moon and/or Sun, and $f(t_{ref})$ and $\nu(t_{ref})$ are amplitude and phase nodal factors accounting for small known astronomical modulations in the tidal forcing. $L = 1 + k_2 - h_2$ is a combination of body tide Love numbers that account for changes in the gravitational potential (k_2) due to deformation of the Earth's crust and mantle from tidal forcing (h_2).

2.2 Self-Attraction and Loading

SAL is implemented as additional body force via the SSH gradient term in Eq. (1). We express the inline SAL for tides in terms of the spherical harmonic decomposition of the SSH (Hendershott, 1972)

$$\eta_{SAL} = \sum_n \frac{3\rho_0}{\rho_{earth}(2n+1)} (1 + k'_n - h'_n) \eta_n. \quad (6)$$

where each spherical harmonic SSH term η_n is multiplied by a scalar coefficient. Here $\rho_0 = 1035 \frac{kg}{m^3}$ is the average density of seawater, $\rho_{earth} = 5517 \frac{kg}{m^3}$ is the average density of the solid Earth, and the multiplicative term $(1 + k'_n - h'_n)$ represents load Love numbers (obtained from Wang et al. (2012)) corresponding to physical effects of SAL. The "1", k'_n , and h'_n terms account for gravitational self-attraction of the ocean, gravitational self-attraction of the deformed solid Earth, and deformation due to loading of the solid Earth respectively. However, the usage of SSH for calculating SAL is only appropriate for tides and wind-driven barotropic motions. For other motions one must use bottom pressure anomalies.

Before this work, SAL was implemented in MPAS-Ocean via the scalar approximation (Accad & Pekeris, 1978; Ray, 1998)

$$\eta_{SAL} = \beta \eta, \quad (7)$$

where η is the SSH prior to alterations, and $\beta = 0.09$ is a scalar parameter used to approximate the influence of SAL. This approximation is a computationally inexpensive method that is sufficiently accurate for many cases. However, it does not capture the spatial dependence and large-scale smoothing of the full calculation (Fig. 1).

Figure 1. Example of spatially-smoothed output (right) of the SAL operator (eqn. 6) applied to an input field (left). The SAL output has amplitude roughly 1/10 that of the original. For the barotropic runs used in this model, we evaluate SAL using the SSH signal, shown here. However, for a full baroclinic model it is necessary to use the bottom pressure as input.

We evaluate Eq. (6) using the fast spherical harmonics transform package, SHTns (Schaeffer, 2013). This package can only be run on a single node with shared memory, not across nodes with a message passing interface (MPI). In contrast, MPAS-Ocean typically runs on hundreds of nodes using MPI. Further, the input data must be arranged on a Gaussian grid, because SHTns takes advantage of the geometry of this grid (i.e., the latitudes are arranged at zeros of Legendre polynomials) to perform faster transforms. To use SHTns within MPAS-Ocean, we first gather the distributed SSH field to a single head node before remapping the data onto the Gaussian grid. The remapped data can then be transformed into spherical harmonics, where η_{SAL} is easily calculated by multiplying the harmonic coefficients by the known load Love numbers. Finally, the process is performed in reverse as η_{SAL} is transformed into a spatial field on the Gaussian grid, remapped onto the MPAS mesh, and sent back out to the nodes (Fig. 2). For each of the quasi-uniform meshes, the Gaussian grid resolution was chosen to match the mesh resolution at the equator. For the variable resolution mesh, the Gaussian grid resolution is equal to the minimum resolution of the mesh, or 5 km. The spherical harmonic order cutoff is determined by the number of latitudes in the Gaussian grid according to Eqs. 8, where l_{max} is the maximum degree, m_{max} is the maximum order, and $nlat$ is the number of latitudes in the Gaussian grid.

$$\begin{aligned} l_{max} &= \text{integer}\left(\frac{nlat}{2}\right) - 1 \\ m_{max} &= l_{max} \end{aligned} \quad (8)$$

Prior to our global tidal simulations, we validated the above approach by initializing the SSH to a single spherical harmonic function on the MPAS mesh, allowing us to easily confirm that the results matched the theoretical expectation.

2.3 Meshes

Several studies have demonstrated the effect of resolution on the accuracy of tidal models (Egbert et al., 2004; Arbic et al., 2008; Pringle et al., 2021). Here, we compare two types of meshes: icosahedral and variable resolution. Icosahedral meshes are spatially quasi-uniform, and have the smallest variations of cell area, vertex angles, and edge lengths across the sphere among any global meshes, so are the perfect choice for com-

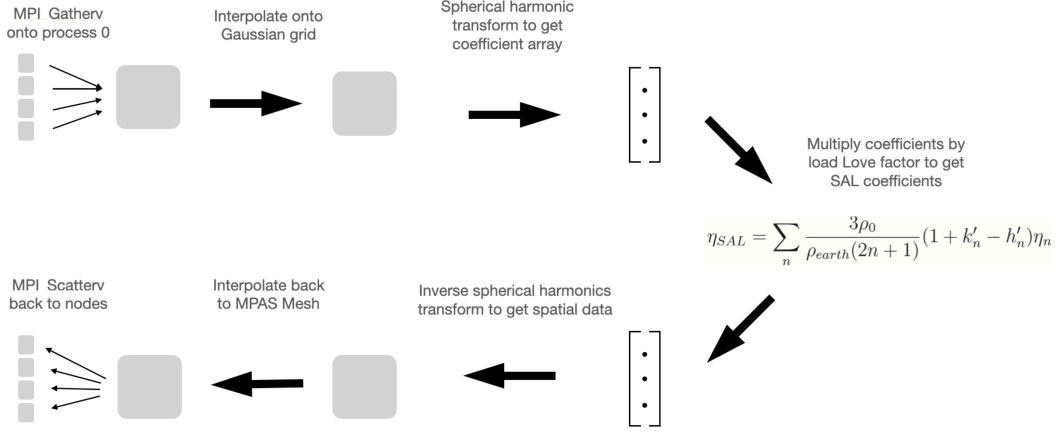

Figure 2. Overview of the procedure used to calculate SAL. The SSH field is sent to process 0, remapped onto a Gaussian grid, then decomposed into spherical harmonics. The perturbation in SSH due to SAL is calculated and then transformed into spatial data, remapped onto the MPAS-Ocean mesh, and sent back to the nodes.

234 comparisons between resolutions. Table 1 shows the resolutions of the icosahedral meshes
 235 used in our simulations. The numbers 7–10 refer to the number of refinement iterations
 236 in the mesh generation process, where each iteration divides every triangle on the pri-
 237 mal (triangular) mesh into four triangles, so that the mesh at step n contains $2 + 10 \cdot$
 238 4^n cells on the dual mesh (12 pentagons and the rest hexagons).

239 The variable resolution 45 to 5 km mesh (Fig. 3 and 4) is an ADCIRC (Advanced
 240 CIRCulation)-style mesh (Pringle et al., 2021). Tides are particularly sensitive to shal-
 241 low coastal areas and steep topographic gradients, where significant tidal energy dissipa-
 242 tion takes place. In fact, about 2/3 of tidal dissipation occurs in coastal regions (Egbert
 243 & Ray, 2000, 2003). In our variable-resolution configuration, we adapt the length scale
 244 of the mesh in critical areas to better capture dynamics in shallow tidal flats and in re-
 245 gions of sharp bathymetric variation; employing the following mesh spacing heuristics
 246 to design a global mesh that captures local tidal processes:

$$l_{wav}(\mathbf{x}) = \beta_{wav} T_{M_2} \sqrt{g\tilde{H}}, \quad (9)$$

$$l_{slp}(\mathbf{x}) = \beta_{slp} \frac{2\pi\tilde{H}}{\tilde{\nabla}H}, \quad (10)$$

$$l^*(\mathbf{x}) = \max(\min(l_{wav}(\mathbf{x}), l_{slp}(\mathbf{x}), l_{max}), l_{min}), \quad (11)$$

$$l^* \rightarrow |\nabla l| \leq \gamma. \quad (12)$$

247 Here, $l_{wav}(\mathbf{x})$ and $l_{slp}(\mathbf{x})$ are barotropic tidal length-scale heuristics, with l_{wav} increas-
 248 ing mesh resolution in shallow regions to resolve the wavelength of shallow-water dynam-
 249 ics, and l_{slp} increasing mesh resolution in areas of large relative bathymetric gradients
 250 to capture topographically-induced flow. β_{wav} and β_{slp} are tunable ‘resolution-selection’
 251 parameters, set to $\beta_{wav} = \frac{1}{80}$ and $\beta_{slp} = \frac{1}{4}$ in this study. To produce smooth distribu-
 252 tions suitable for mesh generation, \tilde{H} and $\tilde{\nabla}H$ represent Gaussian-filtered ($\sigma = \frac{1}{2}$)
 253 depths and gradients obtained from the raw GEBCO2021 bathymetry. $l^*(\mathbf{x})$ is an ini-
 254 tial combined estimate of mesh spacing throughout the domain, taking limiting values
 255 of l_{wav} , l_{slp} at each spatial point and clipping to $l_{min} = 5km$ and $l_{max} = 45km$. To con-
 256 trol the gradation of the mesh overall, this initial estimate is ‘gradient-limited’ to ensure

Figure 3. Comparison of the Icosahedron 10 mesh (top) and the variable resolution mesh (bottom) in the North Atlantic near Delaware Bay. The Icosahedron 10 mesh is a quasi-uniform 8-km mesh while the variable resolution mesh ranges from 45 km to 5 km.

the relative increase in mesh spacing is bounded below a user-defined threshold, here set to $\gamma = \frac{1}{8}$. See Figure 3 for a detailed view of the resulting mesh spacing pattern $l(\mathbf{x})$ in the North Atlantic region. Meshes in this study are generated using the JIGSAW unstructured meshing library (Engwirda, 2017), with pre-processing completed using the scikit-image package (Van der Walt et al., 2014).

2.4 Topographic Wave Drag

Tidal dissipation occurs as a stratified fluid flows over rough topography, causing energy to transfer from barotropic to baroclinic tides (Munk, 1966; Munk & Wunsch, 1998). Including this topographic wave drag has been shown to decrease the tidal elevation errors in tidal models (Egbert et al., 2004; Arbic et al., 2004; Green & Nycander, 2013; Lyard et al., 2006). Different parameterization methods exist, and several studies include comparisons of various methods (Egbert et al., 2004; Green & Nycander, 2013; Buijsman et al., 2015). Here, we have implemented the scheme proposed by Jayne and St. Laurent (2001) which uses a simple tunable scalar,

$$\mathcal{C} = \frac{\pi}{L} \hat{H}^2 N_b. \quad (13)$$

Here \mathcal{C} is the same as that in Eq. (1), \hat{H} represents the bottom roughness and N_b is the buoyancy frequency at the bottom. L is a wave length representing the topography, which

Figure 4. View of the variable resolution mesh around the Atlantic Ocean. The colors indicate the size of each cell in the mesh, with blue indicating smaller cell size and red indicating larger cell size. There is more refinement around 1) shallow depths, and 2) regions of steep topographic gradients.

Mesh Type	Avg. Cell Width	Wave Drag Coeff.	Number of Cells	Time Step (s)
Icosahedron 7	62.9 km	1.80	163,842	60
Icosahedron 8	31.5 km	1.08	655,362	60
Icosahedron 9	15.7 km	0.72	2,621,442	30
Icosahedron 10	7.87 km	0.36	10,485,762	15
VR 45 to 5	45 km to 5 km	0.72	2,359,578	20

Table 1. Details for each mesh used in the simulations. Cell width of a polygon is computed as the diameter of a circle with the same area.

we set to 10 km, as in Jayne and St. Laurent (2001) and Buijsman et al. (2015). MPAS-Ocean reads in the Hycom variable `rinv`, which is H/C . The value of the parameter χ depends on the resolution (Arbic et al., 2008; Buijsman et al., 2020), and required a tuning of the wave drag for each mesh in this study (Fig. 5).

2.5 Bathymetry

The quality of bathymetric datasets can impact the errors found in tidal models. In particular, it has been found that Hudson Bay and other areas can significantly change tides in regions around the globe (Arbic et al., 2009; Pringle et al., 2018). It was demonstrated by Arbic et al. (2009) and Arbic and Garrett (2010) that regions of large resonant coastal tides, such as Hudson Bay, have a substantial “back effect” on the global ocean tidal system. Blakely et al. (2022) showed that tidal errors can be improved by combining GEBCO bathymetry with various high-quality regional bathymetric datasets. Motivated by this, we include a comparison of two different global bathymetric datasets: GEBCO2021 (GEBCO Compilation Group, 2021) and SRTM15+ (Tozer et al., 2019), each with regional patching around Canada (Canadian Hydrographic Service, 2018), northern Australia (Beaman, 2016) and the great barrier reef (Beaman, 2010).

3 Simulation Details

3.1 Tidal Evaluation

It is common to evaluate tidal models by comparing the root-mean squared complex error (RMSE) vs. a benchmark, such as TPXO8 (Egbert & Erofeeva, 2002). Here, as in Arbic et al. (2004), we separate the errors into three regions: *deep* (depths >1000m and between 66°N and 66°S), *shallow* (<1000m) and *global* (no restriction). The point-wise RMSE for the tidal constituent, which we also denote by D (for discrepancy) can be computed as

$$D^2 = \frac{1}{2}(A_{TPXO}^2 + A_{MPAS}^2) - A_{TPXO}A_{MPAS} \cos(\phi_{TPXO} - \phi_{MPAS}), \quad (14)$$

$$RMSE_{areaweighted} = \sqrt{\frac{\int \int D^2 dA}{\int \int dA}} \quad (15)$$

In Eq. 15, A_{TPXO} and A_{MPAS} are the M_2 amplitudes and ϕ_{TPXO} and ϕ_{MPAS} are the phases of TPXO and MPAS-Ocean, respectively. The quantity $RMSE_{areaweighted}$ is weighted by the area dA of each cell.

We also evaluate the model against tide gauge observations as

$$D^2 = \frac{1}{2}(A_{tg}^2 + A_{MPAS}^2) - A_{tg}A_{MPAS} \cos(\phi_{tg} - \phi_{MPAS}), \quad (16)$$

$$RMSE_{tg} = \sqrt{\sum \frac{D^2}{N_{tg}}} \quad (17)$$

where tg denotes tide gauge data and N_{tg} is the number of tide gauge stations. For these comparisons we divide the errors into a different set of categories than we use for the TPXO comparison. These are: *deep* (depths <1000m), *shallow* (depths between 100m and 1000m), and *coastal* (depths <100m). Note that for the tide gauge comparisons, we do not restrict latitude as we do for the TPXO comparisons.

The complete list of simulations is given in Table 2. We compare results from different Icosahedral meshes (7, 8, 9, and 10) to results from a variable resolution mesh. We also compare the results of simulations with inline SAL versus scalar SAL for the highest resolutions: Icosahedral 10 and the variable resolution. Furthermore, we tested two

Mesh	Bathymetry	SAL type	Global	Deep	Shallow
Icosahedron 7	GEBCO2021	Inline	14.1	12.0	30.0
		Scalar	14.8	12.9	28.8
Icosahedron 8	GEBCO2021	Inline	10.7	8.8	22.5
		Scalar	12.9	11.3	22.7
Icosahedron 9	GEBCO2021	Inline	8.0	6.4	16.3
		Scalar	12.2	10.5	20.5
Icosahedron 10	GEBCO2021	Inline	7.4	5.8	14.0
		Scalar	14.3	12.2	23.8
VR 45 to 5 km	GEBCO2021	Inline	6.8	5.4	13.3
		Scalar	10.4	8.9	17.2
		SRTM15+	7.0	5.7	12.6

Table 2. Complex M_2 error (cm) for all simulations, where columns show error calculations for global (all cells), deep, and shallow water.

different bathymetric datasets: GEBCO 2021 and SRTM15+, each with and without refinement in critical areas. We ran all simulations for 120 days using a fourth-order Runge-Kutta time-stepping method. The tidal phases and amplitudes are calculated from harmonic analysis of the final 90 days of the simulation, allowing for a 30-day spin-up.

3.2 Tuning

Two parameters required tuning in order to perform these tests: a wave drag parameter and the interval at which SAL is updated.

3.2.1 Topographic Wave Drag

The MPAS-Ocean model follows the Jayne and St. Laurent drag scheme in that it has a single tunable wave drag parameter, χ , as seen in Eq. (1). It is necessary to tune the wave drag parameter for each resolution to ensure optimally modeled tides and tidal energy dissipation. Table 1, shows the values chosen for each resolution with the sampled wave drag parameters for each resolution shown in Fig. 5. We can also see in this figure that as χ approaches 0 (at which point wave drag would be turned off), the errors begin to increase by up to several centimeters.

3.2.2 SAL Calculation Interval

The full inline SAL calculation can be costly, particularly at high resolution. To help reduce this computational burden, we experimented with updating the value of the SSH perturbation due to SAL at various intervals of 1 minute, 10 minutes, and 30 minutes. We continue to apply SAL at every time step between the update intervals. Table 3 shows the resulting M_2 errors on the Icosahedral 8 and 9 meshes for each of these cases. Decreasing the intervals of calculation does not necessarily lead to decreased tidal errors, likely due to other sources of error dominating. Ultimately, we decided that the 30-minute intervals best optimized the benefits of the inline calculation relative to the computational cost. We include further results of the computational cost in Section 4.3.

Figure 5. Wave drag (χ) tuning for each mesh. These were evaluated with full inline SAL. The optimal wave drag coefficient for each mesh was used to perform all other simulations using that mesh.

Calculation Interval	30 min.	10 min.	1 min.
Icosahedron 8 RMSE (cm)	8.8	8.4	8.4
Icosahedron 9 RMSE (cm)	6.4	6.4	6.5
VR 45 to 5 km RMSE (cm)	6.1	6.1	6.4

Table 3. RMSE error for M_2 constituent at different SAL update intervals.

4 Results

4.1 TPX08 Comparison

The RMSE for the M_2 tidal constituent as compared to TPX08 are shown in Table 2. Figures 6 and 7 show the distribution of the M_2 RMS error D in the solution as compared to TPX08. The decreasing error at finer resolutions demonstrates approximate numerical convergence. The largest errors, particularly in the variable resolution mesh, lie in the region around Antarctica. The E3SM water cycle configurations do not include ice shelf cavities. As such, we are planning a follow-up study focused on the accuracy of tides under those circumstances. For now, the simulations in this paper do not include an explicit representation of ice shelf cavities, which have been shown to impact tidal accuracy, particularly in this region (Stammer et al., 2014; Blakely et al., 2022).

Comparing the results for inline SAL and the scalar approximation (Fig. 8), we can see that at every resolution, the deep ($>1000\text{m}$) RMS error improves with the inline SAL. Finer resolution meshes see a larger benefit to inclusion of inline SAL than the coarser resolutions. As the quasi-uniform meshes increase resolution, inline SAL reduces the error by as much as 50%. For the scalar SAL case, the Icosahedron 10 mesh has unusually larger errors. This could be due to keeping the β constant for all cases, rather than tuning it for specific resolutions. Additionally, the wave drag parameter χ was tuned for the inline SAL cases, so further turning may lead to more typical results for the scalar case on the Icosahedron 10 mesh. For the variable resolution mesh, the improvement is not as large but inline SAL still reduces the error by 39% as compared to the scalar SAL. The lowest error achieved is on the 45 km to 5 km variable resolutions mesh, with a deep M_2 RMS error of 5.4 cm. As a point of comparison, Schindelegger et al. (2018) and Shihora

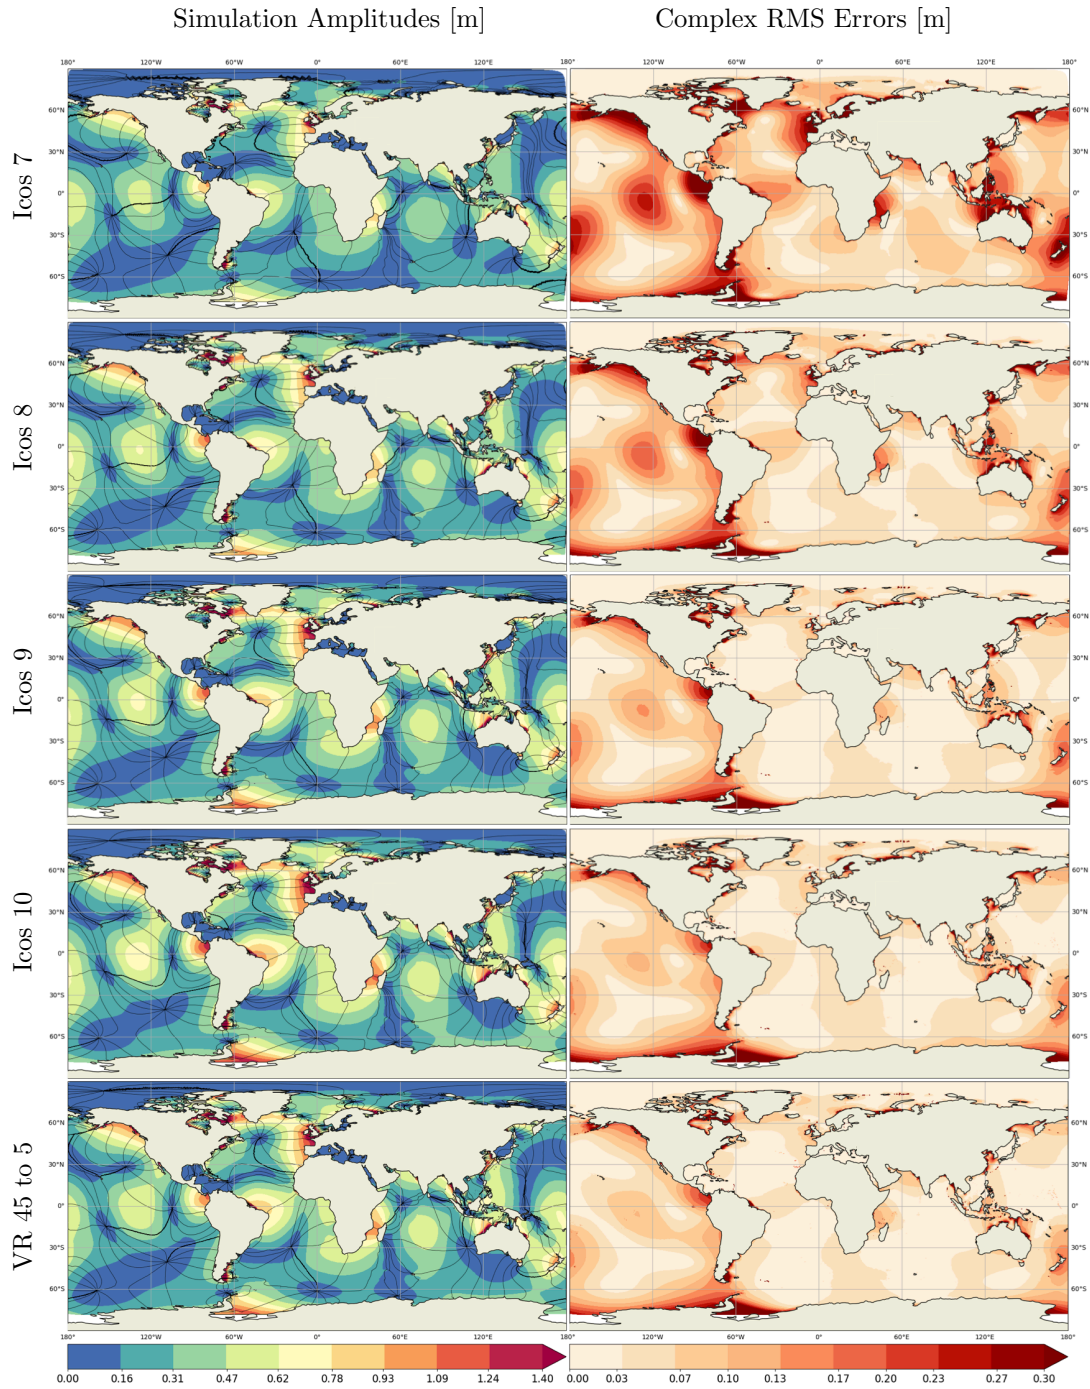

Figure 6. Pointwise complex RMS differences (D) between MPAS and TPXO8, showing simulated M_2 tidal amplitudes (colors) and phases (lines) from MPAS-O at various resolutions (left); M_2 RMS errors calculated with respect to TPXO8 data (right). These represent the errors on each mesh obtained from using inline SAL and GEBCO2021 bathymetry.

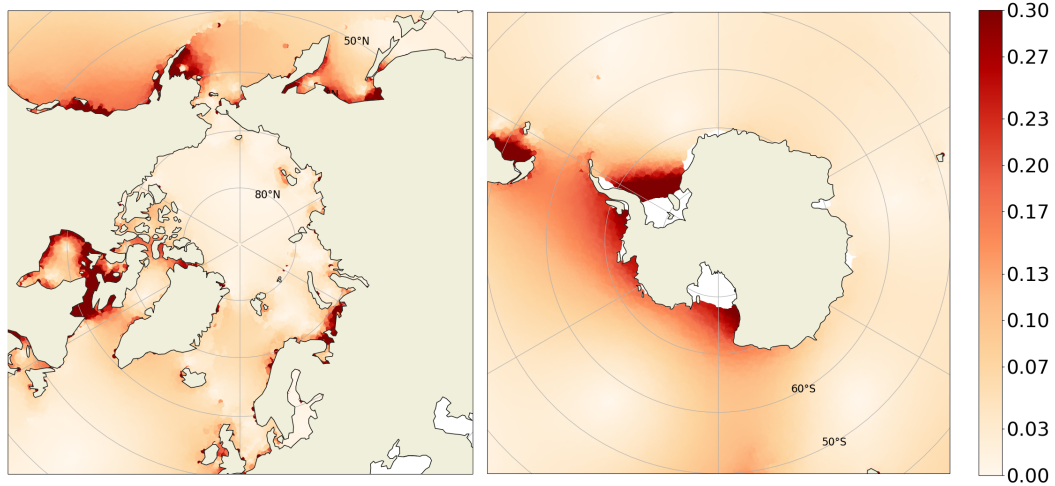

Figure 7. RMS error (m) of the variable-resolution simulation versus TPX08 in the Arctic Ocean (left) and Southern Ocean (right).

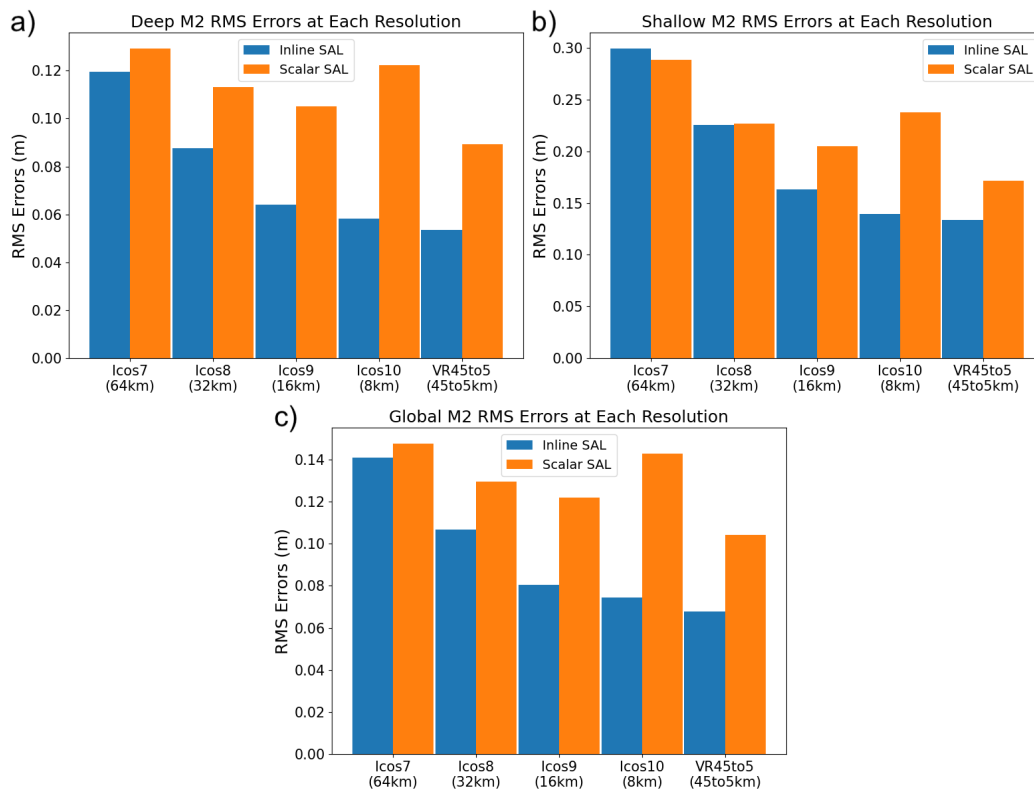

Figure 8. M_2 RMS errors relative to TPX08 for different simulations. The plots show a) deep regions, b) shallow regions, and c) global errors (see Section 3.1). Errors reduce with higher resolution, and inline SAL is better than scalar SAL.

et al. (2022) both included full inline SAL calculations into a barotropic tide model and found deep ocean M_2 RMS errors of 4.4 cm and 3.4 cm, respectively. Both studies used global $1/12^\circ$ resolution regular latitude-longitude grids with ice shelf cavities included. The Schindelegger et al. (2018) model domain ranged from 86°S to 84°N . M_2 RMS errors with ADCIRC were found to be 2.9 cm by Pringle et al. (2021) and were further lowered to 1.9 cm by Blakely et al. (2022). All of the previous studies used more sophisticated wave drag schemes, such as a full tensor calculation or optimization of spatially-dependent coefficients, and evaluated RMSE at depths > 1000 m and latitudes $\leq |\pm 66^\circ|$. The two ADCIRC studies implemented SAL by reading in values from a data-assimilated model and featured a global 2-km to 25-km variable resolution mesh. Stammer et al. (2014) includes a comparison of errors for various purely hydrodynamical, non-data assimilative models ranging from 5.3–7.8 cm. While the tidal errors in MPAS-Ocean are not as competitive as some state-of-the art models that focus exclusively on tidal modeling, they are low enough to represent tides in an Earth system model, thus paving the way for studies of tidal interactions with storm surges, rivers, or components of the cryosphere in the future (see Section 5). In at least one other run using settings not directly tested here, we have achieved an even lower RMS error of 5.1 cm, indicating there is still room for improvement.

Aside from inclusion of explicit ice-shelf cavities, the errors in our model could be improved by using a more sophisticated wave-drag scheme or a better-optimized variable resolution mesh. Optimization for improved tidal errors on the VR mesh include adjusting the maximum and minimum cell size as well as the limiting gradient that determines the relative increase in cell size. As discussed in the tuning section, the wave drag coefficient is highly dependent on the resolution of the mesh. For the variable resolution mesh, the “best” wave-drag coefficient may be different depending on the resolution of a particular region of cells. Furthermore, we may find that the scalar parameterization of wave drag is not as accurate as a full implementation. The generation of the variable mesh itself also requires decisions about minimum / maximum cell width, and the gradient of cell width (i.e., how rapidly the cell sizes change throughout the mesh). Refining these parameters could lead to further improvement in the results found on the VR mesh.

4.2 Tide Gauge Comparison

We compare the results of MPAS-Ocean to tide gauge datasets including the “ground truth” stations (pelagic, shallow, and coastal) from Stammer et al. (2014), as well as stations from NOAA, KHOA, JMA, and GESLA. These stations were consolidated by Pringle (2019), including directly provided tidal harmonics or using UTIDE (Codiga, 2011) on time level histories. Fig. 9, shows the model versus tide gauge amplitudes and phases. The tide gauge datasets have been filtered to exclude gauges generally outside of the domain of the simulation. For the phase data, we shifted the values so that the phase differences were all within 180 degrees. The RMS error when comparing against the 151 pelagic stations is 5.8 cm for the variable resolution mesh and 5.9 cm for the 8 km quasi-uniform mesh (Table 4), which is consistent with the results seen from the TPX08 comparison of 5.4 cm and 5.8 cm, respectively, for the deep ocean. For reference, in the previous studies about full inline SAL, Schindelegger et al. (2018) had an RMS error of 5.9 cm and Shihora et al. (2022) had an error of 4.8 cm when comparing to the pelagic stations.

A large majority of the tide gauges sampled are near the coasts, and we can see from the figures that the MPAS-O has more accurate tides near the deep-ocean gauges (Fig. 9). The R^2 value for M_2 amplitudes increases for increasing depths. In the zoomed-in plot showing only tidal amplitudes between 0-1 m, we can see that most of the spread is due to errors in the shallower locations (mainly regions less than 100m deep). Comparing the two different meshes, we can see that while they both give similar results, the variable resolution mesh does outperform the quasi-uniform mesh slightly in the shal-

Mesh	SAL type	RMSE (pelagic)		R^2		
				Deep	Shallow	Coastal
Icosahedron 10	Inline	5.9	Amplitude	0.986	0.950	0.933
	Scalar	13.1		0.982	0.952	0.928
VR 45 to 5 km	Inline	5.8		0.983	0.974	0.950
	Scalar	9.3		0.986	0.982	0.959
Icosahedron 10	Inline		Phase	0.993	0.975	0.974
	Scalar			0.991	0.933	0.965
VR 45 to 5 km	Inline			0.994	0.969	0.985
	Scalar			0.993	0.930	0.979

Table 4. R^2 values for the M_2 tide gauge amplitude (top) and phase (bottom) comparisons in deep (>1000m), shallow (between 1000m and 100m, and coastal (<100m) regions. The complex RMS error (cm) for the 151 “ground truth” pelagic stations is also included.

410 lower regions. For depths less than 100m, the variable resolution mesh amplitude has
411 a value of $R^2 = 0.950$ compared to the quasi-uniform mesh value of $R^2 = 0.933$. Sim-
412 ilarly, for depths between 100m and 1000m, they have values of $R^2 = 0.974$ and $R^2 =$
413 0.950 respectively. For depths greater than 1000m, we can see a slight advantage in the
414 quasi-uniform mesh, with a value of $R^2 = 0.986$ compared to the variable resolution
415 mesh value of $R^2 = 0.983$. The quasi-uniform mesh has an 8 km resolution over the en-
416 tire ocean, while the variable resolution mesh has cells as large as 45 km in this region.
417 Despite the slight advantage this gives the quasi-uniform mesh for amplitudes, the vari-
418 able resolution mesh also has similar or better phase results, leading to reduced RMSE
419 (Fig. 4) for this mesh. When comparing the scalar results to the inline SAL, we can see
420 that the inline calculation performs better overall for the Icosahedron 10 mesh, but the
421 variable resolution mesh sees most benefit in the phase errors. Even though the RMSE
422 is higher for both meshes, the amplitude R^2 values are actually higher for the scalar while
423 the phase values are lower. We can also consider the physical spread of errors by sep-
424 arating the tide gauges based on whether their errors are larger or smaller than the RMS
425 error (Fig. 10). MPAS-O tidal errors are generally greater than the total RMS error in
426 regions near coastlines, whereas tidal errors in the deep-ocean are generally less than the
427 RMS error. While we expect the shorelines to have larger overall tides and therefore larger
428 errors in the model, the figure also demonstrates that many shallow regions also have
429 lower errors. We expect that once further improvements to the variable resolution mesh
430 allow us to resolve the coastline in better detail, these errors might reduce even further.
431 Additionally, allowing for different wave drag coefficients for different regions may help
432 optimize drag specifically along shelves and coastlines (e.g. Blakely et al., 2022).

433 4.3 Computational Scaling

434 We show differences between performance for the inline SAL updated at various
435 intervals and performance on the variable resolution mesh compared to the Icosahedron
436 mesh. All runs were performed on NERSC Cori compute nodes with 2.3 GHz Haswell
437 processors (Intel Xeon Processor E5-2698 v3). For the mesh comparisons, the variable
438 resolution performance is better than the Icosahedron 10 mesh (Fig. 11), with compa-
439 rable RMS errors (Fig. 2). Table 1 shows the number of cells and the time step needed
440 to run the model on each mesh. The variable resolution mesh allows for significantly fewer
441 cells, leading to improved computational performance. For all meshes, the explicit time
442 step is restricted by the advective CFL condition, defined as the ratio of the cell width

Figure 9. M_2 tidal results from inline SAL Icosahedron 10 run compared to tide gauge data for the deep, shallow, and coastal tide gauges (see Section 3.1). The R^2 values are given in the legend.

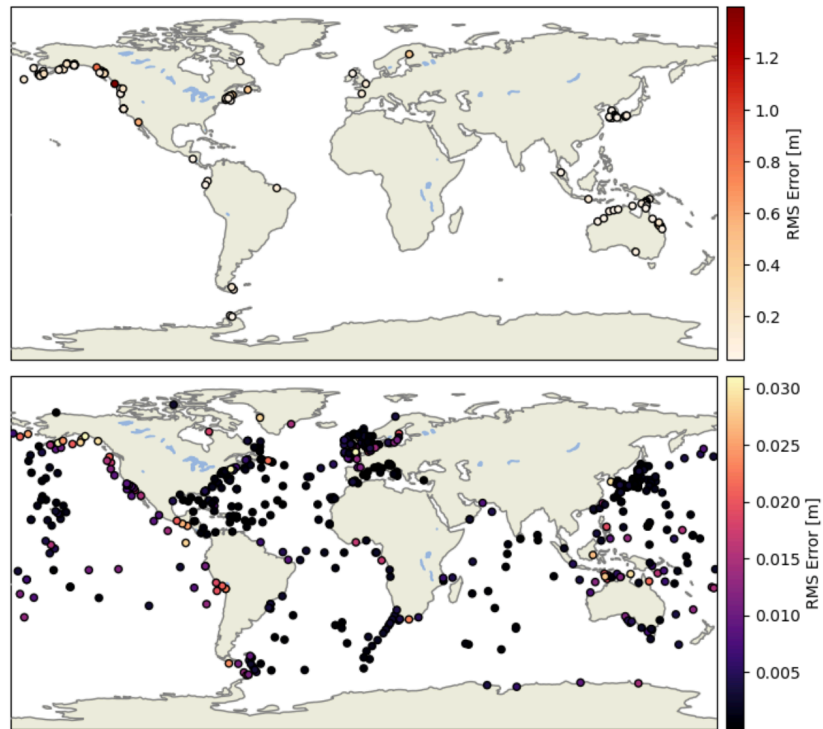

Figure 10. Global distribution of tide gauges, colored by model error from the variable resolution mesh simulation. The top plot shows locations with errors greater than the RMS value of all stations, and the bottom plot shows gauges with errors less than the RMS value. The majority of points have a small error, while the small number of stations with large error are near coastlines. This analysis is restricted to gauges at depths $\geq 100\text{m}$

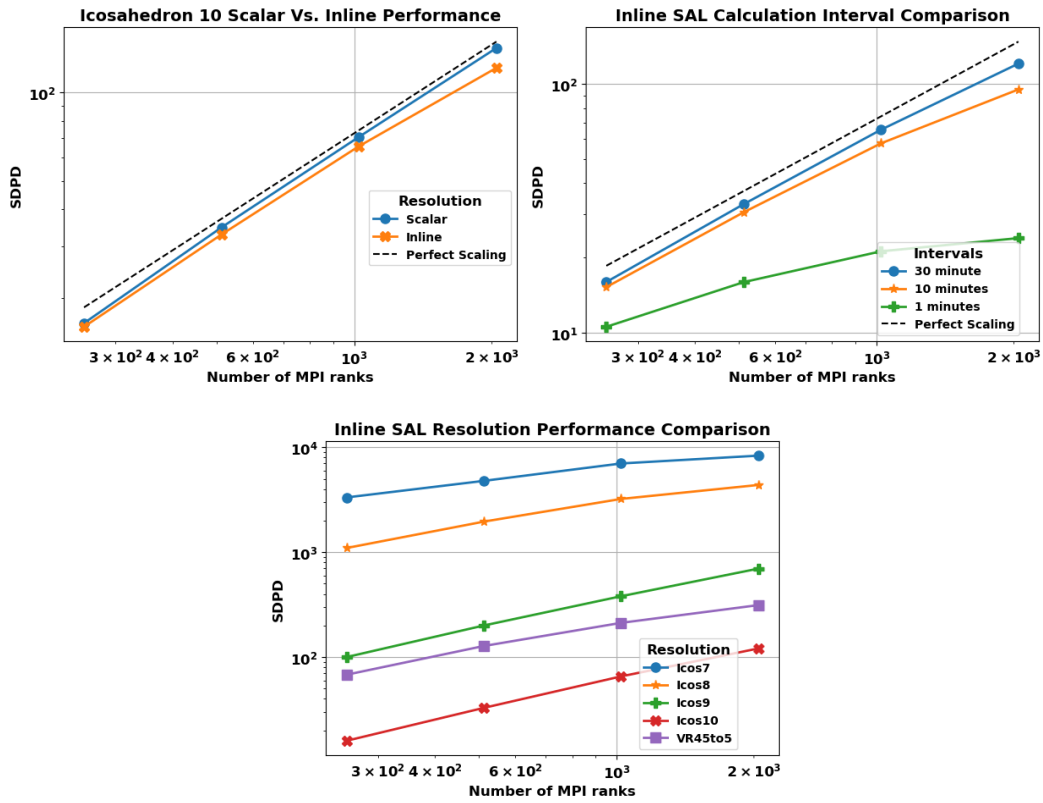

Figure 11. Performance comparisons of MPAS-Ocean including: scalar versus inline on Icosahedron 10; SAL update intervals at 1 minute, 10 minutes, and 30 minutes; and performance with inline SAL on all of the meshes used in this study. The computational throughput is measured in units of simulated days per day (SDPD).

443 to the wave propagation speed,

$$dt < \frac{\text{cell width}}{\text{wave speed}}, \quad \text{wave speed} = \sqrt{gh} \quad (18)$$

444 where dt is the time step, h is the water depth, and g is the gravitational constant. In
 445 ocean flows, the surface gravity wave speeds produces the fastest velocities. For the vari-
 446 able resolution mesh, this condition means that the time step is not necessarily limited
 447 by the minimum cell size alone, but by the relationship between cell sizes and wave speeds
 448 throughout the domain. Noting that our variable resolution heuristics (see Section 2.3)
 449 place fine resolution in shallower, and hence lower wave-speed regions, the overall CFL
 450 restriction is found to be significantly less onerous than quasi-uniform configurations that
 451 employ higher resolution in the deep ocean. In our simulations, not only does the 45 km
 452 to 5 km mesh have fewer cells than the 8 km mesh and higher resolution around the coasts,
 453 it also runs with a larger time step as can be seen in Table 1.

454 While the inline SAL calculations do increase the computational cost, Table 3 shows
 455 that there is only a small difference in the RMS error when updating the SAL term at
 456 larger intervals than the model time step. In fact, at higher resolutions we see that the
 457 more frequent updates may lead to higher errors. Fig. 11, which plots simulation run
 458 time performance, demonstrates that updating the SAL perturbation every 30 minutes
 459 can improve the computational performance as compared to evaluation at more frequent
 460 time steps. When using a 30 minute interval, the computational performance of the full
 461 SAL calculation is marginally but not marginally larger than the scalar implementation.
 462 Based on the scaling and the RMS errors, either 30 minutes or 10 minutes may actually
 463 be the ideal update interval for the SAL, providing computational benefit over the 1 minute
 464 or more frequent intervals with little decrease in tidal accuracy.

465 5 Conclusions

466 In this paper, we demonstrated the feasibility of calculating tides within the MPAS-
 467 Ocean model employing a full inline SAL calculation in high-resolution barotropic sim-
 468 ulations. We also examined sensitivities of the modeled tide to the SAL calculation method,
 469 careful selection of bathymetric datasets, model resolution, and a tuned wave drag co-
 470 efficient. The full SAL calculations showed decreases in tidal RMS elevation errors of sev-
 471 eral centimeters across all meshes tested, relative to results computed using the scalar
 472 approximation for SAL. The variable resolution mesh had tidal errors similar to that of
 473 the Icosahedron 10 mesh, but with better computational performance, lying closer to re-
 474 sults computed on the Icosahedron 9 mesh. Comparison of simulations using the differ-
 475 ent bathymetric datasets show that GEBCO2021 slightly outperforms SRTM15+ on the
 476 variable resolution mesh. The computational performance of the full SAL can incur large
 477 costs when evaluated at every time step. It appears that this cost can be mitigated by
 478 updating SAL at 10 or 30 minute intervals, rather than at every time step, with little
 479 effect on tidal errors. Another avenue for increasing the computational efficiency is eval-
 480 uation of the spherical harmonics in parallel, rather than the serial routines implemented
 481 by the SHTns package used in this study. This can be done by evaluating the integrals
 482 directly on the MPAS mesh so that the interpolation step is not needed, as pursued in
 483 a related study by our group. Comparison to tide gauge data shows that this first at-
 484 tempt at including tides results in slightly larger errors than tides in some other mod-
 485 els (e.g., Pringle et al., 2021; Schindelegger et al., 2018; Stammer et al., 2014; Blakely
 486 et al., 2022). However, we expect that the RMS errors for the M_2 tide could be improved
 487 with a) variable resolution meshes with smaller minimum cell size, b) optimization of pa-
 488 rameters in the variable resolution mesh generation, c) the addition of a spatially-dependent
 489 wave drag coefficient or a more sophisticated wave drag scheme (e.g., Green & Nycan-
 490 der, 2013), and d) the inclusion of ice-shelf cavities.

491 It is becoming clear that inclusion of tides is important for predictions of future
492 climate and extreme sea level events (Bindoff et al., 2019; Oppenheimer et al., 2019). Our
493 results show that MPAS-Ocean has relatively low tidal errors that are small enough to
494 merit inclusion within a full climate system model. An important difference between the
495 setup described for the barotropic case in this paper, and the setup needed for use in a
496 full baroclinic framework, is the variable which is used in the SAL calculations. As men-
497 tioned in the discussion on SAL, tidal elevations can be used for spherical harmonic de-
498 composition in the barotropic case because it is a direct measure of the mass of the wa-
499 ter column. By contrast, baroclinic simulations require bottom pressure anomalies for
500 this purpose. Furthermore, implementation of tides in a baroclinic model calls for some
501 modifications to the topographic wave drag, such as by applying wave drag to the flow
502 averaged over the bottom 500 m (e.g., Arbic et al., 2018) or using different parameter
503 optimizations. The addition of tides in an Earth system model will allow us to exam-
504 ine a number of advanced aspects in the physical Earth system. For example, there is
505 a need for inclusion of tides when considering the Arctic ocean and sea ice (Holloway &
506 Proshutinsky, 2007) as tides can have a substantial effect on sea ice volume and salin-
507 ity (Luneva et al., 2015). A review of tidal influences on ice sheets by Padman et al. (2018)
508 suggests that feedback between ice shelf geometry and tidal currents could imply a need
509 for explicit tides in Earth system models; see also Williams et al. (1985); Dinniman et
510 al. (2016). Tides also have important effects on estuaries. Ruault et al. (2020) found that
511 baroclinic tides can influence the Amazon plume, which itself can impact the Atlantic
512 climate (Jahfer et al., 2017). High-frequency interactions of tides with storm surges and
513 fluvial processes in estuaries (Orton et al., 2012; Spicer et al., 2019) are important for
514 predicting coastal flooding during extreme weather events. In future studies, we plan to
515 use MPAS-Ocean to explore these interactions between tides and other components of
516 the Earth system (e.g., ice shelves and basal melt rates, sea ice, estuaries) and their po-
517 tential impacts on future climate.
