## ACKNOWLEDGMENTS

I wish to acknowledge the interest and supervision of Professor P. L. Cloke throughout the course of the project. Professors W. C. Kelly, D. R. Peacor, W. C. Bigelow and H. N. Pollack were generous in their guidance.

Professor W. C. Bigelow, Frank Drogosz, Fred Bleicher and Jon Rosen of the Department of Materials and Metallurgical Engineering, University of Michigan, provided invaluable advice and assistance in electron probe microanalysis.

The interest and critical discussions of many fellow students, particularly Alex Brown, Judy Moody, Timothy Kurtz and Paul Goldberg are gratefully acknowledged.

The generous financial support provided by the Department of Geology and Mineralogy during my stay at the University of Michigan is sincerely appreciated.

Finally, I wish to thank my wife, Emöke Szathmary, for her help, encouragement and understanding.

## INTRODUCTION

In numerous studies (Fleischer, 1955), attempts have been made to interpret conditions of ore formation (e.g., T, $P, f_{S_{2}}$ ) from the distribution of trace elements in single sulphide phases. Unfortunately, the concentration of a trace element in any one sulphide mineral is dependent not only on temperature and pressure, but also on the chemical characteristics of the hydrothermal solutions from which the mineral formed. Such solutions, however, are generally not available for study, except in the form of fluid inclusions.

It has been shown (Holland, 1956; McIntire, 1963; Kretz, 1961) that the distribution or partitioning of an element between two coexisting minerals, formed in chemical equilibrium, is dependent only on temperature and pressure, provided that the element forms ideal solid solutions in both minerals over the range of concentrations considered. If non-ideal solid solution obtains in one or both of the minerals, the partitioning of the element bears no simple relationship to temperature and pressure. However, if sufficient information is available about the character of such nonideal behaviour, compensation may be made for this added effect. Recent experimental studies (Bethke and Barton, 1971; Halbig, 1969) indicate that the effect of pressure on partitioning between coexisting sulphides is minimal. On the other hand, Bethke and Barton (1971) and others have demonstrated that the distributions of certain
elements among a variety of sulphides may constitute very useful geothermometers.

The association of sphalerite and pyrite is common and ubiquitous in ore deposits. Experimental studies by Barton and Toulmin (1966) and others show that equilibrium assemblages of sphalerite and pyrite can be formed over a wide range of temperatures (Fig. 1). Mn and Co are common constituents, normally at the minor to trace level, of both sphalerite and pyrite in ore deposits (Fleischer, 1955). Their concentration levels in both sphalerite and pyrite, coexisting in ore deposits and apparently formed in equilibrium, are often high enough to be accurately measured by standard analytical techniques (e.g., Troshin, 1965; Doe, 1962; Arnold et al, 1962). In this study, an attempt has been made to define experimentally the partitioning of Mn and Co between sphalerite and pyrite over a geologically meaningful range of temperatures, and to assess the potential of this partitioning in geothermometry.

## Theory of Partitioning

The thermodynamic basis for the partitioning of a component between coexisting mineral phases formed in equilibrium has been outlined in considerable detail by Ramberg (1952), Kretz (1961) and McIntire (1963). Consider some element $i$ which forms solid solutions in two mineral phases, $A$ and $B$, deposited in chemical equilibrium at a specific temperature and pressure. The condition defining this relationship is:

$$
\begin{equation*}
\mu_{i}^{A}=\mu_{i}^{B} \tag{1}
\end{equation*}
$$

where $\mu_{i}^{A}$ and $\mu_{i}^{B}$ are the chemical potentials of $i$ in phase $A$ and $B$ respectively. In general, the relationship between chemical potential and the concentration of element $i$ in phases $A$ and $B$ is:

$$
\mu_{i}^{A}=\mu_{i}^{* A}+R T \operatorname{lnf} A_{i}^{A} X_{i}^{A}
$$

and

$$
\mu_{i}^{B}=\mu_{i}^{* B}+\operatorname{RT} \operatorname{lnf} f_{i}^{B} X_{i}^{B}
$$

where $\mu_{i}^{*}=$ the chemical potential of the element $i$ in some standard state
$f_{i}=$ the activity coefficient for element $i$
$X_{i}=$ the mole fraction of element $i$
$R=$ gas constant
$T=$ absolute temperature
A superscript, A or B, indicates the phase involved.
It could now be assumed that the solid solutions of $i$ in the phases $A$ and $B$ are ideal in character, such that $f_{i}^{A}=f_{i}^{B}=1$ (Raoult's Law). That is, the activity coefficients for $i$ are independent of the concentration of any element in both phases (Denbigh, 1971, p.270). Alternatively, it could be assumed that below some concentration level of $i$ in each of the phases $A$ and $B$, ideal solid solution obtains. The activity coefficients $f_{i}^{A}$ and $f_{i}^{B}$ would then be constants, independent, in those concentration ranges, of composition, but not necessarily equal to one another, nor equal to 1 (Henry's Law). The basic condition is that $f_{i}^{A} / f_{i}^{B}=$ constant, such that the activities and mole fractions of $i$ are directly related to one another by simple proportionality constants. It is important to note that this discussion applies not
only to trace elements, but also to major and minor constituents, since the level of dilution below which the condition of ideal solid solution exists varies from system to system and is not easily predicted on an a priori basis. Under conditions of ideal solid solution:

$$
\mu_{i}^{A}=\mu_{i}^{* A}+\operatorname{RTIn} X_{i}^{A}
$$

and

$$
\mu_{i}^{B}=\mu_{i}^{*}+\operatorname{RT} \ln X_{i}^{B}
$$

Then, from (1):

$$
\mu_{i}^{* A}+R T \ln X_{i}^{A}=\mu \stackrel{* B}{i}+R T \ln X_{i}^{B}
$$

Therefore, by rearranging:

$$
\ln \frac{x_{i}^{A}}{X_{i}^{B}}=\frac{\mu_{i}^{* B}-\mu_{i}^{* A}}{R T}
$$

or

$$
\begin{equation*}
\operatorname{lnK}=\frac{\mu_{i}^{* B}-\mu_{i}^{* A}}{R T} \tag{2}
\end{equation*}
$$

where

$$
k=\frac{x_{i}^{A}}{x_{i}^{B}}
$$

This is a statement of the Nernst distribution law. Since ( $\mu{ }_{i}^{*} \mathrm{~B}_{\mathrm{i}}-\mu_{i}^{*} \mathrm{~A}_{\mathrm{i}}$ ) is independent of the concentration of $i$ (but is dependent on $T$ and $P$ ), $K$, the partition coefficient, is independent of the individual values of $X_{i}^{A}$ and $X_{i}^{B}$, and is solely a function of temperature and pressure under conditions where each solid solution is ideal. A plot of $X_{i}^{A}$ versus $X_{i}^{B}$ would result in a straight line through the origin, whose slope would be a function of $T$ and $P$.

The dependence of K on temperature and pressure is found by differentiating (2). At constant pressure:

$$
\begin{equation*}
\left(\frac{\delta \ln k}{\delta T}\right)_{P}=\frac{\bar{H}_{i}^{A}-\bar{H}_{i}^{B}}{R T^{2}}=\frac{\overline{\Delta H}_{i}}{R T^{2}} \tag{3}
\end{equation*}
$$

where $\bar{H}_{i}=$ partial molar enthalpy for $i$
$\Delta \bar{H}_{i}=$ molar enthalpy of reaction for $i$.
This is the basic relationship between the partition coefficient, K, and T. Similarly, by differentiating (2) at constant temperature, the relationship between $K$ and $P$ is:

$$
\begin{equation*}
\left(\frac{\delta \ln K}{\delta \mathrm{P}}\right)_{\mathrm{T}}=\frac{\overline{\mathrm{V}}_{i}^{B}-\overline{\mathrm{V}}_{i}^{A}}{\mathrm{RT}}=\frac{\overline{\Delta V}_{i}}{\mathrm{RT}} \tag{4}
\end{equation*}
$$

where $\bar{V}_{i}=$ partial molar volume for $i$
$\bar{\Delta} \bar{V}_{i}=$ molar volume of reaction for $i$.
Thus, the partition coefficient, $K$, is only a function of the temperature and pressure at which phases $A$ and $B$ formed in chemical equilibrium. It is not dependent on the chemical characteristics of the solution from which they were formed. This is a very fortuitous situation in the study of ore deposits since such solutions are not normally available for analysis. It has been found that the influence of pressure on the partition coefficient is quite small in sulphide systems (Bethke and Barton, 1971). Lack of correction for variations in $P$ does not lead to large errors in the estimation of $T$. Therefore, the effect of $P$ has not been dealt with in this study.

The working form of equation (3) is found by integration
(assuming $\Delta \bar{H}_{i}$ is independent of temperature) and is:

$$
\log K=\frac{-\overline{\Delta H}_{i}}{2.303 \mathrm{R}}(1 / T)+C
$$

A plot of $\log \mathrm{K}$ versus $1 / T$ should be a straight line with slope equal to $-\Delta \bar{H}_{i} / 2.303 R$.

By experimentally determining $K$ for element $i$ over a range of temperatures, the basis for determining the temperature of formation of phases $A$ and $B$ in natural assemblages can be established. It is theoretically possible to develop a host of geothermometers by doing experimental work on suitable mineral pairs and appropriate substituting ions. Alternatively, the concordance of such temperature estimates with each other and concordance with other independent geothermometers (e.g., fluid inclusions) can be used to define conditions of chemical equilibrium in natural assemblages.

It should be emphasized that the use of partition coefficients in the geothermometry of natural assemblages is subject to certain restrictions (McIntire, 1963; Ghosh-Dastidar et al, 1970) which are:
(1) the substituting element $i$ follows either Raoult's Law or Henry's Law in both phases A and B, at least below certain levels of dilution. The solubilities of element $i$ are not affected by variations in concentration of other elements present in the two phases. However, correction for effects of this type can be carried out if they are well defined;
(2) the mineral phases were formed in chemical equilibrium;
(3) the distribution of element $i$ in phases $A$ and $B$ has not
been affected by post-depositional events (e.g., metamorphism);
(4) the atoms of element i substitute for atoms in phases $A$ and $B$ in their normal structural sites (i.e., substitution does not take place into interstitial sites in the host), and the substituting and host atoms are of the same charge.

## Previous Experimental Studies

The first experimental studies of partitioning between coexisting sulphides were carried out by Bethke and associates (Bethke et al, 1958; Bethke and Barton, 1959; Bethke, personal conmunication, 1967; Bethke and Barton, 1971). They investigated the distribution of $\mathrm{Cd}, \mathrm{Mn}$ and Se between sphalerite or wurtzite and galena over the temperature range from $600^{\circ}$ to $800^{\circ} \mathrm{C}$, and the distribution of Se between galena and chalcopyrite from $390^{\circ}$ to $595^{\circ} \mathrm{C}$. Mixtures between end members and/or binary solid solutions were reacted dry in evacuated silica glass tubes. The compositions of the resulting phases were analyzed by X-ray diffraction techniques using unit cell versus composition relationships. Cd and Mn were found to be strongly fractionated toward sphalerite or wurtzite relative to galena, and the fractionation sequence of Se was found to be: galena>chalcopyrite $>$ sphalerite. Ideal solid solution relationships apparently obtain in the systems which they considered, at least over the concentration ranges normally found in nature.

Pressure effects, calculated from molar volume data, were found to range from $+1^{\circ} \mathrm{C} /$ kilobar at $600^{\circ} \mathrm{C}$ to $-16^{\circ} \mathrm{C} /$ kilobar at $600^{\circ} \mathrm{C}$ in these systems, and were judged to be negligible.

Yund and Giletti (1964) investigated the partitioning of Zn between pyrite and galena at trace element levels. They synthesized the phases in evacuated silica glass tubes using $\mathrm{FeS}, \mathrm{Pb}$ or PbS and $S$ as the starting components. $\mathrm{Zn}^{65}$ was introduced as a radioactive tracer at two temperatures, $600^{\circ} \mathrm{C}$ and $700^{\circ} \mathrm{C}$. Two experiments were performed at each temperature to test for equilibrium. In one, $\mathrm{Zn}{ }^{65}$ was initially present in FeS; in the second, it was initially present in Pb (or PbS ). Zn was found to concentrate in galena, with a partition coefficient ( Zn in $\mathrm{PbS} / \mathrm{Zn}$ in $\mathrm{FeS}_{2}$ ) ranging from 52 to 303. Equilibrium conditions were apparently obtained.
H. D. Wright and several students at the Pennsylvania State University have approached the problem of partitioning in coexisting sulphides by using hydrothermal synthesis and radioactive tracer analytical techniques. They performed a long series of experiments to determine the solubility of a large number of elements, including $\mathrm{U}, \mathrm{Ag}, \mathrm{Sb}, \mathrm{Cu}, \mathrm{As}, \mathrm{Ga}, \mathrm{In}, \mathrm{Tl}, \mathrm{Hg}$, and Se in galena and sphalerite over a temperature range of about $300^{\circ}$ to $600^{\circ} \mathrm{C}$ (Halbig, 1965; Barnard, 1965; Wright, Barnard and Halbig, 1965; Hutta and Barnard, 1963; Hutta and Wright, 1964). Halbig (Halbig and Wright, 1969; Halbig, 1969) determined the partitioning of Se between sphalerite and galena by performing hydrothermal runs over a temperature range of $300^{\circ}$ to $650^{\circ} \mathrm{C}$, and dry silica tube runs at temperatures above $700^{\circ} \mathrm{C}$ at one atmosphere pressure. The relationship between
log $K$ and $1 / T\left(^{\circ} \mathrm{K}\right)$ was found to be linear for Se. However, Halbig's results are at variance with those of Bethke and Barton (1971). Halbig also determined the effect of pressure on the partition coefficient to be small.

## Partitioning Studies on Natural Sulphide Assemblages

The only detailed and systematic study of the distribution oftrace elements between coexisting minerals from sulphide deposits was carried out by Ghosh-Dastidar (Ghosh-Dastidar, Pajari and Trembath, 1970; Ghosh-Dastidar, 1969). The distribution of $\mathrm{CO}, \mathrm{Ni}$, $\mathrm{Ti}, \mathrm{Zn}, \mathrm{Bi}, \mathrm{Mn}, \mathrm{V}, \mathrm{Ga}, \mathrm{Ge}, \mathrm{In}, \mathrm{Cd}, \mathrm{Tl}, \mathrm{Pb}, \mathrm{Sn}, \mathrm{Cu}, \mathrm{Au}, \mathrm{Te}$ and As was determined by spectrochemical methods, in pyrite, pyrrhotite, chalcopyrite, sphalerite and magnetite from six sulphide occurrences in the Canadian Appalachian area, namely: (a) the Gull Pond and Rambler deposits of Newfoundland, and (b) four vein deposits (Oliver, Cameron, South Oliver and Letite) of the Mascarene Peninsula, New Brunswick. Plotting the concentrations of individual trace elements in mineral pairs resulted in distribution patterns ranging from linear through curvilinear to scattered. The majority of the distribution patterns were found to be curvilinear and scattered in character, indicating serious departures from the simple distribution law. Even in cases where the distribution patterns were linear, complexities (possibly due to differences in temperatures of formation of the various deposits) and inconsistencies were noted. The partition coefficient was observed to be dependent
on the element concentrations in either of the phases and/or the presence of other trace elements in the phases in a majority of the scattered and curvilinear distribution patterns, indicating the non-applicability of Henry's Law. Ghosh-Dastidar concluded that the presence of induced point imperfections may have been the effective cause of the deviation from Henry's Law in many cases. The importance of Ghosh-Dastidar's study is to point out the possible complexities involved in the application of experimental studies on the partitioning of elements between coexisting sulphides in natural assemblages. Deviations from ideal solution behaviour may in fact be very common even for trace constituents, and the interaction of trace elements must be assessed in order to establish a useful body of experimental data. Similar deviations from ideality have been noted, by Halbig and Wright (1969), by Kretz (1959, 1960, 1961), and by Hall et al, (1971).

Crystallographic and Chemical Considerations

Solubilities of Mn and Co in ZnS and $\mathrm{FeS}_{2}$ :
Kroger (1938; 1939) found that the maximum solubility of MnS in ZnS is about 52 mole per cent at $1180^{\circ} \mathrm{C}$ and 46 mole per cent at $900^{\circ} \mathrm{C}$. More recently, Bethke and Barton (1971) determined that a miscibility gap appears at about 50 mole per cent MnS between manganese-bearing wurtzite and alabandite (MnS). Skinner (1961) pointed out that wurtzite is stabilized relative to sphalerite by high concentrations of MnS. The amount of MnS required to stabilize
wurtzite decreases with increasing FeS content in ZnS . Bethke and Barton (1971) found that the limit of sphalerite stability is about 7 mole per cent MnS at $600^{\circ} \mathrm{C}$ in an iron free phase. The solubility of Mn in $\mathrm{FeS}_{2}$ is known to be low despite the fact that $\mathrm{MnS}_{2}$ (hauerite) is isostructural with pyrite. Fleischer (1955) gives the maximum concentration of Mn in pyrite from natural occurrences as $1 \%$.

Both experimental studies and studies on natural occurrences (Klerm, 1962, 1965; Straumanis et al, 1964; Springer et al, 1964; Riley, 1965, 1968) show that $\mathrm{CoS}_{2}$ and $\mathrm{FeS}_{2}$ may form a complete solid solution series. Hall (1961) determined the maximum solubility of $\operatorname{CoS}$ in ZnS to be 33 mole per cent at $850^{\circ} \mathrm{C}$.

The high solubility of FeS (up to 60 mole per cent) in ZnS (Barton and Toulmin, 1966) is well known and constitutes a complicating factor in these experiments. It is possible that variations of FeS in ZnS may have an effect on the concentration of MnS and $\operatorname{CoS}$ in ZnS , and thus would also affect partitioning coefficients. This point is discussed fully in a later section. The solubility of Zn in $\mathrm{FeS}_{2}$ is very low and can be neglected.

Substitutional Sites in ZnS and $\mathrm{FeS}_{2}$ :
$\mathrm{Zn}^{+2}$ is in four-fold (tetrahedral) coordination in both sphalerite (cubic) and wurtzite (hexagonal). It has been normally assumed, because of the high solubility of $\mathrm{Mn}, \mathrm{Fe}$ and Co in ZnS , that $\mathrm{Mn}^{+2}, \mathrm{Fe}^{+2}$ and $\mathrm{Co}^{+2}$ substitute for $\mathrm{Zn}^{+2}$ at tetrahedral sites in ZnS . However, ZnS also contains octahedrally coordinated
interstitial sites which are not usually occupied. Czamanske and Goff (1973) suggest that occupancy of these sites by metal ions is energetically unfavourable because they are tetrahedrally coordinated in sphalerite and octahedrally coordinated in wurtzite by near-neighbour metal ions. Manning (1967) suggested, on the basis of absorption spectra for sphalerite containing 6.15 weight per cent Fe , that Fe is distributed in sphalerite as $\mathrm{Fe}^{+2}$ in tetrahedral sites (substitutional) and as $\mathrm{Fe}^{+3}$ in octahedral sites (interstitial). He estimated the ratio of $\mathrm{Fe}^{+2} / \mathrm{Fe}^{+3}$ in the sphalerites studies to be about 10. His findings led to the idea that the $\mathrm{Fe}^{+2} / \mathrm{Fe}^{+3}$ ratio in sphalerite might be useful in determining the oxidation-reduction potential of hydrothermal solutions (paleo- $E_{h}$ ). Mössbauer spectroscopy on iron rich sphalerites, by Marfunin and Mkrtchyan (1967) and Scott (1971), showed that iron in sphalerite occurs as $\mathrm{Fe}^{+2}$ and is randomly distributed over tetrahedral (substitutional) sites. This conclusion is supported by Cabri's (1969) density measurements of synthetic iron-bearing sphalerites.

Octahedral coordination of $\mathrm{Co}^{+2}$ in pyrite is confirmed because of the complete solution between $\mathrm{CoS}_{2}$ and $\mathrm{FeS}_{2}$, the isostructural character of $\mathrm{CoS}_{2}$ (cattierite) and $\mathrm{FeS}_{2}$ (pyrite), and similar physical properties of the two compounds (Hulliger, 1968). It also seems to be a safe assumption that small amounts of $\mathrm{Mn}^{+2}$ are octahedrally coordinated in substitutional sites in pyrite because $\mathrm{MnS}_{2}$ (hauerite) is isostructural with $\mathrm{FeS}_{2}$ (pyrite).

Application of Crystal Field Theory:

A review of the ionic radii and electronegativities (Table 1), for $\mathrm{Mn}^{+2}, \mathrm{Co}^{+2}, \mathrm{Fe}^{+2}$ and $\mathrm{Zn}^{+2}$, indicates that the relative solubilities of $\mathrm{Mn}^{+2}, \mathrm{Co}^{+2}$, and $\mathrm{Fe}^{+2}$ in ZnS , and of $\mathrm{Mn}^{+2}$ and $\mathrm{Co}^{+2}$ in $\mathrm{FeS}_{2}$ cannot be explained by applying the now classical rules of Goldschmidt and Ringwood. In recent years, geochemists (Burns, 1970; Czamanske and Goff, 1973; Nickel, 1968, 1970) have used a more sophisticated approach, arystal field theory, to explain the differences in geochemical behaviour between transition-metal ions with similar oxidation states and ionic sizes.

Elements of the first transition series have varying numbers of electrons distributed in two groups of 3d orbitals, which are: (I) $t_{2 g}\left(d_{x y}, d_{y z}\right.$ and $\left.d_{x z}\right)$; (2) $e_{g}\left(d_{z^{2}}\right.$ and $\left.d_{x^{2}-y^{2}}\right)$. Each of the 3d orbitals may contain up to 2 spinpaired electrons. $t_{2 g}$ electrons may be thought of as forming lobes about a transition-metal ion which point between cartesian axes. Similarly, $e_{g}$ orbitals form lobes about the transition metal ion which point along cartesian axes. In an unperturbed state, these orbitals are degenerate (have the same energy). However, anions (ligands) arranged symmetrically about the transition-metal ion, may cause the orbitals to "split" due to repulsive, electrostatic interaction of the outer electrons of the cation and the ligands. That is, the relative energies of the $t_{2 g}$ and $e_{g}$ orbitals are dependent on the type, position and symmetry of the coordinating ligands relative to the cation. In addition, the character of this interaction is influenced by the distribution of electrons in the 3d orbitals of the cation (number of electrons, their symmetry, number of spin paired and

unpaired electrons, number of vacant orbitals). In other words, for a certain type of ligand (e.g., $\mathrm{S}^{-2}$ ), the most stable configuration (e.g., octahedral or tetrahedral) of the ligands about the cation is determined by the energy difference between the $t_{2 g}$ and $e_{g}$ orbitals and by the distribution of electrons in the five orbitals of the cation. The crystal field stabilization energy (CFSE) measures the combined effect of these two factors and is a direct measure of the relative stabilities of different ligand symmetries (Table 2).
$\mathrm{Mn}^{+2}$ and $\mathrm{Zn}^{+2}$ contain 5 and 10 3d electrons respectively. These electrons are spherically distributed about the ions so that $S^{2-}$ ligands are not stabilized in either an octahedral on a tetrahedral configuration (Table 2). The coordination of these two cations is determined by their ionic radius ratios relative to $S^{2-}$. The tetrahedral coordination of $\mathrm{Zn}^{+2}$ in sphalerite and wurtzite, and the occurrence of $\mathrm{Mn}^{+2}$ in both MnS (wurtzite structure) and $\mathrm{MnS}_{2}$ (octahedral coordination) is neatly explained in this way. Substitution of $\mathrm{Mn}^{+2}$ in ZnS causes strain in the ZnS structure because of its larger ionic radius (Table 1). This explains the limited solid solution of Mn in ZnS and also the stabilization of the wurtzite structure relative to the sphalerite structure by Mn . The CFSE's (Table 2) of both $\mathrm{Fe}^{+2}$ and $\mathrm{Co}^{+2}$ indicate a small preference to coordinate octahedrally with $S^{2-}$ ligands. However, this does not explain the marked tendency of these two ions to form strongly covalent disulphides. The magnetic properties and bond lengths of $\mathrm{FeS}_{2}$ and $\mathrm{CoS}_{2}$ show that $\mathrm{Fe}^{+2}$ and $\mathrm{Co}^{+2}$ occur in these compounds in low spin configuration (spin pairing in $t_{2 g}$ ), with $t_{2 g}$ electrons available for

Note: CFSE = crystal field stabilization energy for oxide structures
$\Delta=$ octahedral-site preference energy for oxide structures
The CFSE's quoted here apply in strict sense only to oxide structures. However, their
relative magnitudes are also applicable to sulphide structures (Burns, 1970, p.130).
extensive $\pi$ bond formation with $\mathrm{S}^{2-}$ (Burns, 1970, p.192). The close similarity of the bonding properties of $\mathrm{Co}^{+2}$ and $\mathrm{Fe}^{+2}$ explains the complete solid solution between $\mathrm{CoS}_{2}$ and $\mathrm{FeS}_{2}$. Magnetic studies on $\mathrm{MnS}_{2}$ indicate that $\mathrm{Mn}^{+2}$ has a high spin configuration. $\pi$ bond formation is minimal in $\mathrm{MnS}_{2}$ and its bonding is predominantly ionic (Burns, 1970, p. 190). The marked difference in the facility on $\mathrm{Mn}^{+2}$ and $\mathrm{Fe}^{+2}$ to form $\pi$ bonds explains the low solubility of Mn in $\mathrm{FeS}_{2}$.

The ionic radii (Table l) of $\mathrm{Co}^{+2}$ and $\mathrm{Fe}^{+2}$ are close to that of $\mathrm{Zn}^{+2}$. Also, the octahedral-site preference energy of both ions is small (Table 2). Therefore, extensive substitution of $\mathrm{Co}^{+2}$ and $\mathrm{Fe}^{+2}$ into tetrahedral sites in ZnS is allowed (Czamanske and Goff, 1973).

It has been found that bonding in ZnS is $80 \%$ ionic and $20 \%$ covalent in character (Title, 1965). This suggests that a discussion based on molecular orbital theory (Burns, 1970) would probably not change the conclusions very much.

Prediction of Partition Coefficients

An outline of the thermodynamic basis and importance of partition coefficients has already been given. A quantitative estimate of partition coefficients, and their variation with temperature and pressure, could be made using this thermodynamic schema. However, in this case, sufficient thermodynamic data are not available. A combination of crystal field theory and molecular orbital theory can be used for the rough prediction of partitioning in sulphides. Again,
quantitative estimates are, at present, impossible. There is, then, no feasible alternative to the experimental determination of partitioning coefficients.

## EXPERIMENTAL PROCEDURES

Fused Salt Techniques

Boorman (1966, 1967) and Schröcke (1958) demonstrated that the reaction rates for zinc and iron sulphides are considerably increased by the addition of suitable eutectic salt mixtures. In a study of the $\mathrm{ZnS}-\mathrm{FeS}-\mathrm{FeS}_{2}$ system, Boorman employed the salt systems $\mathrm{KCl}-\mathrm{LiCl}$ (eutectic at $358^{\circ} \mathrm{C}$; 41 mole per cent KCl ) and $\mathrm{NH}_{4} \mathrm{Cl}$-LiCl (eutectic at $267^{\circ} \mathrm{C}$; 50 mole per cent $\mathrm{NH}_{4} \mathrm{Cl}$ ) over a temperature range of 303 to $714^{\circ} \mathrm{C}$. He found that apparent equilibrium was attained in four to seven days at temperatures from 600 to $400^{\circ} \mathrm{C}$.

Fused salt techniques provide other experimental advantages (Boorman, 1966). They allow experimentation over an extended temperature range and the techniques are experimentally simpler than hydrothermal methods of crystal growth. In addition, a large number of metallic sulphides are at least moderately soluble in eutectic salt mixtures such as $\mathrm{KCl}-\mathrm{LiCl}$ and $\mathrm{NH}_{4} \mathrm{Cl}-\mathrm{LiCl}$ (Delarue, 1960, 1962). The salt systems mentioned above are chemically inert relative to the $\mathrm{ZnS}-\mathrm{FeS}$ system, and the salt components are not soluble in the various mineral phases of the $\mathrm{ZnS}-\mathrm{FeS}$ system to any significant extent. In short, they have a merely catalytic effect.

All experimental runs of this study were carried out using fused salt techniques. A KC1-LiCl eutectic mixture was employed
for runs at temperatures of $403,420,475,525,575,625$ and $675^{\circ} \mathrm{C}$. A $\mathrm{NH}_{4} \mathrm{Cl}$-LiCl eutectic mixture was employed for runs at a temperature of $305^{\circ} \mathrm{C}$. The length of the runs varied from 5 to 47 days.

It should be noted that the solubilities of the various sulphides of the study, particularly MnS and $\mathrm{CoS}_{2}$, in the fused eutectic salts, as well as the chemical character of such solutions, are unknown (Delarue, 1962). A considerable number of preliminary runs were performed in order to determine the amounts of MnS or $\mathrm{CoS}_{2}$ which had to be added to the sulphide charges in order to produce ZnS and $\mathrm{FeS}_{2}$ with detectable amounts of Mn or CO in both phases over a reasonably large concentration range.

Reagents

Pyrite was synthesized from polysulphide solution. A l. OM solution of $\mathrm{Na}_{2} \mathrm{~S} \cdot 9 \mathrm{H}_{2} \mathrm{O}$ was prepared to which was added 4 moles of sublimed S. The solution was stirred overnight, and became very dark brown, due to the formation of polysulphides $\left(S_{5}{ }^{2-}\right.$ ?). The solution was filtered to remove a small amount of undissolved $S$, and then was mixed with a solution containing one mole of $\mathrm{FeCl}_{2}$. A dark green gelatinous precipitate was formed immediately. The precipitate was heated for one day at $70^{\circ} \mathrm{C}$, and for an additional day at 93 to $98^{\circ} \mathrm{C}$. The precipitate settled out to a compact powder. The solution was decanted and a 2.0 M solution of NaOH was added to
dissolve the native $S$ precipitated at the same time as the pyrite. The solution was again decanted after stiming overnight. The pyrite was washed with distilled water followed by acetone. Subsequently, it was filtered and dried. An X-ray diffraction pattern for this material showed only diffuse peaks characteristic of pyrite. The broad form of the peaks, combined with microscopic examination of the precipitate, indicated the microcrystalline character of the pyrite.

Microcrystalline $\mathrm{CoS}_{2}$ was synthesized in a similar fashion from a polyshulphide solution. 2.0 moles of native $S$ were dissolved in a 1.0 M solution of $\mathrm{Na}_{2} \mathrm{~S} \cdot 9 \mathrm{H}_{2} \mathrm{O}$. A 1.0 M solution of $\mathrm{COCl}_{2} \cdot 6 \mathrm{H}_{2} \mathrm{O}$ was mixed with the polysulphide solution to produce a gelatinous, black precipitate. The precipitate was heated at $90^{\circ} \mathrm{C}$ for two days to promote recrystallization. It was decanted and a 2.0 M NaOH solution was added to dissolve any excess native $S$. The precipitate was washed with distilled water, followed by acetone, before filtering and drying. An X-ray diffraction pattern confirmed that the precipitate was microcrystalline $\operatorname{CoS}_{2}$.

A reagent grade, microcrystalline wurtzite $(\alpha-\mathrm{ZnS})$ was used in all runs. Its crystal structure was determined by X-ray diffraction.

The synthesis of MnS was effected by the mixing of $\mathrm{Na}_{2} \mathrm{~S} \cdot 9 \mathrm{H}_{2} \mathrm{O}$ and $\mathrm{MnCl}_{2} \cdot 4 \mathrm{H}_{2} \mathrm{O}$ solutions. A 1.2 M solution of $\mathrm{Na}_{2} \mathrm{~S}_{2} \cdot 9 \mathrm{H}_{2} \mathrm{O}$ was prepared and saturated with $\mathrm{H}_{2} \mathrm{~S}$ to limit hydrolysis reactions so as to maintain a maximum sulphide ion ( $\mathrm{S}^{2-}+\mathrm{HS}^{-}$) concentration in the aqueous solution, according to the equations:

$$
\mathrm{S}^{2-}+\mathrm{H}_{2} \mathrm{O} \leftrightharpoons \mathrm{HS}^{-}+\mathrm{OH}^{-}
$$

and

$$
\mathrm{HS}^{-}+\mathrm{H}_{2} \mathrm{O}=\mathrm{H}_{2} \mathrm{~S}+\mathrm{OH}^{-}
$$

A $1.0 \mathrm{M} \mathrm{MnCl}_{2} \cdot 4 \mathrm{H}_{2} \mathrm{O}$ solution was prepared and saturated with $\mathrm{H}_{2} \mathrm{~S}$ to reduce any $\mathrm{Mn}^{+3}$ ions to $\mathrm{Mn}^{+2}$. The solutions were mixed slowly with the evolution of $\mathrm{H}_{2} \mathrm{~S}$. A bright orange, curdy precipitate was instantly formed. The precipitate was heated at $70^{\circ} \mathrm{C}$ for two days to drive off residual $\mathrm{H}_{2} \mathrm{~S}$ and to recrystallize the precipitate. The precipitate settled in one day to a compact powder. It was decanted and washed with distilled water followed by acetone. The precipitate was then filtered and dried. X-ray diffraction methods indicated that the precipitate was $\beta-\mathrm{MnS}$ (wurtzite structure).
$\mathrm{KCl}-\mathrm{LiCl}$ and $\mathrm{NH}_{4} \mathrm{Cl}$ - LiCl eutectic salt mixtures were prepared from reagent grade materials by mixing the appropriate eutectic proportions of each component together. The mixtures were then fused, crushed and dehydrated ready for use.

Preparation And Heating Of Charges

Microcrystalline ZnS and $\mathrm{FeS}_{2}$ were mixed thoroughly in the mole ratio of $1: 1$. Batches of sulphide reactant were prepared in which MnS or $\mathrm{CoS}_{2}$ was present in amounts of from 0.2 to 40 weight per cent of the total sulphide $\left(\mathrm{ZnS}+\mathrm{FeS}_{2}+\mathrm{MnS}\right.$ or $\left.\mathrm{CoS}_{2}\right)$. An eutectic salt mixture was added to portions of these batches in a proportion varying from 1:1 to 1:4 (sulphide:eutectic salt mixture). The sulphide-eutectic salt
mixture charges were loaded in 6 mm (OD) Pyrex and Vycor tubes. The tubes were evacuated for 20 minutes with gentle heating (to eliminate residual moisture) prior to sealing.

The charges were heated in vertical tube furnaces, controlled to ${ }^{+} 5^{\circ} \mathrm{C}$. Runs were performed at eight temperatures, namely: 675, 625, 575, 525, 475, 420, 403 and $305^{\circ}$ C. Normally, six charges, representing a range in the amount of MnS or $\mathrm{CoS}_{2}$ present in the charge, were heated together at each temperature. Run times varied from 5 to 47 days. At the end of each run, the tubes were air quenched. The tubes were broken and the eutectic salt mixture was dissolved away with several washings of distilled water. The remaining run products, a loose assemblage of sulphide crystals, were washed with acetone and then allowed to dry.

## Run Products

Figure 2 is an example of the microcrystalline, sulphide reactant material prior to heating. The photograph illustrates that the grain size of the material is considerably less than one micron. Figure 3 shows the remarkable degree of recrystallization of the sulphides caused by heating at $575^{\circ} \mathrm{C}$ for a period of 21 days in a KCl -LiCl fused salt eutectic mixture.

The usually discrete, sulphide crystals were anhedral to euhedral in character, showed very little intergrowth, and were usually in the order of tens of microns in size. Difficulties were encountered with runs of $400^{\circ} \mathrm{C}$ and below because the grain size of the run products approached one micron in size, the limit of resolution for analysis

Figure 3
by the electron microprobe. Sphalerite crystals were light amber in colour and tetrahedral in form, with cubic and dodecahedral modifications. The crystals were nomally clear of inclusions, but they occasionally contained fine, dusty inclusions of pyrite at their centres, and a few, larger, discrete grains of pyrite (Figure 3). Wurtzite, when present, was tabular in form. Pyrite occurred as pyritohedrons, with rare inclusions of sphalerite or wurtzite.

All mun products were checked by X-ray diffractometer methods (Cu - K $\alpha$ radiation), using smear mounts, for the presence of sphalerite or wurtzite (stabilized by the inclusion of MnS ), and for the presence of extra phases. No attempt was made to identify polytypes of ZnS in the run products since in all cases, the grain size was too small for single crystal X-ray diffraction techniques (Scott, 1968; Scott and Barnes, 1972).

One interesting sidelight of this study was the formation of salt inclusions, complete with vacuoles, within ZnS crystal.s (Figure 4). They appear to be entirely analogous to fluid inclusions in such minerals as quartz and calcite (Roedder, 1967). The inclusions were not commonly present, and in fact, were observed only in some abnormally large crystals formed in one run at $575^{\circ} \mathrm{C}$. The salt inclusions could theoretically, be used as a means of internal temperature calibration of the runs by determining the filling temperatures of the salt inclusions with a heating stage. Unfortunately, a heating stage capable of reaching $575^{\circ} \mathrm{C}$ safely was not available and so this idea could not be checked.

Figure 4: Salt inclusions in sphalerite crystal, formed at $575^{\circ} \mathrm{C}$. Note vacuoles within inclusions. Unpolished grain mount. Reflected light. In oil. X390.

Figure 4

## Chemical Equilibrium

The definition of equilibrium conditions in any experimental environment is difficult. The classical method of ensuring that experimental results represent a condition of chemical equilibrium is by approaching equilibrium from two different and independent directions. In many systems, this procedure is not technically feasible (for example, Boorman's (1967) work on the so-called sphalerite geothermometer), since the rates of reaction for runs involving unmixing may be very slow (Barton et al, 1963). In this study, reactions have been run in only one direction. However, three other criteria of equilibrium conditions have been used, namely:
(1) pronounced recrystallization of the sulphide charge;
(2) sharp peaks in the X-ray diffractometer patterns of the run products
(3) intra- and inter-crystalline chemical homogeneity of the run products (e.g., no zonation of sphalerite).

All of these are indicative of chemical equilibrium, but only in a permissive sense.

The first two criteria were easily and routinely tested. Of the three criteria, chemical homogeneity of the run products is the most important and the most difficult to check. This criterion was tested in two ways. Several electron microprobe scanning images (Figures 5 and 6) were completed of the various run products. In most cases no obvious zonation of the phases was observed. The most common inhomogeneities detected by this method were discrete inclusions of

Figure 6
other phases in single crystals (Figure 5). The application of statistical methods on the analytical data to test for chemical homogeneity of the phases in each run is discussed fully below.

## ANALYTICAL METHODS

## Analytical Conditions

All analyses were carried out on an Applied Research Laboratories electron microprobe X-ray analyzer (Model EMX - SM) in the Department of Materials and Metallurgical Engineering at the University of Michigan. A beam, normal to the specimen surface, focussed to a size of $l \mu$ or less in diameter, and with a potential of 15 KeV , was employed. The X-ray take-off angle of this instrument is fixed at $52.5^{\circ}$. Pulses were counted for fixed times ranging from 10 to 100 seconds. Beam current was monitored by means of a sensitive microammeter, and it was kept constant at from 1.0 to $1.2 \mu \mathrm{~A}$. Sample currents were found to be approximately 0.04 to $0.06 \mu \mathrm{~A}$.

Pure metallic standards were used in the analysis of Mn, Co and Zn , in addition to synthetic MnS and ZnS . Pure metallic Fe and a large euhedral pyrite crystal from Gilman, Colorado were used as standards for Fe. Both the metallic and the sulphide standards gave essentially the same results.

Both the samples and standards were mounted in polyester resin and were polished with $5 \mu$ and $1 \mu$ diamond paste, and finally $0.25 \mu$ carborundum on nylon covered laps. The standards and samples were coated simultaneously with a light film of carbon to ensure conductivity.

Counts were taken on the $\mathrm{K} \alpha$ peaks of $\mathrm{Mn}, \mathrm{Co}, \mathrm{Fe}$ and Zn . Pulse height discrimination of the peaks effected a lowering of the
background and the elimination of possible interferences by high order lines. Background counts were taken on both sides of the $K_{\alpha}$ peaks, on both standards and samples. All sample counts were bracketed by counts on each of the standards to provide an effective drift correction.
$S$ was not determined directly. Sulphur concentration was calculated by the stoichiometry of ( $\mathrm{Zn}, \mathrm{Fe}, \mathrm{Mn}, \mathrm{Co}$ ) S and ( $\mathrm{Fe}, \mathrm{Zn}$, $\mathrm{Mn}, \mathrm{Co} \mathrm{S}_{2}$.

Correction Procedures

The raw probe data were corrected by means of two computer programs, Probe 1 and Probe 2, written in the Fortran IV language. Both programs are extensive revisions of programs developed by Frazer, Fitzgerald and Reid (1966) at the Scripps Institution of Oceanography. The first program, Probe l, corrects probe data for background, deadtime and drift, and by comparing sample counts with the appropriate readings on standards, calculates initial probe ratios. The second program, Probe 2, corrects the data for the effects of absorption, fluorescence and atomic number.

Background Correction:

Bombardment by high energy electrons (Keil, 1967) produces both continuous radiation and characteristic X-rays. The continuous
radiation is directly proportional to the accelerating potential, the electron beam current and the average atomic number of the target. Small contributions to background are caused by cosmic rays, scattered X-rays and electrons, circuit noise and fluorescence radiation produced in the diffracting crystal. Backgrounds were measured on both sides of the $\mathrm{K} \alpha$ peaks for both standards and samples. These readings were averaged and subtracted from the appropriate counts on peaks. Accurate background readings were found to be essential for elements in low concentration.

Deadtime Correction:

Deadtime constants ( $\tau$ ) were determined for each element by measuring count rates on standards over a range of sample currents. Counts per second ( $N$ ) were divided by sample current ( $i_{S}$ ) and a linear function between these values ( $N / I_{S}$ ) and sample current ( $i_{S}$ ) was calculated by means of a least-squares technique incorporated in the Probe 2 program as a subroutine. This is the same as fitting the counts per second values with a parabola of the form $A i_{s}+B i_{S}{ }^{2}=0$, where $\tau=-B / A^{2}$ (Frazer et al, 1966).

Deadtime constants ( $\tau$ ) were found to be $0.6,2.8,0.9$ and 1.0 microseconds for $\mathrm{Co} \mathrm{K} \alpha, \mathrm{ZnK} \alpha, \mathrm{MnK} \alpha$, and FeK radiation, respectively. The deadtime correction was applied through the relation

$$
N=N^{\prime} /\left(1-N_{\tau}^{\prime}\right)
$$

where $N^{\prime}$ is the observed count rate and $N$ is the true count rate.

Drift Correction:

All sample readings were bracketed by standard readings. A linear drift curve was calculated by program Probe 1 and counts on samples wene corrected according to the time each count was taken relative to the beginning of counting for each element.

Absorption Correction:

The absorption correction accounts for the loss of intensity of characteristic X-rays by interactions with sample atoms along the path from their point of origin to the surface of the sample (Keil, 1967). Philibert's (1963) formula for $f(x)$ was used to calculate absorption correction factors:

$$
f(x)=\frac{1+h}{(1+x / \sigma)[1+h(1+x / \sigma)]}
$$

In this expression:
(1)

$$
\begin{aligned}
h= & 1.2 \sum_{i} a_{I} A_{I} /\left(\sum_{i} a_{i} Z_{i}\right)^{2} \\
\text { where } a_{i}= & \text { the atomic fraction } \\
A_{i}= & \text { the atomic weight and } \\
Z_{i}= & \text { the atomic number of } \\
& \text { element } i \text { in } \\
& a \text { composite target. }
\end{aligned}
$$

(2)
$\left.x=(\mu /)_{\rho}\right) \operatorname{cosec} \theta$
where $\left./_{\rho}=\sum_{i} C_{i}(\mu /)_{\rho}\right)_{i}$
and $C_{i}=$ weight $\%$ of element $i$
$\theta=$ take-off angle of emitted radiation,
$\quad$ in this case $52.5^{\circ} . \quad(\mu /)_{i}=$ the mass absorption coefficient of element $i$ for the $X$-ray line used in the analysis.
(3)

Heinrich's expression for $\sigma$ was used (Goldstein and Comella, 1969, p.10) and is:

$$
\sigma=\frac{4.5 \times 10^{5}}{E_{0}^{1.65}-E_{C}^{1.65}}
$$

where $E_{0}=$ the operating voltages of the electron beam in KeV $E_{C}=$ the excitation potential of the analyzed element in KeV .

It should be noted that all mass absorption coefficients were calculated in the Probe 2 program using a set of equations proposed by Frazer (1967). This method calculates mass absorption coefficients which are essentially the same as those given by Heinrich (1966). An attempt was made to analyze Zn by means of an $\mathrm{L} \alpha$ line, using Frazer's equation to determine mass absorption coefficients for $\mathrm{Zn} \mathrm{L} \alpha$ by extrapolation. The resulting analytical data were found to be seriously
in error due to a gross overcorrection for absorption.

Fluorescence Correction:

The intensity of the analytical line of one of the elements in a sample is enhanced when the wavelength of a characteristic line from one of the other elements in the sample is shorter than the absorption edge of the analyzed element. The ratio $(\gamma)$ of intensity due to secondary fluorescence to the intensity of primary radiation was calculated for $\mathrm{K}-\mathrm{K}, \mathrm{K}-\mathrm{L}, \mathrm{L}-\mathrm{K}$ and $\mathrm{L}-\mathrm{L}$ interactions using the formula of Reed (1965). This formula is:

$$
\gamma=0.5 P_{i j} C_{B}\left(\frac{r_{A}-1}{r_{A}}\right) W_{B} \frac{A^{\prime}}{B^{\prime}}\left(\frac{U_{B}-1}{U_{A}-1}\right)^{1.67} \frac{\mu_{B}^{A}}{\mu_{B}}\left(\frac{\ln (1+x)}{x}+\frac{\ln (1+y)}{y}\right)
$$

where $A=$ analyzed element
$B=$ element causing secondary fluorescence of $A$
$C_{B}=$ mass concentration of element $B$
$r_{A}=$ absorption edge jump ratio of element $A$
$W_{B}=K$ or $L$ shell fluorescence yield of element $B$, given by $W=Z^{4} /\left(a+Z^{4}\right)$, with $Z=$ Atomic number of element $B$ and $a=1.02 \times 10^{8}$ for $K$ shell
$A^{\prime}$ and $B^{\prime}=$ atomic weights of elements $A$ and $B$ $\mathrm{U}_{\mathrm{A}}=$ the overvoltage ratio, ${ }^{\mathrm{Eo} /{ }_{E c} \text { for element } \mathrm{A}}$
$U_{B}=$ the overvoltage ratio, Eo/Ec for element $B$
$\mu_{B}^{A}=$ the mass absorption coefficient of element $A$ for radiation from element $B$
${ }_{4}^{\mu}=$ the mass absorption coefficient of the specimen.
for radiation from element $B$
$x=\left(\mu_{A} / \mu_{B}\right) \operatorname{cosec} \theta$, with $\mu_{A}=$ the mass absorption coefficient of the specimen for radiation from element $A$
$y=\sigma /_{\mu_{B}}$, with $\sigma=$ the electron mass absorption coefficient
$P_{i j}$ is a constant whose value depends upon the type of interaction ( $\mathrm{K}-\mathrm{L}, \mathrm{L}-\mathrm{K}, \mathrm{K}-\mathrm{K}, \mathrm{L}-\mathrm{L}$ ) was considered. For $\mathrm{K}-\mathrm{K}$ and $\mathrm{L}-\mathrm{L}$ interactions, $P_{K K}=P_{L L}=1$. For $K-L$ and $L-K$ interactions, $P_{\mathrm{KL}}=0.24$ and $\mathrm{P}_{\mathrm{LK}}=4.2$.

No corrections were made for secondary fluorescence caused by $K_{\beta}$ or $L_{\beta}$ lines, or for secondary fluorescence due to continuous radiation. Both of these effects are usually negligible (Reed, 1965; Springer, 1967).

In this study $\mathrm{Zn} \mathrm{K} \alpha$ caused enhancement of Mn , Co and $\mathrm{Fe} \mathrm{K} \alpha$ lines.

Atomic Number Correction:

Electron backscattering and electron retardation depend upon the average atomic number of the target (Keil, 1967). These effects lead to analytical values which are too low for heavy elements in a light matrix and too high analytical values for light elements in a heavy matrix.

An atomic number correction was calculated by means of a method described by Duncumb and Reed (1968). The loss of ionization efficiency due to backscattering ( $\mathrm{R}_{\mathrm{i}}$ ) was calculated for each element using a set of polynomial equations given by Duncumb and Reed (1968). The fraction of the total energy loss of an electron going into the ionization of a particular shell ( $S_{i}$ ) in a specific element ( $i$ ) is given by the equation:

$$
S_{i}=\frac{Z_{i}}{A_{i} \ln \left[\frac{1.166 \times 10^{3}\left(\frac{E_{0}+E_{c}}{2}\right)}{J_{i}}\right]}
$$

where $E O=$ the operating voltage in keV
Ec = the excitation voltage of the X-ray line of interest in keV
$Z_{i}=$ atomic number of element $i$
$A_{i}=$ atomic weight of element $i$
$J_{i}=$ mean ionization potential for element $i$
For a multielement sample, an average $R$ and $S$ are calculated by:

$$
\begin{aligned}
\bar{R} & =\sum_{i} C_{i} R_{i} \\
\text { and } & \bar{S}
\end{aligned}=\sum_{i} C_{i} S_{i}
$$

where $C_{i}$ is the weight fraction for an element in the sample. The atomic number correction is effected by finding the ratio $\bar{R} / \bar{S}$ for the analyzed element in the sample and in its standard, and combining these two factors as shown below.

Combined Correction for Absorption, Fluorescence and Atomic Number:

The true concentration of an element in a sample ( $W_{i}$ ) was calculated by:

$$
W_{1}=c_{i} \times \frac{|\bar{R} / \bar{S}|_{s t}}{|\bar{R} / \bar{S}|_{\text {sa }}} \times \frac{\left|f(x)_{i}\right|_{\text {st }}}{\left|f(x)_{i}\right|_{\text {sa }}} \times \frac{\left(1+\left.\gamma_{i}\right|_{\text {st }}\right.}{\left|1+\gamma_{i}\right|_{\text {sa }}}
$$

$C_{i}$ is the initial estimate (probe ratio) of element $i$ in the sample, or the most recently calculated concentration of element $i$. The subscripts st and sa refer to correction factors for standand and sample. The true concentration of element $i$ was calculated by an iterative procedure in which the most recently calculated concentration of each element was used in the calculation of the correction factors. Iteration was continued until the change in concentration between consecutive iterations for all elements present in concentrations greater than $1 \%$ was less than $0.001 \%$. The correction procedure was usually completed within three to four iterations.

Analytical Accuracy

The accuracy of the correction procedures of the computer program, Probe 2, was checked by running a test problem (Goldstein and Comella, 1969, p.48) for a silicate analyzed using K - alpha lines at 20 KeV with a take-off angle of $52.5^{\circ}$ (Table 3). The two sets of final

| 0 | 43.78 | 45.0 | 44.57 |
| Total | 98.38 | 100.91 | 99.89 |

Note: The compositions of the six silicate standards used in this problem are given by Goldstein and Comella (1969, p.69).
calculated compositions show very close agreement, with program Probe 2 giving slightly lower calculated compositions for most elements, but a better analytical total ( $99.89 \%$ for program Probe 2 compared with $100.91 \%$ given by Goldstein and Comella).

The accuracy of the whole analytical procedure has been estimated by determining the compositions of a series of Bolivian sphalerites (Table 4) which had been analyzed by atomic absorption and X-ray diffraction techniques (Kelly and Turneaure, 1970, p.635). Grain mounts were made and three grains per mount were analyzed. Ccunting was done on two points in each grain to test for within-grain homogeneity. The electron microprobe data indicate that the distributions of Fe and Mn in the sphalerites are sufficiently uniform so that comparisons may be made with the atomic absorption and X-ray diffraction analyses. Both the quantitative data and semiquantitative scans indicate no marked zonation of either Fe or Mn . Considering that the electron microprobe analyses were carried out on a limited number of individual grains, whereas the atomic absorption analyses were done on bulk samples, the two methods are in good agreement for both MnS and FeS. The X-ray diffraction data for FeS are consistently higher, by as much as 7.1 mole $\% \mathrm{FeS}$, than the equivalent electron microprobe data. The positive error is caused by expansion of the sphalerite unit cell by Mn and Cd (Kelly and Turneaure, 1970, p.635).

Another measure of accuracy is provided by the analytical totals derived during routine analysis. Analytical totals were found to range from 95.0 to 105.7 per cent, with a mean of $100.4 \%$ and a standard deviation of $2.0 \%$ of the mean. The scatter of analytical totals increased due to the fact that $S$ was determined stoichiometrically.

Any error in the estimation of $\mathrm{Mn}, \mathrm{Co}, \mathrm{Fe}$ or Zn is magnified by the calculation of $S$ content. The analytical totals of this study compare favourably with those found by Williams (1967, p. 490) for the electron microprobe analysis of 50 sphalerites. His analytical totals ranged from 95.6 to $104.2 \%$, with a mean of 99.7 and a standard deviation of 2.1\% of the mean. S was determined stoichiometrically by Williams.

## Sensitivity

In this study, sensitivity is defined as the concentration of an element which produces a peak equal to three times the standard deviation of the background. Sensitivities have been calculated by means of a formula provided by Norrish and Chappell (1967, p. 204).
Lower limit of detection $=\frac{6}{m} \sqrt{\frac{C b}{T}}$
where $m=$ the number of counts per second obtained per unit of concentration for the element, $\mathrm{c}_{\mathrm{b}}=$ background counts per second, and $\mathrm{T}=$ counting time in seconds. For typical counting rates of this study, using a 100 second counting time, the calculated sensitivities for Mn , $\mathrm{CO}, \mathrm{Fe}$, and Zn are 75,7095 and 520 ppm respectively.

## Partitioning Of Mn Between Sphalerite Or Wurtzite And Pyrite

The analytical data for all sphalerite - or wartzite-pyrite pairs containing Mn are listed in Appendices I and II in terms of mole percent. The runs are in order of temperature from 675 to $305^{\circ} \mathrm{C}$. The concentration of MnS in sphalerite or wurtzite varies from very low levels to about 42 mole percent. The concentration of FeS is fairly constant. Most analyses fall within the range of 2 to 10 mole percent FeS. There is a slight increase in FeS to 16 mole percent at $675^{\circ} \mathrm{C} . \mathrm{MnS}_{2}$ in pyrite is usually less than 1 mole percent. $\mathrm{ZnS}_{2}$ in pyrite was found to be low at 1 mole percent or less, a concentration probably too low to affect the partitioning of Mn.

Homogeneity Of Run Products:

As mentioned previously, an important criterion of chemical equilibrium is homogeneity of the run products. Several electron microprobe scanning images of both sphalerite and wurtzite showed no obvious zonation of Mn and Fe in either polymorph. However, because of the common growth zoning present in sphalerite from natural occurrences (Barton et al, 1963) and because of the iron-rich "patches" in hydrothermally synthesized sphalerites found by Scott and Barnes (1972), a more accurate test of homogeneity was carried out on the sphalerite and wurtzite run products. In the analysis
of 32 of the runs, counts were taken on two distinct points in each of the crystals. One - way analysis of variance (Snedecor and Cochran, 1967, chapter 10) indicated that the within - crystal variation of both MnS and FeS is much less than the between - crystal variation at the $99 \%$ level of confidence. In general, then, both MnS and FeS are homogeneously distributed within the sphalerite and wurtzite crystals. Electron microprobe scanning images of the distribution of Mn within pyrite crystals showed no obvious zonation of the crystals. Because of the low concentration of $\mathrm{MnS}_{2}$ in the pyrite crystals, this cannot be taken as a discriminating test. The Mn analyses for each phase in each run were tested for between - crystal homogeneity by a statistical method (Dixon and Massey, 1957, p.276) designed to detect extreme values in a group of data. For a group of $k$ analyses, $x_{1}, x_{2}, \cdots-\ldots, x_{k}$, which are ranked in order of magnitude, the statistic:

$$
r_{10}=\frac{x_{2}-x_{1}}{x_{k}-x_{1}}
$$

where $x_{2}-x_{1}=$ the difference between the maximum on minimum value and the next highest or lowest value and

$$
\begin{aligned}
x_{k}-x_{1}= & \text { the difference between the maximum and } \\
& \text { minimum value }
\end{aligned}
$$

is a measure of the deviation of the minimum or maximum value from the whole group of analyses. Ratios of this type were calculated and compared with a set of critical values tabulated by Dixon and

Massey (1957, Table 8e, p.412) for the $95 \%$ confidence level for $k$ observations. Ratios higher than the appropriate critical value were taken to indicate that the phase, in the particular run considered, contains extreme concentrations of Mn and must be considered to be heterogeneous. In cases where duplicate analyses were performed at different spots on single crystals, the duplicate analyses were averaged before this test was performed. Phases found to be heterogeneous by this method are marked in Appendices I and II. The results of the corresponding runs were not used in the determination of partition coefficients.

Consideration was given to the use of Boyd's (1969) "homogeneity index" which tests the statistical fit of the distribution of a group of X-ray counts to the Poisson distribution. That is, if the variation in counts for a particular group of crystals follows the Poisson distribution, the apparent chemical variation among the crystals is due solely to counting errors. Boyd's index has two drawbacks. It is not a sensitive test for elements at the trace element level. Secondly, it makes the a priori assumption that the only permissible component of variation in a group of analyses must be due to counting errors. This latter assumption seems restrictive and would probably lead to the rejection of potentially meaningful data.

The occurrence of heterogeneities of the type detected in the data may have several causes. Extreme values of Mn in sphalerite, wurtzite or pyrite may reflect incomplete mixing of MnS in the original sulphide charge, particularly at high concentrations of

MnS. Heterogeneities in runs at $305^{\circ} \mathrm{C}$ (e.g. run 200) are probably due to lack of reaction. Anomalously low concentrations in crystals from runs at other temperatures could indicate the presence of urreacted or partially reacted material. High concentrations of $\mathrm{ZnS}_{2}$ in pyrite (greater than 1.5 mole percent) may be caused by micro-inclusions of sphalerite or wurtzite in pyrite, and should be accompanied by a corresponding increase of $\mathrm{MnS}_{2}$ in the same pyrite crystals. This is apparently what has happened in a few of the runs (e.g. mun 138, Appendix II), in spite of the fact that pains were taken to avoid all inclusions during the microprobe analyses. An error of this type would cause anomalously low partition coefficients for the runs involved. To further investigate this point, a rank correlation coefficient (Snedecor and Cochran, 1967, p.194) was calculated for the $\mathrm{ZnS}_{2}$ and $\mathrm{MnS}_{2}$ analyses in pyrite. The rank correlation coefficient was found to be non-significant at the 95\% confidence level, indicating that contamination of this sort is not a common problem. Finally, apparent heterogeneities may result from the relatively high errors inherent in measuring $\mathrm{MnS}_{2}$ in pyrite at low concentrations.

Distribution Of Mn Between Sphalerite Or Wurtzite And Pyrite:

The distribution of Mn in sphalerite - or wurtzite-pyrite pairs for seven different temperatures, from 675 to $403^{\circ} \mathrm{C}$, is shown in Figures 7 to 13 . The error bars about each point in these diagrams represent the variation of MnS in sphalerite or wurtzite

Figure 7: Partitioning of Mn between sphalerite or wurtzite and pyrite at $675^{\circ} \mathrm{C} .0=$ sphalerite. $\bullet$ wurtzite.

Figure 8: Partitioning of Mn between sphalerite or wurtzite and pyrite at $625^{\circ} \mathrm{C} .0=$ sphalerite. $\cdot$ = wurtzite.

Figure 13: Partitioning of Mn between sphalerite or wurtzite and pyrite at $403^{\circ} \mathrm{C} .0=$ sphalerite $\cdot \bullet$ wurtzite.
and of $\mathrm{MnS}_{2}$ in pyrite as $\pm$ lo. If no error bar is present about a point, the value of $\pm l \sigma$ was found to be too small to plot. No diagram has been plotted for runs at $305^{\circ} \mathrm{C}$ because a reasonable approach to chemical equilibrium was probably not attained in any of the runs at this temperature.

A partition coefficient, $\mathrm{K}_{\mathrm{ZnS}}^{\mathrm{Mn}} \mathrm{FeS}_{2}$, for each temperature has been estimated by linear regression (Krumbein and Graybill, 1965, p.240; Snedecor and Cochran, 1967, p.166), according to the model:

$$
y=b X+e
$$

In this case:

$$
\begin{aligned}
& \mathrm{Y}=\text { concentration of } \mathrm{MnS} \text { in sphalerite or wurtzite } \\
& \mathrm{X}=\text { concentration of } \mathrm{MnS}_{2} \text { in pyrite } \\
& \mathrm{b}=\mathrm{K}_{\mathrm{ZnS}}^{\mathrm{Mn}}: \mathrm{FeS}_{2} \\
& \mathrm{e}=\mathrm{a} \text { normally distributed random erron in } \mathrm{Y} .
\end{aligned}
$$

It is assumed in this model that the calculated line passes through the origin of the diagram. The slope of such a line is $K_{\mathrm{ZnS}}^{\mathrm{Mn}}: \mathrm{FeS}_{2}$ and is an estimate of the mean value of the partition coefficients for all sphalerite - or wurtzite-pyrite pairs at a specific temperature. The calculated values of $\mathrm{K}_{\mathrm{ZnS}}^{\mathrm{Mn}}: \mathrm{FeS}_{2}$ are given on the appropriate distribution diagrams (Figures 7 to 11 and 13) along with the standard deviations of their estimates. No value of $K^{\mathrm{Mn}} \mathrm{ZnS}: \mathrm{FeS}_{2}$ was calculated for runs at $420^{\circ} \mathrm{C}$ (Figure 12 ) since the remaining data points do not represent a sufficiently large range of concentration of Mn .

The statistical fit of the data points in each distribution diagram (Figures 7 to 11 and 13) to a straight line passing through the origin was tested by calculating a linear correlation coefficient, $r$, according to a method described by Krumbein and Graybill (1965, p.240). At each temperature considered, the value of $r$ was found to be significantly different from zero at the $95 \%$ confidence level, indicating that there is a statistically significant linear relationship between MnS in sphalerite or wurtzite and $\mathrm{MnS}_{2}$ in pyrite and that the calculation of $\mathrm{K}_{\mathrm{ZnS}}^{\mathrm{Mn}} \mathrm{FeS}_{2}$ is justified since Herry's Law is at least approximated in both phases over the range of concentrations considered.

Wurtzite is apparently stabilized relative to sphalerite by concentrations of MnS between 5 and 10 mole percent and there is very little variation with temperature of the amount of MnS required to stabilize wurtzite. This is in agreement with the work of Bethke and Barton (1971, p.149). The change from sphalerite to wurtzite is probably transitional in character due to : (1) within run variation in the concentration of MnS in ZnS ; and (2) the possible presence of polytypes which cannot be identified except by single-crystal X-ray diffraction methods. These effects may have led to the misclassification of some runs as either sphalerite or wurtzite runs.

No distinction has been made in the calculation of $\mathrm{K}_{\mathrm{ZnS}}^{\mathrm{Mn}}: \mathrm{FeS}_{2}$ between sphalerite-pyrite and wurtzite-pyrite pairs since there is no clustering of the sphalerite-pyrite as opposed to the wurtzitepyrite data points in the distribution diagrams. A clustering of
this sort would mean that different straight lines could be calculated for the partitioning of Mn between sphalerite-pyrite and wurtzitepyrite, and as a consequence, different partition coefficients ( $\mathrm{K}_{\mathrm{Sp}: \mathrm{Py}}^{\mathrm{Mn}}$ and $\mathrm{K}_{\mathrm{Wz}: \mathrm{Py}}^{\mathrm{Mn}}$ ) would be calculated at each temperature. Bethke and Barton (1971) describe an effect similar to this for the partitioning of Cd and Mn between sphalerite-galena and wrotzitegalena. They concluded that the character of the polymorph of ZnS significantly affects partitioning behaviour, and that polytypism in natural sphalerites would significantly affect temperature estimates. This phenomenon has not been demonstrated here.

Variation of $\mathrm{K}_{\mathrm{ZnS}: \mathrm{FeS}_{2}}^{\mathrm{Mn}}$ With Temperature :
A plot of $\log \mathrm{K}_{\mathrm{ZnS}}^{\mathrm{Mn}}: \mathrm{FeS}_{2}$ versus $10^{3} / \mathrm{T}\left({ }^{\circ} \mathrm{K}\right)$ is given in Figure 35 in terms of mole percent. The error ( $\pm \mathrm{l} \mathrm{\sigma}$ ) in determining $\mathrm{K}_{\mathrm{ZnS}: \mathrm{FeS}_{2}}$ at each of the six temperatures is shown as an error bar.

Two things are inmediately apparent. The partition coefficients are in the order of $10^{2}$, denoting a strong selective uptake of Mn in sphalerite or wurtzite relative to pyrite. Secondly, there is a slight but distinct increase of the partition coefficient with temperature. The statistical significance of the variation of $\log K_{\mathrm{ZnS}: \mathrm{FeS}_{2}}^{\mathrm{Mn}}$ versus $10^{3} / \mathrm{T}\left({ }^{\circ} \mathrm{K}\right)$ has been tested by linear regression. The linear equation representing the variation among these data is:

$$
\log K_{\mathrm{ZnS}: \mathrm{FeS}_{2}}^{\mathrm{Mn}}=2.828-\frac{735.1}{\mathrm{~T}(\circ \mathrm{~K})}(\text { mole } \%) .
$$

The corresponding linear correlation coefficient is -0.773 , a value which is significant at the $90 \%$ confidence level and which
indicates a significant linear relationship between $\log K_{\mathrm{ZnS}}^{\mathrm{Mn}} \mathrm{FeS}_{2}$ and $10^{3} / \mathrm{T}$.

Using the $\log K_{\mathrm{ZnS}: \mathrm{FeS}_{2}}^{\mathrm{Mn}}$ versus $10^{3} / \mathrm{T}$ line plotted in Figure 35 for the determination of the temperature of formation of a natural sphalerite-pyrite assemblage, assuming an analytical error of $\pm 10 \%$ would result in an error of $\pm 50^{\circ} \mathrm{C}$ at $500^{\circ} \mathrm{C}$ in the temperature estimate. This is a rather large erron and it is a reflection of the low slope of the line. In addition, at expected concentrations of Mn in natural sphalerites ( 1000 to 2000 ppm ), the concentration of Mn in coexisting pyrite would be about 10 to 20 ppm , a concentration too low for measurement with an electron microprobe. This would necessitate chemical analysis of pyrite by a more sensitive method (e.g. atomic absorption), with the attendant problems of phase separation and sample purity. It is tempting to extrapolate the line to temperatures outside the experimental range. However, there is no basis for assuming that $\overline{\Delta H}$ (partial molar enthalpy of reaction) and therefore the slope of the line is constant beyond the range of temperatures considered. In surmary, these data may be useful for both rough determinations of temperature of formation for natural sphalerite-pyrite assemblages and as a means of detecting and defining conditions of chemical equilibrium in such assemblages.

Interaction Of MnS and FeS In Sphalerite Or Wurtzite:

One of the major assumptions in partitioning theory is that changes in composition of either of the phases involved does not influence the partitioning of the element common to both phases. FeS is a very common constituent of both sphalerite and wurtzite and its concentration ranges up to about 60 mole percent. It is reasonable to assume that there may be an interaction of MnS and FeS in sphalerite or wurtzite. This is a particularly important consideration in view of the strong influence of total pressure on the FeS content of sphalerite (Scott and Barnes, 1972). An interaction of this type would almost certainly cause the partition coefficient for Mn to be sensitive to changes in total pressure.

To test for interaction of MnS and FeS in sphalerite or wurtzite, mole percent FeS has been plotted against mole percent MnS for sphalerites and wurtzites for each point analyzed in all of the runs at each of the eight temperatures (Figures 14 to 21). A correlation coefficient (Snedecor and Cochran, 1967, chapter 13) was calculated between MnS and FeS for all sphalerite and wurtzite analyses at each temperature. In no case were the correlation coefficients found to be significant at the $95 \%$ level of confidence. No interaction of FeS and MnS is evident at any of the run temperatures. It should be noted that the amount of FeS in sphalerite or wurtzite does not vary widely in any of the runs and the apparent lack of interaction of FeS and MnS can be assumed only within the range of FeS concentrations in this study.

Figure 17: Interaction of MnS and FeS in sphalerite or wurtzite at $525^{\circ} \mathrm{C}$.

Figure 21: Interaction of MnS and FeS in sphalerite or wurtzite at $305^{\circ} \mathrm{C}$.
$305^{\circ} \mathrm{C}$

Variation Of FeS In Sphalerite Or Wurtzite:

Figure 22 shows the variation of FeS in sphalerite or wurtzite with temperature. The error bars at each point on this diagram represent twice the pooled standard deviation of $F e S$ for all runs at each temperature. FeS in the sphalerite or wurtzite of these runs was derived from the breakdown of $\mathrm{FeS}_{2}$, according to a reaction of the type:

$$
2 \mathrm{FeS}_{2, \mathrm{ss}}=2 \mathrm{FeS}_{\mathrm{ss}}+\mathrm{S}_{2}
$$

The concentration of FeS in sphalerite or wurtzite was controlled by the amount of sulphur that could be released during reaction in the closed and originally evacuated reaction tubes. For all runs, only a ZnS phase, a $\mathrm{FeS}_{2}$ phase and sulphur vapour were present, at temperature, in addition to the molten fused salt. The concentration of FeS , at each temperature, was controlled by: (1) the amount of vapour space available in the reaction tubes relative to the size of the sulphide charge; and (2) the solubility of sulphur in the molten fused salt. The ratio of $(\mathrm{ZnS}+\mathrm{MnS}) / \mathrm{FeS}_{2}$ in the sulphide charge was maintained constant at 1:1 throughout the runs.

The relatively narrow compositional range for FeS in sphalerite or wurtzite at temperatures at and below $625^{\circ} \mathrm{C}$ (Figure 22) is the result of uniform experimental conditions. Variations of FeS , at any one temperature, are caused by random weighing errors and changes in the vapour space relative to the sulphide charge,

Figure 22: Variation of FeS in MnS-bearing sphalerite or wurtzite with temperature.
in addition to analytical errors. To illustrate this point, the FeS concentration in the wurtzites of runs 26 ( $2.6 \mathrm{~mole} \% \mathrm{FeS}$ ) and 103 ( 6.4 mole \% FeS) may be compared (Appendix I). The runs were carried out under almost identical conditions, except that the vapour space relative to the size of the sulphide charge was approximately double in run 103. The increase of FeS to about 16 mole percent in runs at $675^{\circ} \mathrm{C}$ (Figure 22) was caused by the use of a much smaller sulphide charge and a much larger vapour space than in runs at other temperatures.

For runs in which MnS in sphalerite or wurtzite is heterogeneous, FeS tends to be homogeneous (Appendix I). This may mean that FeS equilibrates mone rapidly than MnS . This observation can be compared with the work of Doe (1962) on sphalerite-pyrite assemblages from No. 2 Mine of the Balmat area, New York. Doe found that the ratio of Mn ( $\mathrm{mole} \%$ ) in sphalerite relative to pyrite varies from 3 to 1100 . FeS (mole \%) in sphalerite, in the same suite of samples ranges from 8.1 to 13.6. Doe concluded that Mn had not equilibrated between sphalerite and pyrite, but that $F e$ had equilibrated.

Partitioning Of Co Between Sphalerite And Pyrite

The analytical data for all sphalerite-pyrite pairs containing Co are listed in Appendices III and IV, in terms of mole percent and in order of temperature from 675 to $305^{\circ} \mathrm{C}$. The concentration of $\operatorname{CoS}$ in sphalerite ranges from very low values to
approximately 2.6 mole percent. The FeS content of sphalerite varies from less than 1 to about 14 mole percent. It is relatively uniform in runs at and below $625^{\circ} \mathrm{C}$ but there is a slight increase of FeS to 14 mole percent at $675^{\circ} \mathrm{C}$, similar to that found in the previous system. Only sphalerite, and not wurtzite, was found in the experimental runs. This is in agreement with the results of Hall (1961) who determined that sphalerite is stable at concentrations of $\operatorname{CoS}$ up to 33 mole percent at $850^{\circ} \mathrm{C}$. The concentration of $\mathrm{CoS}_{2}$ in pyrite ranges up to 80 mole percent. The concentration of $\mathrm{ZnS}_{2}$ in pyrite is usually less than 1 mole percent. Its concentration and limited variation in pyrite is not likely to influence the partitioning of Co .

Homogeneity Of Run Products:

The analyses of Co in both sphalerite and pyrite for each run were tested for the occurrence of extreme values by the same statistical method used for runs containing Mn (Dixon and Massey, 1957, p.276). Phases found to be heterogeneous by this method are marked in Appendices III and IV. The results of the corresponding muns were not used in the determination of partition coefficients.

The distribution of Co in sphalerite was found to be uniform by means of electron microprobe scanning images. However, this is not a definitive test because of the low concentration of Co in sphalerite. In the analysis of 24 of the runs, counts were taken on two distinct points within each of the sphalerite crystals. A
one-way analysis of variance of these data indicates that withincrystal variation of both CoS and FeS is much less than the betweencrystal variation of those elements at the $99 \%$ confidence level. With few exceptions, the runs contain no extreme values for $\cos$ in sphalerite. The sphalerite crystals appear to be quite homogeneous for $\cos$.

Scanning images of Co-bearing pyrites from runs at 675, 625 and $575^{\circ} \mathrm{C}$ showed no within-crystal heterogeneity. However, for runs at and below $525^{\circ} \mathrm{C}$ irregular zonation of pyrite is evident. Moreover, a crystal to crystal variation of $C O$, considerably more pronounced than the within-crystal zoning (Figure 6, E to $H$ ) is present. Inspection of Appendix IV for runs at and below $575^{\circ} \mathrm{C}$ indicates that there is wide variation of $\mathrm{CoS}_{2}$ content among pyrite crystals in any one run.

Klemm (1965) reported a solubility gap in the $\mathrm{CoS}_{2}-\mathrm{FeS}_{2}$ system at temperatures below $700^{\circ} \mathrm{C}$. According to Klerm, the gap lies between 55 and 75 mole percent $\mathrm{CoS}_{2}$ at $600^{\circ} \mathrm{C}$, between 33 and 83 mole percent $\operatorname{CoS}_{2}$ at $500^{\circ} \mathrm{C}$, and 7 and 83 mole percent $\operatorname{CoS}_{2}$ at $400^{\circ} \mathrm{C}$. This could explain the heterogeneity of pyrite in these runs, since two varieties of the $\mathrm{CoS}_{2}-\mathrm{FeS}_{2}$ solid solution should be present within runs below $600^{\circ} \mathrm{C}$. However, $\mathrm{CoS}_{2}$ compositions lying within Klenm's solubility gap have been found (Appendix IV) at temperatures below $575^{\circ} \mathrm{C}$. Assuming Klemm's data to be correct, chemical equilibrium was not attained in the Co bearing runs below $575^{\circ} \mathrm{C}$. Even if there is complete solid solution of $\mathrm{CoS}_{2}$ and $\mathrm{FeS}_{2}$ at these temperatures, as indicated by the study of natural bravoites (Riley, 1965; 1968),
the same conclusion must be accepted.
The pyrite crystals produced in this temperature range are subhedral to anhedral in character, and are much smaller and more mumerous than the corresponding sphalerite crystals. It is possible that the pyrite crystals nucleated rapidly at many centres, preserving and reflecting original inhomogeneities in the sulphide charge. The sphalerite crystals probably grew at a slower rate, maintaining only surface equilibrium with the $\mathrm{FeS}_{2}-\mathrm{CoS}_{2}$ fraction of the sulphide charge. The subhedral to anhedral nature of the pyrite crystals may be due to surface etching subsequent to their formation.

Distribution Of Co Between Sphalerite And Pyrite:

Figures 23 to 25 show the distribution of Co between sphalerite and pyrite at three different temperatures from 675 to $575^{\circ} \mathrm{C}$. The plots are in terms of mole percent. The error bars about each point in these diagrams represents the variation of $C O S$ in sphalerite and of $\mathrm{CoS}_{2}$ in pyrite as $\pm 1 \sigma$. No diagrams have been plotted for runs below $575^{\circ} \mathrm{C}$ because of the gross disequilibrium evident at these temperatures.

A partition coefficient, $\mathrm{K}_{\mathrm{FeS}_{2}}^{\mathrm{Co}} \mathrm{ZnS}$, has been estimated for runs at $675^{\circ} \mathrm{C}$ and $625^{\circ} \mathrm{C}$ by linear regression in the same way as in the case of runs containing Mn (Krumbein and Graybill, 1965, p.240; Snedecor and Cochran, 1967, p.166). The calculated values of $\mathrm{K}_{\mathrm{FeS}_{2}: \mathrm{ZnS}}^{\mathrm{Co}}$ for each temperature are given in Figures 23 and 24 along with their appropriate standard deviations of estimate. The

Figure 23: Partitioning of Co between sphalerite and pyrite at $675^{\circ} \mathrm{C}$.

Figure 24: Partitioning of Co between sphalerite and pyrite at $625^{\circ} \mathrm{C}$.

Figure 25: Partitioning of Co between sphalerite and pyrite at $575^{\circ} \mathrm{C}$.
statistical fit of the data points in each distribution diagram (Figures 23 to 25) to a straight line passing through the origin was tested by calculating a linear correlation coefficient (Krumbein and Graybill, 1965, p.240) for each temperature. For temperatures of 675 and $625^{\circ} \mathrm{C}$, the correlation coefficient was found to be significantly different from zero at the $95 \%$ confidence level, indicating that the calculation of $\mathrm{K}_{\mathrm{FeS}}^{2}$ : ZnS is justified at those temperatures. For runs at $575^{\circ} \mathrm{C}$, a statistically significant linear relationship does not exist between CoS in sphalerite and $\mathrm{CoS}_{2}$ in pyrite and a value of $\mathrm{KeS}_{2} \mathrm{CO}: \mathrm{ZnS}$ has not been calculated. Henry's Law has been approximated in both phases only in runs at 675 and $625^{\circ} \mathrm{C}$ over the range of concentrations considered.

Variation of $\mathrm{FeS}_{2}$ : ZnS , with Temperature:
Two values of $\log \mathrm{K}_{\mathrm{FeS}}^{2}$ : ZnS versus $10^{3} / \mathrm{T}\left({ }^{\circ} \mathrm{K}\right)$ are shown in Figure 35 in terms of mole percent. The error ( $\pm 1 \sigma$ ) in determining $\mathrm{K}_{\mathrm{FeS}_{2}}^{\mathrm{CO}} \mathrm{ZnS}$ at each temperature is shown as an error bar.

The value of $\mathrm{K}_{\mathrm{FeS}}^{2}$ : ZnS at 675 and $625^{\circ} \mathrm{C}$ are, respectively, $24.2 \pm 2.5$ and $38.1 \pm 21.2$. There is a strong selective uptake of $C o$ in pyrite relative to sphalerite. Nothing definitive can be said about the variation of $\log \mathrm{K}_{\mathrm{FeS}}^{2}$ : ZnS with $10^{3} / \mathrm{T}\left({ }^{\circ} \mathrm{K}\right)$ since onIy two valid data points exist. There could be a rapid increase of the concentration of Co in sphalerite relative to pyrite with increasing temperature, but this has not been firmly established.

Interaction Of CoS and FeS In Sphalerite:

Variations of FeS in sphalerite may affect the partitioning of Co between sphalerite and pyrite. Mole percent CoS in sphalerite has been plotted against mole percent $F e S$ in sphalerite, for each point analyzed in all of the runs at each of the eight temperatures (Figures 26 to 33). A linear correlation coefficient (Snedecor and Cochran, 1967, chapter 13) was calculated between CoS and FeS for all sphalerite analyses at each temperature. Four statistically significant (at the $95 \%$ confidence level) interactions between $\operatorname{CoS}$ and FeS have been found, namely at $675,525,420$ and $305^{\circ} \mathrm{C}$ (Figures 26, 29, 31, and 33). In each case, the corresponding correlation coefficient and the equation of the calculated regression line is given in the appropriate diagram (Figures 26, 29, 31, and 33).

The inverse relationship between CoS and FeS in sphalerite at $675^{\circ} \mathrm{C}$ (Figure 26) is very similar to the inverse relationship of NiS and FeS in sphalerite formed at $755^{\circ} \mathrm{C}$ reported by Czamanske and Goff (1973, p.260). They explained the preferential acceptance of $\mathrm{Fe}^{+2}$ relative to $\mathrm{Ni}^{+2}$ in terms of crystal field theory. $\mathrm{Fe}^{+2}$ has a lower octahedral site preference energy than $\mathrm{Ni}^{+2}$ and should be more stable in the tetrahedral sites available in sphalerite. Differences in ionic size are apparently of secondary consideration. In a similar way, the preference of sphalerite for $\mathrm{Fe}^{+2}$ at the expense of $\mathrm{CO}^{+2}$ may be due to the small octahedral site preference energy of $\mathrm{Fe}^{+2}$ relative to $\mathrm{Co}^{+2}$ (Table 2). No significant inverse

Figure 29: Interaction of CoS and FeS in sphalerite at $525^{\circ} \mathrm{C}$.

Figure 33: Interaction of CoS and FeS in sphalerite at $305^{\circ} \mathrm{C}$.

correlation between FeS and CoS in sphalerite is evident at $625^{\circ} \mathrm{C}$. The absence of this interaction with decreasing temperature is probably due to slight lowering in the concentration range of FeS and not to a reduction in the potential of such an interaction.

At 525, 420 and $305^{\circ} \mathrm{C}$, the concentration of COS and FeS in sphalerite are directly correlated. This curious reversal can be explained in two ways. The direct correlation may be due to the presence of microinclusions of $(\mathrm{Fe}, \mathrm{Co}) \mathrm{S}_{2}$ in some of the sphalerite crystals. This would result in anomalously high analyses of both CoS and FeS. For example, in Figure 33, if the analysis at 4.2 mole percent $C o S$ and 12 mole percent $F e S$ is disregarded, the significant correlation between FeS and CoS disappears. This sort of effect is also possible for analyses at $420^{\circ} \mathrm{C}$ (Figure 31). The direct correlation between CoS and FeS at $525^{\circ} \mathrm{C}$ (Figure 29) may be due entirely to chance. On the other hand, it could reflect small but sympathetic variations of CoS and FeS in sphalerite in response to random fluctuations of relative vapour space in the reaction tubes. It should be noted that the concentration of FeS in sphalerite from runs at $525^{\circ} \mathrm{C}$ is less than 10 mole percent, a level probably too low to cause a significant inverse interaction between FeS and $\operatorname{CoS}$ of the type detected at $675^{\circ} \mathrm{C}$.

The significant influence of changes of FeS in sphalerite on the concentration of $C o S$ in sphalerite means that the partitioning of Co between sphalerite and pyrite cannot be used as a geothermometer without a thorough evaluation of this interaction, over a wide range of FeS concentrations in sphalerite.

Variation Of FeS In Sphalerite:

Figure 34 shows the variation of FeS in sphalerite with temperature. The error bars at each point on this diagram represent twice the pooled standand deviation of FeS for all runs at each temperature. If an error bar is not present, the error is too small to plot. The narrow range of FeS content in sphalerite below $675^{\circ} \mathrm{C}$ is again, due to uniform experimental conditions. The marked increase of FeS to 14 mole percent at $675^{\circ} \mathrm{C}$ is, as in the case of runs containing Mn , due to a large increase in the relative vapour space in the reaction tubes.

Figure 34: Variation of FeS and CoS-bearing sphalerite with temperature.

Figure 35: Variation of partition coefficients with temperature.

## CONCLUSIONS

An attempt has been made to determine the partitioning of Mn and Co between sphalerite on wrutzite and pyrite as a function of temperature from 675 to $305^{\circ} \mathrm{C}$. Microcrystalline wurtzite and pyrite were recrystallized in the presence of variable concentrations of MnS and $\mathrm{CoS}_{2}$ in $\mathrm{KCl}-\mathrm{LiCl}$ and $\mathrm{NH}_{4} \mathrm{Cl}-\mathrm{LiCl}$ eutectic fused salt mixtures for periods of time up to 47 days. The distribution of Mn and Co in the sphalerite or wrotzite and pyrite reaction products was determined by means of an electron probe microanalyzer.

Mn is selectively concentrated in sphalerite and wrotzite relative to pyrite by a factor of about 100. Both sphalerite and wurtzite as well as pyrite were found in the reaction products. Wurtzite is stabilized relative to sphalerite by concentrations of MnS in ZnS above 7 to 10 mole \%. This transition is relatively insensitive to changes in temperature. Equilibrium conditions were apparently attained in most runs at temperatures down to $400^{\circ} \mathrm{C}$. The partitioning of Mn obeys Henry's Law at concentration levels above those normally found in natural assemblages. No distinction could be drawn in the partitioning of Mn between sphalerite-pyrite and wurtzite-pyrite pairs. The amount of Mn in sphalerite or wurtzite relative to pyrite increases slightly with temperature. The partition coefficient ( $K$ ) for $M n$ is a linear function of temperature ( $\log K$ versus $l / T$ ) within the range of temperatures considered. This variation in the partition coefficient can probably be used for the rough estimation of temperature of formation of natural sphalerite-
pyrite assemblages, although the magnitude of the partition coefficient would make the simultaneous chemical analysis of both phases by electron microprobe methods difficult if not impossible. No interaction of MnS and FeS in sphalerite and wartzite is evident. Variations of FeS in sphalerite or wurtzite, up to a concentration of 16 mole \% FeS in sphalerite or wurtzite should not affect the partitioning of Mn between sphalerite or wurtzite and pyrite.

Co is selectively concentrated in pyrite relative to sphalerite by a factor of 22 to 38 . Only sphalerite and pyrite were present in the reaction products. Equilibrium conditions were probably attained only at temperatures of 675 and $625^{\circ} \mathrm{C}$. Gross disequilibrium was evident at temperatures below $575^{\circ} \mathrm{C}$, possibly due to differential rates of recrystallization of sphalerite and Co-rich pyrite. There may be a rapid decrease in the partitioning coefficient (K) for Co between pyrite-sphalerite pairs with increasing temperature. Sphalerite may become relatively more erriched with Co as temperature increases. A relationship between $\log \mathrm{K}$ and $1 / T$ was not established since partitioning coefficients could be calculated only at two temperatures ( 675 and $625^{\circ} \mathrm{C}$ ). A marked inverse interaction of FeS and CoS in sphalerite was found to exist at $675^{\circ} \mathrm{C}$. It may be due to the preferential inclusion of FeS in the tetrahedral sites of sphalerite. Significant direct correlations between CoS and FeS in sphalerite were found at 525, 420 and $305^{\circ} \mathrm{C}$ for lower concentration levels of FeS in sphalerite than at $675^{\circ} \mathrm{C}$. These could be due to contamination effects of microinclusions of $(\mathrm{Co}, \mathrm{Fe}) \mathrm{S}_{2}$ in sphalerite or to random fluctuations of
the relative vapour space in reaction tubes changing the concentrations of COS and FeS sympathetically. These interactions between CoS and FeS invalidate the use of this system as a geothermometer until the character of this effect is fully investigated over a wide range of FeS concentrations in sphalerite.

The qualitative character of the partitioning of CO and Mn between sphalerite or wurtzite and pyrite can be adequately explained using crystal field theory. An analysis of this type should be carried out as a preliminary step in any experimental work on partitioning between sulphide phases.

Kinetic problems leading to lack of equilibrium in some of the runs, particularly those involving $\mathrm{CoS}_{2}, \mathrm{ZnS}$ and $\mathrm{FeS}_{2}$, point up the fact that thorough examination of reaction products by electron microprobe methods was absolutely necessary. The chemical analysis of mixtures of heterogeneous crystals by other techniques would give average values and would lead to highly erroneous conclusions. Kinetic difficulties of the type encountered here could probably be solved by: (1) considerably longer run times; (2) simultaneous precipitation of microcrystalline sulphide reagents to increase the homogeneity of the sulphide charges; (3) use of other eutectic fused salt mixtures.

The use of eutectic fused salt mixtures in the study of partitioning between sulphide minerals seems to hold promise, and it constitutes a viable alternative to methods of hydrothermal synthesis. For example, an extension of Bethke and Barton's (1971) investigation of the distribution of $\mathrm{Cd}, \mathrm{Mn}$ and Se between galena
and sphalerite could be carried out down to $400^{\circ} \mathrm{C}$ by means of KCl LiCl eutectic mixtures. In addition, partitioning between such sulphide pairs as pyrite-pyrrhotite and pyrite-chalcopyrite would be studied in this way.

The application of experimental data on partitioning between coexisting sulphides to ore deposits is fraught with numerous problems. The most important of these is the frequent inability to identify precisely equilibrated sulphides in natural assemblages. Even if a specific pair of coexisting sulphides were in chemical equilibrium at some time, it may be very difficult to determine whether partition coefficients reflect conditions of ore formation or some later metamorphic event. The apparently simple procedure of sampling can present severe obstacles due to the requirement of sample purity, when analyses are done by such methods as atomic absorption, and due to compositional inhomogeneities commonly present in natural sulphide crystals as a result of growth zonation and exsolution. It should be emphasized that the compositional homogeneity of sulphide crystals has usually not been considered in any detail either in experimental partitioning studies (e.g. Bethke and Barton, 1971) or in partitioning studies on natural sulphide assemblages (e.g. Ghosh-Dastidar, 1970) despite the fact that the occurrence of heterogeneous sulphides can lead to major errors in the calculation of partition coefficients. Finally, a strong selective concentration of trace elements in one phase of a specific mineral pair may be a common feature of sulphides, making the analysis of the depleted phase difficult.

Some of the problems outlined above may be solved by the use of ion probe techniques. This method provides greater analytical sensitivity than electron microprobe methods, chemical analysis on a micron scale and the potential of simultaneously measuring trace element concentrations and stable isotope ratios. Trace element distributions between coexisting sulphides in natural assemblages could be compared with fluid inclusion data and temperature estimates derived from sulphur isotope partitioning.

## Appendix I

## Analyses Of Mn In Sphalerite Or Wurtzite

## Note - Appendix I

In the following tables, the numbered column headings refer to:
(1) Analysis identification number. For example, the identifier 14901 refers to an analysis of a single crystal of sphalerite or wurtzite from run 149. Repetition of the identifier indicates that analyses were carried out at two or more distinct spots on the crystal.
(2) Run temperature in ${ }^{\circ} \mathrm{C}$
(3) Run time in days
(4) Weight per cent Mn in sulphide charge
(5) Mole per cent MnS in sphalerite or wrrtzite
(6) Mole per cent FeS in sphalerite or wurtzite
(7) Mole per cent ZnS in sphalerite on wurtzite
(8) Deviation of original analytical total (in weight per cent) from $100 \%$.

Lines started by "AV" give the averages for the preceding set of analyses. The presence of an asterisk (*) preceding the average value of MnS indicates that the distribution of MnS is heterogeneous and that the calculation and use of an average for the set of analyses is probably not justified.

## Appendix II

Analyses of Mn In Pyrite

## Note - Appendix II

In the following tables, the numbered column headings refer to:
(1) Analysis identification number. For example, the identifier 14901 refers to an analysis of a single crystal of pyrite from run 149. Repetition of the identifier indicates that analyses were carried out at two or more distinct spots on the crystal.
(2) Run temperature in ${ }^{\circ} \mathrm{C}$
(3) Run time in days
(4) Weight per cent $M n$ in sulphide charge
(5) Mole per cent $\mathrm{MnS}_{2}$ in pyrite
(6) Mole per cent $\mathrm{FeS}_{2}$ in pyrite
(7) Mole per cent $\mathrm{ZnS}_{2}$ in pyrite
(8) Deviation of original analytical total (in weight per cent) from 100\%

Lines started by "AV" give the averages for the preceding set of analyses. The presence of an asterisk (*) preceding the average value of MnS indicates that the distribution of $\mathrm{MnS}_{2}$ is heterogeneous and that the calculation and use of an average for the set of analyses is probably not justified.

- = element not detected

## Appendix III

Analyses Of Co In Sphalerite

Note - Appendix III

In the following tables, the numbered column headings refer to:
(1) Analysis identification number. For example, the identifier 15501 refers to an analysis of a single crystal of sphalerite from run 155. Repetition of the identifier indicates that analyses were carried out at two or more distinct spots on the crystal.
(2) Run temperature in ${ }^{\circ} \mathrm{C}$
(3) Run time in days
(4) Weight per cent Co in sulphide charge
(5) Mole per cent CoS in sphalerite
(6) Mole per cent FeS in sphalerite
(7) Mole per cent ZnS in sphalerite
(8) Deviation of original analytical total (in weight per cent) from $100 \%$

Lines started by "AV" give the averages for the preceding set of analyses. The presence of an asterisk (*) preceding the average value of $\operatorname{CoS}$ indicates that the distribution of CoS is heterogeneous and that the calculation and use of an average for the set of analyses is probably not justified.

## Appendix IV

Analyses of Co In Pyrite

In the following tables, the numbered column headings refer to:
(1) Analysis identification number. For example, the identifier 15501 refers to an analysis of a single crystal of pyrite from run 155. Repetition of the identifier indicates that analyses were carried out at two or more distinct spots on the crystal.
(2) Run temperature in ${ }^{\circ} \mathrm{C}$
(3) Run time in days
(4) Weight per cent Co in sulphide charge
(5) Mole per cent $\mathrm{CoS}_{2}$ in pyrite
(6) Mole per cent $\mathrm{FeS}_{2}$ in pyrite
(7) Mole per cent $\mathrm{ZnS}_{2}$ in pyrite
(8) Deviation of original analytical total (in weight per cent) from $100 \%$.

Lines started by "AV" give the averages for the preceding set of analyses. The presence of an asterisk (*) preceding the average value of $\mathrm{CoS}_{2}$ indicates that the distribution of $\mathrm{CoS}_{2}$ is heterogeneous and that the calculation and use of an average for the set of analyses is probably not justified. - = element not detected.

Manuscript copies of theses submitted for the doctor's degree and deposited in The University of Michigan Library and in the Office of the Graduate School are open for inspection, but are to be used only with due regard to the rights of the authors. For this reason it is necessary to require that a manuscript thesis be read within the Library or the Office of the Graduate School. If the thesis is borrowed by another library, the same rules should be observed by it. Bibliographical references may be noted, but passages may be copied only with the permission of the authors, and proper credit must be given in subsequent written or published work. Extensive copying or publication of the thesis in whole or in part must have the consent of the author as well as of the Dean of the Graduate School.

This thesis by
has been used by the following persons, whose signatures attest their acceptance of the above restrictions.

A Library which borrows this thesis for use by its readers is expected to secure the signature of each user.
