Preface

Over the last decades, scientists have been intrigued by the fascinating microorganisms that inhabit extreme environments including extreme temperature, pressure, salinity, pH, etc. They grow optimally under one or several of these diverse conditions for their growth and are termed as extremophiles, which include acidophiles, alkaliphiles, halophiles, psychrophiles, thermophiles, hyperthermophiles, radioresistant microbes, barophiles, and endoliths. They thrive in habitats that are intolerably hostile or even lethal to other life-forms. Based on technological advances, the study of extremophiles has provided ground-breaking discoveries that challenge the paradigms of modern biology. In view of the nearly unlimited reservoir of extremophilic organisms existing in nature and the exciting achievements of modern biotechnology, there remains an enormous potential waiting for further progress in synthetic biology, drug discovery, bioenergy, and bioremediation. It is envisaged that biotransformations employing extremophiles will be increasingly exploited as a useful and often a unique tool for biotechnological and industrial applications.

Extremophiles have been identified to belong mainly in the domain archaea. However, extremophiles have also been identified in eubacterial and eukaryotic organisms such as fungi. Most fungi that are able to grow or survive under extreme conditions are in fact extremotolerant species, meaning they can also thrive under mesic conditions. It is still unclear how many fungi might clearly grow better under extreme conditions such as *Wallemia ichthyophaga*, which cannot grow without salt. In any case, the ecological versatility of these extremophilic/extremotolerant fungi may have potential impact in biotechnology. Fungi in general have played a very role in addressing major global challenges, being instrumental for improved resource efficiency, making renewable substitutes for products from fossil resources, upgrading waste streams to valuable food and feed ingredients, counteracting lifestyle diseases and antibiotic resistance through strengthening the gut biota (Lange, 2014: IMA Fungus 5, 463–471), making crop plants more robust to survive climate change conditions, and functioning as host organisms for the production of new biological drugs. This range of new uses of fungi all stand on the shoulders of the efforts of mycologists over generations. The next in demand are regimes of enzymes active under low-temperature conditions and enzymes active and stable at high

temperatures for decomposition of both plant- and animal-derived biomasses. The expansion of commercialized enzymes from highly extreme ecological niches therefore calls for new breakthroughs. Here, mycologists specialized in fungi adapted to the extremes can contribute significantly. We follow the developments in this area and see how contemporary technologies help scientists to achieve a better understanding of biology at the extremes of life. This book builds on a platform of knowledge generated through the combined efforts of scientists and academics in the field of mycological research, where extremophilic fungi are seen as having the potential to contribute significantly toward a more sustainable world. This book puts together a rapidly growing and often scattered information on fungal life in the whole range of extreme environments and explores their habitats, biodiversity, ecology, evolution, genetics, biochemistry, and biotechnological applications in a collection of exciting reviews and original articles. It is a comprehensive and reliable source of information on the recent advances and challenges of extremophilic fungal research and a dependable reference text for readers interested in this field of research.

The book will be organized in five parts. Part I is designed to underpin the biodiversity, ecology, genetics, and physiology of extremophilic fungi. It is aimed to provide a sufficient overview of the fungal world found in extreme environments and to enable readers to fully understand and appreciate the diversity of these organisms and their metabolic capabilities. It reviews the literature on the diversity of fungi growing at extreme conditions. The readers should soon come to recognize the versatility of fungi, their ability to grow on a wide range of extreme environments.

Parts II and III explore the biotechnological potential of these fascinating organisms. It introduces the variety of extremophilic fungi as well as their osmolytes and enzymes. These parts also discuss the problems of experimental design associated with extremophiles/extremotolerants in biotechnological implications and the challenges and possibilities of developing extremolytes and novel biomolecules for commercial purposes. Several research programs have also focused on natural product isolation from microbes dwelling in marine environments, which, in this book, is defined as being in extreme environments with high salinity, extreme temperatures, minimal light, as well as variable acidities and pressures. With improved sampling, culturing, and molecular-based techniques, the number of bioactive metabolites reported from marine fungi has increased significantly over the last 30 years. For instance, cephalosporins and plinabulin are bioactive compounds inspired by marine fungal natural products and either have been clinically approved or are currently in phase III clinical trials. An important area of research is the synthesis of nanoparticles by halophilic/halotolerant fungi. These nanoparticles have found uses in biomedical and environmental fields. It is expected that with the advancement of the understanding of bionanoparticle synthesis pathways in fungi, the application of bionanoparticles will expand to many more fields than biomedical and environmental and will be potentially applied in diverse nanotechnological industries.

Part IV is devoted to the applications of extremophilic fungi in bioenergy and biofuel synthesis. Thermophilic fungi produce many thermostable enzymes that are of biotechnological importance, particularly for degradation of lignocellulosic

biomass to make value-added biomaterials. This section reviews the function and utility of thermophilic enzymes and highlights the potential application of lignocellulose-degrading thermophilic fungi and their thermozymes in the extraction of natural rubber and biofuels.

Part V examines the application of extensive degradative capabilities of extremophilic/extremotolerant fungi, particularly the harnessing of these properties in waste treatment, bioremediation, and pollution control.

Part I
Biodiversity, Ecology, Genetics and Physiology of Extremophilic Fungi

Chapter 1
Diversity and Ecology of Fungi in Mofettes

Irena Maček

1.1 Introduction

Mofette fields are areas with gas vents of ambient temperature geological CO_2 and consequent permanent soil hypoxia. These specific and extreme ecosystems have been used to investigate soil microbial communities with the majority of the existent studies focusing on soil archaea and bacteria while much less work has been published on soil fungal diversity (Maček et al. 2016b). In research of soil fungi, particular emphasis has been on the ubiquitous and ancient symbiotic interaction between plants and arbuscular mycorrhizal (AM) fungi subjected to soil hypoxia (low O_2 concentration), while other filamentous fungal groups from mofette sites have not yet been described, and a single report on the diversity of yeasts in wet and dry mofettes in Slovenia has been published (Šibanc et al. 2018). Nevertheless, all the existent studies confirm that mofette fields can be a rich source of information on how organisms, their populations and communities cope with long-term environmental pressures in situ in their natural habitats. There is substantial evidence demonstrating that organisms in mofette areas are subject to intense selection pressures from the abiotic environment, such as soil hypoxia (Maček et al. 2011, 2016b; Šibanc et al. 2018). The objective of this chapter is to summarise the current knowledge on the subject of soil fungal diversity and ecology in mofette sites, with the emphasis on the two groups of fungi that have been the focus of the published reports, yeasts and AM fungi. With this work the first review that is fully focused on mofette fungal biology, including the recently published findings on the yeast diversity in Slovenian mofettes (Šibanc et al. 2018), is presented. Finally, future

directions in microbial ecology research in these specific extreme ecosystems and advances in the use of locally extreme environments for long-term ecological studies are addressed and discussed, with an acknowledgement of the possibilities for widening the scope of research, which could include environmental impact assessments in case of CO_2 leakage from carbon capture and storage (CCS) systems, bioprospecting for industrially important microbes, research into potential hypoxia-tolerant fungal pathogens as well as research of specific mofette food webs and mofette ecological networks (Maček et al. 2016b).

1.2 Mofettes or Natural CO_2 Springs

Mofettes are extreme ecosystems present in tectonically or volcanically active areas worldwide (Pfanz et al. 2004; Maček et al. 2016b). In mofettes, ambient temperature geological CO_2 of deep mantle origin reaches the surface, resulting in a severe and relatively constant change in concentrations of soil gases, in particular CO_2 and O_2 (Fig. 1.1). Traces of other gases can also be present, including methane (CH_4), nitrogen (N_2), hydrogen sulphide (H_2S) or noble gases, but concentrations of those

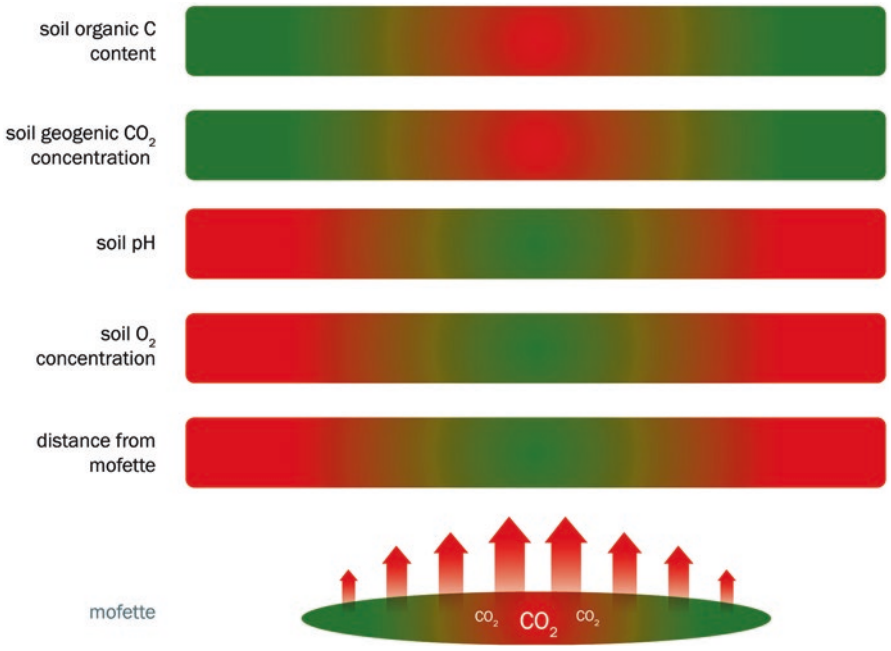

Fig. 1.1 Schematic of the effect of CO_2 venting at mofettes on abiotic factors. The gradients in different factors are indicated by different colours. Red is indicative of a higher value of the specific parameter closer to the mofette centre (e.g. CO_2 concentration); green indicates the opposite (e.g. O_2 concentration)

differ in different mofette sites with some locations emitting very pure CO_2 (e.g. in Slovenian, German and Czech mofettes with 99.9 vol. % pure CO_2) (Pfanz et al. 2004; Vodnik et al. 2006; Beulig et al. 2015).

The first reports of possibilities of using mofettes in environmental and biological studies were published at the beginning of the 1990s (e.g. Miglietta et al. 1993; Raschi et al. 1997). Following the initial use (primarily for research of the vegetation and plant above-ground responses to elevated, atmospheric CO_2 concentrations—e.g. Raschi et al. 1997), a second feature, the importance of changed gas regime in mofette soils and its impact on soil biota, was observed (Maček et al. 2005). The major characteristics of practically all mofette sites are relatively stable and high CO_2 concentrations and hypoxia (low O_2 concentration) in soil horizons, while aboveground CO_2 concentrations are lower and more variable. At 1–2 m, the surface atmosphere is most frequently only slightly enriched with CO_2 (van Gardingen et al. 1995; Kies et al. 2015). However, as it is heavier than air, mofette CO_2 may accumulate within depressions in the landscape, which if large enough may even form gas lakes with concentrations ranging from 5% to nearly 100% CO_2, forming deadly animal CO_2 traps (Fig. 1.2, see Maček et al. (2016b) for detailed descriptions on the mofette fauna and flora). In locations with an open topology and common windy conditions (e.g. Stavešinci mofettes in Slovenia), such lakes rarely form and are transient as CO_2 quickly dilutes due to high concentration gradients in the Earth's atmosphere (0.04% CO_2). As a consequence of CO_2 solubility in soil water and its conversion to carbonic acid, the pH also decreases in high geological CO_2-impacted soils. A linear correlation between CO_2 concentrations and pH values in soil was reported (Maček et al. 2012, 2016b), with high CO_2 soils and groundwater typically reported pH between 4 and 5 (Maček et al. 2016b; Šibanc et al. 2018).

Apart from mofettes, soil hypoxia also affects a range of other more common ecosystems, e.g. submerged, flooded or compacted soils (Perata et al. 2011; Maček 2017a). Furthermore, as projected by climate change models, the frequency and severity of flooding events will dramatically increase in the future (Hirabayashi et al. 2013). Therefore, understanding the response of different organisms to soil

Fig. 1.2 CO_2 traps serving as sampling sites for the local mofette faunal community, Stavešinci mofette, Slovenia (see Maček et al. 2016b for more details on mofette fauna and flora)

hypoxia, including crop plants, and their interaction with symbiotic and ubiquitous AM fungi is becoming increasingly important in order to enhance plant yield and to promote sustainable agriculture in the future (Maček 2017a). In this respect, mofettes can serve as model ecosystems to study the impacts of long-term levels of soil hypoxia and other soil abiotic factors on soil biota (Maček et al. 2016b).

1.3 Mofette Soil Biodiversity and Microbial Communities

With the new biotechnological breakthroughs in the recent decades, soil life has become the focus of biological studies in mofettes with an increasing number of papers reporting on soil biota responses to long-term elevated CO_2 and soil hypoxia, which include mesofauna (Collembola, Nematoda (Frerichs et al. 2013; Hohberg et al. 2015)) and microorganisms: fungi (Maček et al. 2011; Šibanc et al. 2018), microalgae (Collins and Bell 2006; Beulig et al. 2016), archaea and bacteria (e.g. Krüger et al. 2011; Šibanc et al. 2014; Beulig et al. 2016). The soil gas regime at mofettes, and in particular soil hypoxia, has a substantial impact on the communities of predominantly obligatory aerobic eukaryotic organisms, such as plants (e.g. Maček et al. 2016b), soil fauna (e.g. Hohberg et al. 2015) and fungi (Maček et al. 2011, 2016b; Šibanc et al. 2018). Soil O_2 concentration was also the strongest abiotic predictor of the composition of soil archaeal and bacterial communities in the Slovenian Stavešinci mofettes, with the secondary effects of other soil factors, such as CO_2 concentrations, soil pH and nutrient availability (Šibanc et al. 2014). Bacterial and archaeal communities from all mofettes exhibit increased abundance of methanogenic and anaerobic taxa, and in some cases also acidophiles (e.g. Krüger et al. 2009, 2011; Oppermann et al. 2010; Frerichs et al. 2013; Šibanc et al. 2014). Even though most of the existing mofette studies examining the community composition of different organisms represent single snapshots or, at best, a few time points, this suggests a general and relatively stable pattern in the development of mofette soil microbial communities. Furthermore, this also appears to extend to other groups of organisms, e.g. fungi (Maček et al. 2011, 2016b) with recently described novel species of soil yeast *Occultifur mephitis* sp. nov. (Šibanc et al. 2018) (Fig. 1.3) and invertebrates (collembolans) (Schulz and Potapov 2010).

In contrast to more available published data on soil prokaryotes, the diversity of fungi at mofette sites remains mostly unexplored (Maček et al. 2016b; Maček 2017b), and it has even been reported that the majority of soil fungi are potentially excluded from mofette soil food webs due to sensibility to soil hypoxia (Beulig et al. 2016). Indeed, most fungi are considered to be aerobes, although their habitats can often be hypoxic or even anoxic (e.g. due to soil infiltration with water or metabolic activity during infection of other organisms, in the deep biosphere) (Simon and Keith 2008; Drake et al. 2017). However, the existent studies show that diverse fungal communities inhabit also hypoxic mofette sites (Maček et al. 2011, 2016b; Šibanc et al. 2018) with the fungal gene number copies only slightly decreasing at high geological CO_2

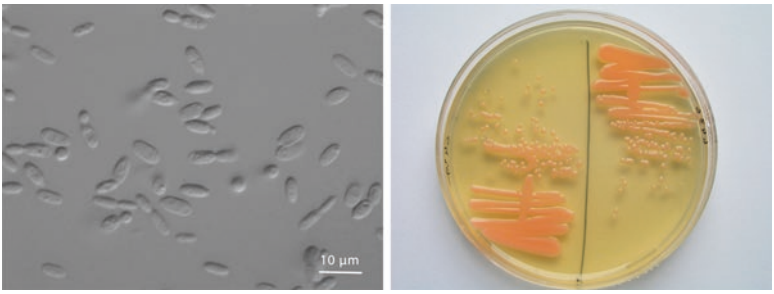

Fig. 1.3 A newly described yeast species *Occultifur mephitis* f.a., sp. nov., isolated from soil at Stavešinci mofette (NE Slovenia) and named after Mephitis, a Roman goddess of gasses emitting from ground (*me.phi¢tis*. L. fem. Gen. n. *mephitis*). Yeast morphology (left). Colonies in 9 cm diameter petri dish (right). All from EXF-6436 (holotype); see Šibanc et al. (2018) for details. Photo: N. Šibanc

fluxes and with severe decrease of fungal gene copies only when exposed to the most extreme sites, as reported for Spanish mofettes (Fernández-Montiel et al. 2016). There are only a few published studies of fungi in mofettes (e.g. Maček et al. 2011, 2016b; Šibanc et al. 2018), and further investigation is urgently needed to understand the complex biological processes and ecological interactions of soil biota in this extreme environment that also involves the fungal part.

1.4 Fungi in Mofette Habitats

Fungi are eukaryotes with complex cell structures; some have the ability to make tissues and organs typical for higher organisms. They are a large, diverse and widespread group, consisting of different forms that spread from the filamentous fungi, such as moulds, mushrooms and mycorrhizal fungi, to unicellular yeasts. Like other multicellular organisms, fungi are considered to be aerobes; however, their habitats can often be hypoxic or even anoxic, e.g. due to soil infiltration with water, metabolic activity in their environments or during infection of other organisms (Maček et al. 2011, 2016b; Grahl et al. 2012). The majority of the known fungal taxa is associated with terrestrial environments where they play crucial roles in C-cycling and mineralisation. Soilborne organisms, including fungi, have evolved to tolerate low or rapidly changing oxygen levels (e.g. Maček et al. 2011) and are exposed to occasional hypoxia, where the hypoxic response also starts in fungi (similar as in multicellular eukaryotes) at an oxygen level of about 6% (Simon and Keith 2008). Yeasts are an exception in the fungal kingdom, as many are known to have fermentation ability (e.g. Šibanc et al. 2018). Fungal diversity and community composition have only been reported for the mofettes in Slovenia, including the existent research on the fungal ecology of plant symbiotic AM fungi (Fig. 1.4). Yeasts are a second diverse group of fungi that are known to be competitive in hypoxic

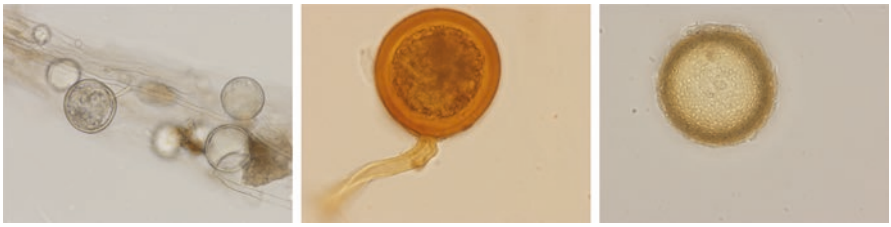

Fig. 1.4 Spores of arbuscular mycorrhizal fungi isolated from Stavešinci mofette soil. *Glomus* sp. (left, middle), *Acaulospora* sp. (right). Photo: F. Oehl

environments and have been inventoried on the mofette sites in Slovenia (Table 1.1) (Šibanc et al. 2018). Apart from those, there are no published data of any other specific fungal group from mofettes.

1.4.1 Yeasts

Yeasts are a widespread group of microfungi that colonise terrestrial and aquatic systems. Soil yeasts are essential in ecosystem functioning as they are involved in the mineralisation of organic material and the assimilation of plant-derived carbohydrates as well as nutrient cycling (Botha 2006, 2011). Recently, a report on the yeast diversity from mofette sites in northeast Slovenia has been published, including an inventory of cultivable yeasts from the mofette soil (dry mofettes) and water (wet mofettes) (Table 1.1, Šibanc et al. 2018). In total, 142 yeast strains were isolated and identified from high geological CO_2-exposed soil and groundwater in a meadow, a forest pond and stream water. They were assigned to six basidiomycetous yeast genera (six species) and 11 ascomycetous genera (18 species) (Table 1.1, Šibanc et al. 2018). Using high dilution plating of a mofette soil sample, four strains of an unknown basidiomycetous species were isolated and were newly described as *Occultifur mephitis* f.a., sp. nov. (Fig. 1.3), based on molecular phylogenetic and phenotypic criteria (Šibanc et al. 2018). *O. mephitis* did not show any fermentative abilities and was not able to grow in 100% CO_2 atmosphere in vitro conditions (Šibanc et al. 2018). Nevertheless, it was growing in a hypoxic atmosphere generated by 100% N_2 in an anaerobic jar, where respiration resulted in an accumulation of up to 32% CO_2, while the remaining O_2 level was up to 5% (Table 1.1, Šibanc et al. 2018). This suggests that the hypoxic conditions in mofette soils probably include microenvironments with a minimum O_2 supply required for this and probably also other species to survive.

In the Slovenian mofettes, the highest yeast species richness (15 species), all ascomycetes, was found in water from forest mofette (pond and stream) that included yeast species only encountered in forest water: *Candida boleticola*, *Debaryomyces hansenii*, *Kazachstania exigua*, *Kluyveromyces dobzhanskii*, a representative of the *Metschnikowia pulcherrima* species complex (Lachance 2016),

Table 1.1 A list of yeast species isolated from the Stavešinci mofette site (according to Šibanc et al. 2018)

Substrate	DNA barcode-based identification retrieved from isolated strains	Growth in CO_2 atmosphere	Growth in N_2 atmosphere

Ascomycetous (second column, A) and basidiomycetous yeast species (B) including results from in vitro tests (growth in CO_2 and N_2 atmospheres). Most abundantly isolated yeast species are in bold. See Šibanc et al. (2018) for more details on isolation methods, in vitro tests, ex-stain accession numbers and GenBank accession numbers

Metschnikowia pulcherrima, *Pichia kudriavzevii*, *Suhomyces species* and *Torulaspora delbrueckii* (Šibanc et al. 2018). Among those, isolates identified as *Metschnikowia pulcherrima* species complex differ in 11/462 nucleotide positions of the D1/D2 (98% identity) from the sequence of the type strain of *Metschnikowia fructicola* and might represent another not-yet-described species. From the isolated taxa, all ascomycetous yeasts, with the exception of *Debaryomyces hansenii*, were able to grow under elevated CO_2 and fermented glucose. *Candida sophiae-reginae*, *Pichia fermentans* and *Candida vartiovaarae* were the dominating species in meadow and forest high CO_2-exposed water. *Meyerozyma guilliermondii* and *Wickerhamomyces anomalus* predominated in high CO_2-exposed soils (Šibanc et al. 2018). The frequent occurrence of *M. guilliermondii* and *W. anomalus* and their in vitro ability to grow in high CO_2 and N_2 atmospheres and fermentative ability suggest that they might be well-adapted to ecological niches characterised by increased CO_2 and consequently decreased O_2. The same may apply to the majority of other ascomycetous yeast species isolated from mofettes (Table 1.1). The most abundant ascomycetous yeast species found in meadow mofette soils are also described as fermentative taxa in the literature (Kurtzman et al. 2011). Among isolated yeast species, all ascomycetous taxa except *Debaryomyces hansenii* that were able to ferment glucose were also able to grow under elevated CO_2 concentrations (incubation under initial 100% CO_2) (Table 1.1). Tested strains representing these species were also able to grow under 100% N_2 (Table 1.1, Šibanc et al. 2018). The low pH encountered in high CO_2 mofette environments may also favour yeast species that are known to survive in environments with an at least moderately reduced pH value. This proves that mofette habitats enable new insights into microbial responses and adaptations to long-term changes in the soil abiotic environment and are a valuable source for the discovery of novel taxa.

1.4.2 Arbuscular Mycorrhizal (AM) Fungi

AM fungi (Fig. 1.4) were the first group of fungi whose diversity and community have been characterised from any mofette site (the Slovenian Stavešinci mofette) (Maček et al. 2011). Research in mofette fungal ecology has primarily focused on these functionally important and ubiquitous soil fungi with diverse communities in the hypoxic mofette environment (Maček et al. 2011, 2016b). The widely distributed AM fungi, obligately biotrophic plant root endosymbionts, are a ubiquitous functional group in soils. They are present in all terrestrial ecosystems and are estimated to colonise roots of around two-thirds of plant species (Fitter and Moyersoen 1996). They are also the most common fungal group in agroecosystems and may be important in promoting sustainable agriculture (Smith and Read 2008). The AM fungi have the potential to exert a profound influence on ecosystem function. For their host plants, they are the principal conduit for phosphorus uptake, and they can influence them in a variety of other ways, including defence against pathogens, improved water relations and uptake of micronutrients and nitrogen

(Smith and Read 2008). Roots of plants of several species growing in the most extreme locations in mofette area Stavešinci (NE Slovenia) have consistently been shown to be highly colonised by AM fungi, despite the prolonged stress and the carbon cost of colonisation (Maček et al. 2011, 2012; Maček 2013). Fungal hyphae are finer than roots by at least an order of magnitude and the costs to a plant of acquiring nutrients symbiotically will be lower than those of doing so by new root growth, although the functional aspects of arbuscular mycorrhiza in mofette sites are not understood. It is not yet clear how these fungi cope but the extraradical mycelium is likely to be severely restricted in highly hypoxic soils, and it is unknown whether the plants benefit from the symbiosis in this environment (Maček et al. 2011; Maček 2017a). However, the mofette fungal types are probably not being subsidised by mycelium in surrounding soil, which might explain how these aerobic fungi survive. Therefore they must be adapted to, or at least competitive in, hypoxic conditions, presumably either tolerating low O_2 or acquiring sufficient O_2 from the roots; either explanation has profound implications for their biology (Maček et al. 2011). Acquiring sufficient O_2 from roots (Maček et al. 2011) is a novel and unexplored concept of facilitation in AM fungal ecology (Maček et al. 2016b; Maček 2017a), not only relevant for mofette fungi (Maček et al. 2011), but also for microbes colonising submerged plants in aquatic environments. Therefore, arising from physically extreme environments, plant-AM fungal interactions could, in addition to nutrient (trophic) interaction, be expanded to the additional benefit of a positive effect of one species on another by reducing physical or biotic stress in existing habitats and by creating new habitats for AM fungi (Maček et al. 2016b; Maček 2017a). In the context of an extreme environment, this means that some species modify conditions sufficiently to make life more hospitable for others that otherwise would not be able to survive in this environment. The concept is in plant literature well known under the term ‘facilitation’ and is used to beneficial (non-trophic) interactions that occur between physiologically independent plants and that are mediated through changes in the abiotic environment (Brooker and Callaway 2009). The cross-trophic and cross-system level interactions in this concept of facilitation are still a matter of debate and a challenge to a current ‘working’ definition of facilitation as being limited to the plant-plant interactions, mostly in terrestrial environments (Brooker and Callaway 2009; Maček et al. 2016b).

Regarding AM fungal community ecology, different studies suggest that when an extreme environmental stress occurs in soils, there are a small number of AM fungal lineages that are better able to tolerate those conditions, which results in unique, adapted populations (Helgason and Fitter 2009; Dumbrell et al. 2010; Maček et al. 2011). AM fungi form an extensive mycelial network in soil and, therefore, will be subject to strong selection pressures from the abiotic soil environment (e.g. Dumbrell et al. 2010; Maček et al. 2011). However, reports on molecular community analyses and diversity studies of AM fungi in extreme ecosystems remain scarce (e.g. Appoloni et al. 2008; Maček et al. 2011, 2016a; Maček 2017b). Maček et al. (2011) report on significant levels of AM fungal community turnover (beta diversity) between soil types and the numerical dominance of specific AM fungal taxa in hypoxic mofette soils. This work shows that direct environmental selection

acting on AM fungi is a significant factor in regulating AM fungal communities and their phylogeographic patterns. Consequently, some AM fungi are more strongly associated with local variations in the soil environment than with their host plant's distribution (Dumbrell et al. 2010; Maček et al. 2011). The higher temporal predictability (stability) is also evident from the preliminary results on AM fungal communities, which suggest that under permanent (long-term) selective pressure, community composition is more constant relative to control sites (Maček et al. 2011, 2016b). In the latter, stochastic processes and other environmental factors (e.g. vegetation) play a much more significant role in structuring communities over time. The major shifts in AM fungal community composition within and between consecutive years happen each spring, when the winter community supported by low photosynthetic carbon flux into roots is shifted to the summer community (with high photosynthetic carbon flux into roots), and the pattern of new community assembly during each year is largely stochastic (Dumbrell et al. 2011). However, this pattern may be less prominent in extreme environments, such as mofettes. The case of AM fungal community composition shows the potential of the mofettes to serve as model ecosystems to study some of the significant unresolved questions in microbial community ecology (Maček et al. 2011, 2016b). Importantly, the observed stability may be more ubiquitous than currently acknowledged in many other environments with long-term disturbances or specific selective pressures (Maček et al. 2016b; Maček 2017b). Thus, the strong environmental gradients of mofette sites, which include extreme and lethal conditions, make them ideal models for further study of community assembly rules, temporal dynamics (e.g. interannual variability), facilitation (plant O_2 supply) and symbiosis in AM fungi and provide an insight into different pathways of plant mineral assimilation and the role of the fungal partner in this process in hypoxic environments (Maček et al. 2016b).

1.4.3 Other Fungi

Apart from AM fungi and yeasts from the Slovenian mofette site at Stavešinci, there is only a single published study reporting on fungal abundance from mofette sites (Fernández-Montiel et al. 2016). In this study, microbial communities have been studied in a range of CO_2 fluxes from a natural volcanic vent in Campo de Calatrava, Spain, using a range of different techniques (quantitative PCR, DGGE and Biolog EcoPlates™) to assess changes in the abundance, diversity and functionality of the main groups of soil microbiota (bacteria, archaea and fungi). A general decrease for all studied variables (gene copies and band richness of bacteria, archaea and fungi, and Biolog activities) was observed from control to high CO_2 fluxes. In contrast, at extreme CO_2 fluxes, the communities of archaea and bacteria increased their abundance and activity but remained less diverse. The fungal community, however, showed a decrease in the number of fungal gene copies as CO_2 fluxes increased. In the case of fungi, extreme CO_2 fluxes diminished fungal gene copy numbers, with a significant decrease of three orders of magnitude in gene copy numbers in the high

CO_2 flux exposed sampling point. There are no detailed data available on the overall fungal community composition and taxa identity for this site.

1.5 Frontiers in Mofette Microbial Ecology Research

Mofettes show much potential for further investigation in a range of different fields, from soil ecology and biodiversity research to bioprospecting for new taxa with potential for biotechnological applications, research into hypoxia-tolerant human pathogens and others. Below is a description of recent and future advances in mofette research and potential applications, which is by no means exclusive, as further developments in this field may occur in the future.

1.5.1 Impact Assessment of Carbon Capture and Storage (CCS) Systems

Mofettes have been used as models that enable the evaluation of the potential risks to native ecosystems of geological carbon capture and storage (CCS) (CO_2 leakage) (Holloway et al. 2007), which has significant potential as a mitigation technique for climate change, both within the EU and internationally (see Maček et al. 2016b). Mofette studies can be of use to researchers and policy-makers in assessing the value of this technology and have the potential to inform the design of future experiments and models.

1.5.2 Mofettes and Bioprospecting for New Taxa

To date, apart from initial studies on AM fungi and yeasts (Maček et al. 2011, 2016b; Šibanc et al. 2018), there have been no reports on diversity, ecology or function of fungi from mofette areas. In general, reports on any aspect of AM fungal biology from extreme habitats or hypoxic environment are relatively scarce (Maček 2017a, b; Drake et al. 2017) while other fungal groups (e.g. yeasts) have been more widely studied in extremes (see Cantrell et al. 2011; Rangel et al. 2018). Extreme environments can serve as novel study systems to examine how long-term abiotic selection pressures drive natural communities and their evolution and possibly result in new specialist taxa (e.g. *Occultifur mephitis*, Šibanc et al. 2018). Isolation of hypoxia (stress)-tolerant microbes and microbial communities can have great potential in biotechnology (e.g. new drug discovery). As many biotechnological applications, such as industrial fermentation, require the capacity to grow in high-CO_2/low-O_2 environments, mofettes are likely ideal locations for bioprospecting for

industrially important microbes. For now, the biotechnological and medical potential of mofette sites and their biota remains mostly unknown and untapped.

1.5.3 Hypoxia and Fungal Human Pathogen Research

Hypoxia/anoxia-tolerant microbes are among the most resistant human fungal pathogens. Several moulds, typically found in soil and decaying organic matter like *Aspergillus fumigatus* and *Fusarium oxysporum*, can cause human disease in immunodeficient individuals, when O_2 levels in their host tissues can be very low (Grahl et al. 2012). As most eukaryotic human fungal pathogens are generally considered obligate aerobes, O_2 availability during fungal pathogenesis may play a critical role in the outcome of infection from the perspective of both the human host and the fungus (Grahl et al. 2012). In the context of microbial pathogenesis, it is generally accepted that hypoxia occurs at sites of infection, thus generating significant environmental stress on most host and microbial pathogen cells (e.g. Cramer et al. 2003; Peyssonaux and Johnson 2004; Nizet and Johnson 2009). In healthy tissues in the human body, O_2 levels of 2.5–9% are considered normal, while oxygen levels of 1%, which have been described in tumours and wounds, are considered hypoxic (Arnold et al. 1987; Simmen et al. 1994; Nizet and Johnson 2009). Furthermore, the human gastrointestinal tract, where one of the most frequently occurring human fungal pathogens *Candida albicans* is normally located, contains significant regions of hypoxia (He et al. 1999; Karhausen et al. 2004). Oxygen concentrations in the human brain are also significantly lower than in the atmosphere, indicating that *Cryptococcus neoformans*, causing cryptococcal meningitis, is also exposed to reduced O_2 levels during infection (Erińska and Silver 2001; Sharp and Bernaudin 2004). Thus, pathogenic fungi like *C. albicans*, *C. neoformans* and *A. fumigatus* can be exposed to oxygen-limited or even hypoxic microenvironments during fungal pathogenesis. Soil environments where levels of O_2 are low (e.g. submerged, flooded and compacted soil and mofettes) or can rapidly change with the microbial metabolic activity (e.g. in compost piles) could be a source of human pathogenic fungi, adapted to hypoxia (Grahl et al. 2012). Although most moulds are traditionally considered obligate aerobes, *A. fumigatus* has been observed to tolerate O_2 levels as low as 0.1%, and some studies even suggest that *A. fumigatus* can survive and grow anaerobically (Tabak and Cooke 1968; Park et al. 1992; Hall and Denning 1994). In addition, *Fusarium* species seem particularly adept at tolerating hypoxic and even anoxic conditions, which is consistent with their resident ecological niche in soil (Gunner and Alexander 1964; Hollis 1948). Thus, these studies strongly suggest that many fungal taxa, which cause human disease, may not be typical obligate aerobes but rather are likely to be facultative anaerobes. Therefore, with the research into mofette and other hypoxic environments, potential risks for hypoxic habitats in nature serving as reservoirs of pathogens can be identified and further studied.

1.5.4 Mofettes as Long-Term Experiments in Ecology

As many natural phenomena and ecological processes take place exceptionally slowly, long-term observations and experiments to investigate them are required (Franklin 1989), but are still mostly missing for many microbial groups. Mofettes can serve as long-term natural experiments in ecology and evolution and thus have a potential to enable better predictions of the impacts on ecosystems due to induced long-term environmental change (Maček et al. 2016b). Soil is one of the most biodiverse habitats on Earth, and soil microbes are an essential driver of many vital biogeochemical cycles and processes (Fitter 2005). Different taxa of soil microbes have different benefits and/or negative interactions with plants and human and are functionally differentiated. Changes in population densities of soil microbes in response to long-term environmental factors have the potential to impact the productivity of plant communities and affect human health. Importantly, questions about long-term-related changes in soil microbial communities are not only relevant for research into hypoxia as a stress factor, but also many other long-term anthropogenic drivers, including nutrient input, soil pollution, land-use change and more (e.g. Maček et al. 2016b; Maček 2017b). Studying mofettes can be one of the ways to increase the knowledge of microbial and fungal ecology under long-term environmental changes.

1.5.5 Mofettes and Ecological Networks

Aided by advances in sequencing technologies in recent years (e.g. Dumbrell et al. 2016), more and more studies also focus belowground, and this has been particularly true for the microbial taxa. Not only soil community composition but also the various interactions (networks) that occur among taxa are helping in monitoring the response of taxa interactions to human alterations in the environment, which is crucial in preserving ecosystems (Vacher et al. 2016). Ecological networks are now becoming a standard method for representing and simultaneously analysing interactions among taxa (e.g. Coyte et al. 2015; Vacher et al. 2016; Tylianakis and Morris 2017). In particular, the question on how networks change across environmental gradients, motivated by the need to understand how communities respond to the environment, is becoming increasingly important in the face of the global change as it may allow us to predict how networks might respond to future environmental change (Tylianakis and Morris 2017). However, ecological networks in soils are still mostly unknown. The reduction of the soil community to the microbial component makes the mofette a valuable model environment for studying diversity effects on specific soil functions. This all highlights the need for studies examining mofette systems within a broader food-web context. Namely, mofettes are characterised by a permanent exclusion of higher trophic levels and their associated physical and ecological traits from the local food webs (Maček et al. 2016b). As a significant

portion of the specific ecology of these systems is microbial, mofettes provide an ideal opportunity to explore network-based approaches for incorporating next-generation sequencing-based data into food-web ecology (e.g. Vacher et al. 2016; Maček et al. 2016b).

1.6 Conclusions and Future Perspectives

Mofettes have previously been identified as a locally extreme environment that can be used as a natural analogue for the research of long-term ecological and evolutionary processes in soil biota, including fungi (Maček et al. 2016b). There remains an extensive research space in which a blend of state-of-the-art technology (e.g. next-generation sequencing), ecological network analysis and the power of the long-term natural model ecosystems (like mofettes) could open new horizons in the study of the long-term effects of press disturbance on soil microbial communities, their stability, ecological networks, as well as bioprospecting for new taxa and industrially important microbes, and the studying of ecology of human pathogens. All these research topics are of great importance for the future directions of soil ecological explorations and the maintenance of well-being and diversity on our planet. Mofette research is one possible step towards the realisation of that aim.

Chapter 2
Eukaryotic Life in Extreme Environments: Acidophilic Fungi

Angeles Aguilera and Elena González-Toril

2.1 Introduction

Exploration of the biosphere has led to continued discoveries of life in environments that were previously considered uninhabitable. Thus, life can survive and sometimes thrive under what seem to be harsh environmental conditions. Extreme environments (defined from our anthropocentric view) usually possess various factors incompatible with most life forms. Thus, certain environmental conditions such as low water availability in hyperarid deserts or high temperatures seem to be close to the limit of biological activity. On the contrary, other parameters such as radiation or pressure remain well within the limits of life on Earth. An example is pressure in the deep oceans which does not seem to affect life's abundance and diversity. This does not mean, however, that all localities are habitats, places where life is actively metabolizing and reproducing. In many localities life simply survives in a dormant state, waiting for environmental conditions to change and become more suitable (Schulze-Makuch et al. 2017). However, in spite of the apparent hostility of these extreme habitats, they contain a higher level of biodiversity than expected.

On the other hand, extreme habitats are large sources of biodiversity and new adaptation mechanisms. In these habitats, evolution works with a special intensity. These are extreme, greatly selective, and confined habitats, which constitute a favorable environment for the creation of a unique type of biodiversity and specific adaptation mechanisms. Extreme ecosystems are real sources of biological uniqueness. This makes these ecosystems especially interesting for the study of biodiversity and for the protection of the biological patrimony. Uniqueness and specificity also make these extreme habitats especially fragile. Two factors can end with this type

of biodiversity specifically linked to the environment: breaking the balance in ecosystems which are already under extreme conditions and reestablishing the normal or non-extreme conditions in the environment.

The number of different organisms known to reside and thrive in these environmentally extreme conditions has grown rapidly in recent years. For example, we find robust microbial communities at high temperature ranges, i.e., the hot springs acidophilic algae (*Cyanidiaceae*) grow at 45–56 °C (Skorupa et al. 2013), while the hyperthermophilic archaea tolerate a temperature range above the boiling point (>100 °C) (Antranikian et al. 2017). Other organisms live in cold polar zones, such as the psychrophiles of the Antarctica, which are able to live in briny waters, with several times the salinity of seawater and temperatures below −10 °C, beneath 20 m thick ice (Lopatina et al. 2013; Bakermans et al. 2014). Recently, multicellular eukaryotes such as the lichen *Umbilicaria* and the yeast *Rhodotorula glutinis* have been shown to still grow at −17 and −18 °C, respectively (De Maayer et al. 2014). Similarly, there are microbes living in very alkaline environments (as high as pH 12) (Kambura et al. 2016). On the other end of the pH scale there are the acidophilic archaea (i.e., *Thermoplasma acidophilum*) (González-Toril et al. 2003), or the unicellular alga *Cyanidium caldarium* thriving in very acidic habitats (pH ranges from 0–4) (Seckbach 1994). Some microbial communities have been isolated from hypersaline areas, lakes, or mines containing saturated salt solutions such as those present in the Dead Sea, or are able to grow under potent ionizing radiation fields in nuclear reactors. We can also find some microbes that grow under extremely dry conditions and we find others that grow in the deepest parts of the oceans and require 500–1000 bars of hydrostatic pressure. To survive, organisms can assume forms that enable them to withstand freezing, complete desiccation, starvation, high levels of radiation exposure, and other physical or chemical challenges. Furthermore, they can survive exposure to such conditions for weeks, months, years, or even centuries (Rothschild and Mancinelli 2001).

In addition, interest in discovering extreme environments and the organisms that inhabit them has grown over the past years due to both basic, the idea that extreme environments are believed to reflect early Earth conditions in which prokaryotes originally evolved and adapted, and applied aspects, i.e., extremophiles as sources of enzymes and other cell products. Although originally considered to be nothing more than "scientific curiosities," the biotechnological potential of extremophiles and their cellular products is now a major impetus driving research. The fields of biotechnology that could benefit from mining the extremophiles are numerous and include the search for new bioactive compounds for industrial, agricultural, environmental, and pharmaceutical uses (Tiquia and Mormile 2010, Tiquia-Arashiro 2014; Krüger et al. 2018).

In this chapter, we will review the general trends concerning the diversity and ecophysiology of extremophilic fungi, paying a special attention to acidophilic ones, because unlike many other extremophiles that can adapt to diverse geophysical constraints, acidophiles actually thrive in the extreme conditions their chemolithotrophic metabolisms generate. In addition, the inorganic products of this metabolism may play an important part in the formation of specific minerals which are, in turn,

extremely important biosignatures that very well may lead to the detection of similar microorganisms in remote locations.

2.2 Extremophilic Fungi

When we think of extremophiles, prokaryotes come to mind first. Thomas Brock's pioneering studies of extremophiles carried out in Yellowstone's hydrothermal environments set the focus of life in extreme environments on prokaryotes and their metabolisms (Brock 1978). While archaea and bacteria are mostly the record holder for adapting to a particular kind of extreme environmental stress or a combination of stresses, there are also eukaryotic organisms, even relatively complex animals and plants that can withstand or even metabolize and reproduce in harsh environments (Schulze-Makuch et al. 2017). Thus, eukaryotic microbial life may be found actively growing in almost any extreme condition where there is a source of energy to sustain it, with the only exception of high temperature (>70 °C) (Roberts 1999) and the deep subsurface biosphere. The development of molecular technologies and their application to microbial ecology has increased our knowledge of eukaryotic diversity in many different environments (Caron et al. 2004). This is particularly relevant in extreme environments, generally more difficult to replicate in the laboratory.

Recent studies based on molecular ecology have demonstrated that eukaryotic organisms are exceedingly adaptable and not notably less so than the prokaryotes, although most habitats have not been sufficiently well explored for sound generalizations to be made. In fact, molecular analysis has also revealed novel protist genetic diversity in different extreme environments (Caron et al. 2004; Ragon et al. 2012). Extremophiles are promising models to further our understanding of the functional evolution of stress adaptation. Their biology widens our views on the diversity of terrestrial life and it has come as a surprise that not only prokaryotes but also eukaryotes have a great capacity to adapt to extreme conditions. Particularly successful examples can be found in the fungal kingdom. Thus, specialized fungi have been discovered in extreme cold, dry, salty, acidic, and deep-sea habitats (Gostincar et al. 2010) (Fig. 2.1).

Cold Environments: Several fungal species have been isolated in considerable numbers from subglacial ice of polythermal glaciers (Gunde-Cimerman et al. 2003). Among these, there are cosmopolitan species belonging to common mold genera that do not, at first glance, look much different from isolates from elsewhere. Several *Penicillium* species are found in cold environments. Thus, *Penicillium crustosum* populations isolated from glaciers (Svalbard, Norway) demonstrated that the majority of these Arctic isolates cluster into two main groups that are distinct from strains isolated in other parts of the world (Sonjak et al. 2009). One of these groups cannot use creatine as the sole carbon source and produces a secondary metabolite, andrastin A, two properties never found previously in this species (Sonjak et al. 2007a). Another *Penicillium* species reported in cold environments is closely related to

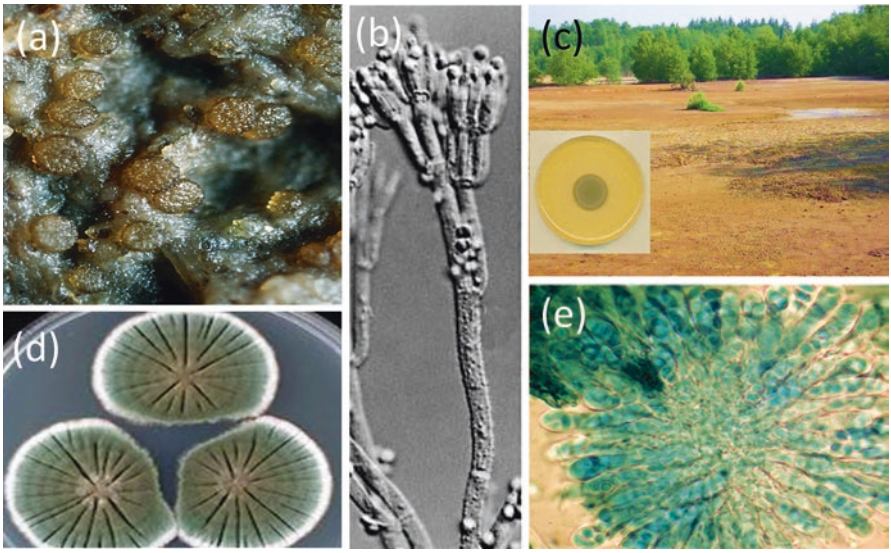

Fig. 2.1 Images of extremophilic fungi species. (**a**) *Thelebolus microspores*, psychrophilic fungi isolated from Antarctic soils samples, (**b**) *Penicillium crustosum* micrograph, psychrophilic fungi isolated from glaciers in Svalbard, Norway, (**c**) colony of the acidophilic fungi *Purpureocillium lilacinum* isolated from Rio Tinto (SW Spain) waters, (**d**) *Penicillium crustosum* 2 weeks colonies, (**e**) micrograph of *Thelebolus microspores*

other temperate *Penicillium* species, but differs in the production of secondary metabolites and in the morphology of its conidia and penicilli; it has been named *Penicillium svalbardense* (Sonjak et al. 2007b). Species of the genus *Thelebolus* tend to be psychrophilic (Wicklow and Malloch 1971). *Thelebolus microsporus* occurs globally in boreal climate zones, while in the extreme climate of the Antarctic, it has evolved into two endemic genotypes; these have a strongly reduced morphology and cannot undergo sexual interactions. These two genotypes were described as novel species: *Thelebolus ellipsoideus* and *Thelebolus globosus* (De Hoog et al. 2005).

Saline Habitats: Until recently, it was believed that microbial communities at high salinities are dominated exclusively by Archaea and Bacteria and one eukaryotic species, the alga *Dunaliella salina* (Oren 2002). However, it has become evident that there is a higher diversity of eukaryotic microorganisms in hypersaline waters of solar salterns than previously presumed (Casamayor et al. 2002).

In this regard, studies of fungal populations in natural hypersaline environments on several continents have revealed the abundant and consistent occurrence of several specialized fungal species (Gunde-Cimerman et al. 2000). These species are characterized by extensive and complex molecular adaptations to low water activities and high concentrations of toxic ions (for reviews, see, e.g., Gunde-Cimerman et al. 2005a, b; Plemenitas et al. 2008).

Melanized fungi are a new group of eukaryotic halophiles, represented by black, yeast-like hyphomycetes: *Hortaea werneckii*, *Phaeotheca triangularis*, *Trimmatostroma salinum*, and *Aureobasidium pullulans*, together with phylogenetically closely related *Cladosporium* species, all belonging to the order Dothideales (De Hoog et al. 1999, Sterflinger et al. 1999, Gunde-Cimerman et al. 2000). Melanized fungi have been isolated from hypersaline waters on three different continents, indicating their global presence in hypersaline waters of man-made salterns. Besides, these fungi display some distinctive features that help them to adapt both to high and low salt concentrations. They are able to survive periods of extreme environmental stress in a viable, resting state. When conditions change, they respond immediately with increased metabolic activity, growth, and propagation. Their pleomorphism and adaptive halophilic behavior enables a continual colonization of salterns (Butinar et al. 2005).

The species *Hortaea werneckii* is one of the most halotolerant fungi, with a broad growth optimum from 1.0 to 3.0 M NaCl (Gunde-Cimerman et al. 2000), and it can grow in nearly saturated salt solutions, as well as without sodium chloride. Hypersaline waters appear to be its primary ecological niche in nature, such as those found in salterns (Gunde-Cimerman et al. 2000; Butinar et al. 2005). Despite its ability to grow without salt, it has been isolated only occasionally in NaCl concentrations <1.0 M, while at 3.0–4.5 M NaCl, this species can represent as much as 85–90% of all of the fungal isolates from salterns. *Hortaea werneckii* is well adapted to environments with low water activities through several of its traits: plasma membrane composition, enzymes involved in fatty acid modifications (Turk et al. 2004, 2007; Gostincar et al. 2010), osmolyte composition and accumulation of ions (Petrovic et al. 2002; Kogej et al. 2005, 2006), melanization of the cell wall (Kogej et al. 2004), differences in the high osmolarity glycerol signalling pathway (Turk and Plemenitas 2002), and differential gene expression (Petrovic et al. 2002; Vaupotic and Plemenitas 2007).

Extreme dry ecosystems: Water is an essential component of all active cells as it is the matrix in which cellular reactions occur. Availability of water can be limited by a low relative humidity, e.g., in hot, dry deserts, or when water is bound up in ice or by a high concentration of solutes (e.g., in salterns and at high sugar concentrations) (Williams and Hallsworth, 2009; Gostincar et al. 2010). Microorganisms have developed various strategies to grow in each of these conditions, and fungi are among those best adapted to growth when little water is available (Leong et al. 2015). *Xeromyces bisporus* is an ascomycete filamentous fungus that has the unique trait of being, arguably, the most xerophilic organism discovered to date (Grant 2004; Williams and Hallsworth 2009; Leong et al. 2011). *X. bisporus* actively grows in conditions of decreased water availability. Indeed, it has an absolute requirement for lowered water availability in order to grow and has an optimal water activity for growth around 0.85 (where water activity, aw, is the vapor pressure of water above a sample divided by that of pure water in the sample, pure water having aw = 1) (Grant 2004). Only a small number of microbial systems can retain activity at <0.710 water activity (Stevenson et al. 2015a).

In this way, *X. bisporus* shares its preference for decreased water availability with other extremophiles, such as the halophilic microbiota of salterns (bacteria, e.g., *Salinibacter ruber*; archaea, e.g., *Haloquadratum walsbyi*; the alga *Dunaliella salina*; yeasts, e.g., *Hortaea werneckii*) (Ma et al. 2010). But unlike the halophiles, *X. bisporus* prefers sugars or glycerol as a solute in the growth medium and given such conditions can even grow at 0.61 *a*w (Leong et al. 2011), lower than any other organism reported to date. The majority of *X. bisporus* strains have been isolated from high-sugar foods, including dried fruits (Pitt and Hocking 2009), and thus, wizened berries and fruits are likely to be the natural habitat for this fungus. *Xeromyces bisporus* increased glycerol production during hypo- and hyper-osmotic stress, and much of its wet weight comprised water and rinsable solutes; leaked solutes may form a protective slime. *X. bisporus* and other food-borne molds increased membrane fatty acid saturation as water activity decreased. Such modifications did not appear to be transcriptionally regulated in *X. bisporus*; however, genes modulating sterols, phospholipids, and the cell wall were differentially expressed.

Additionally, a number of recent studies indicate that *Aspergillus penicillioides* is active close to the water-activity limit of Earth's biosphere (Stevenson et al. 2015a, b). *A. penicillioides* is at the same time xerophilic, osmophilic, and halophilic (in relation to low water activity, high sugar- and NaCl concentrations, respectively), grows close to 0 °C (and almost certainly at sub-zero temperatures, as well), and can function anaerobically (Chin et al. 2010; Zhang et al. 2013; Nazareth and Gonsalves 2014). When growing in saline conditions, xerophilic aspergilli synthesize and accumulate molar concentrations of glycerol at low water activity (Nazareth and Gonsalves 2014; de Lima Alves et al. 2015).

2.3 Acidic Extreme Environments and Acidophilic Fungi

As mentioned before, eukaryotic organisms are exceedingly adaptable, and they are present in all the extreme environments reported until now. In this regard, acidophilic environments are not an exception. Although it is usually assumed that high metal concentrations in acidic habitats limit eukaryotic growth and diversity due to their toxicity, most of these extreme environments showed an unexpectedly high degree of eukaryotic diversity. Extreme acidic ecosystems usually include as well different abiotic extremes than low pH (Rothschild and Mancinelli 2001; Tiquia-Arashiro and Rodrigues 2016). Thus, eukaryotes thriving at these habitats are often also exposed to low nutrient levels (Brake and Hasiotis 2010), high concentrations of toxic metals (Aguilera et al. 2007a), and/or extreme temperatures (González-Toril et al. 2015). Additionally, several studies have revealed representatives from multiple evolutionary eukaryotic lineages, suggesting that the ability to adapt to pH extremes may be widespread (Amaral-Zettler et al. 2002). This raises the question of whether there are cosmopolitan eukaryotic taxa that have adapted to a wide range of pH extremes. Which environmental parameters are most

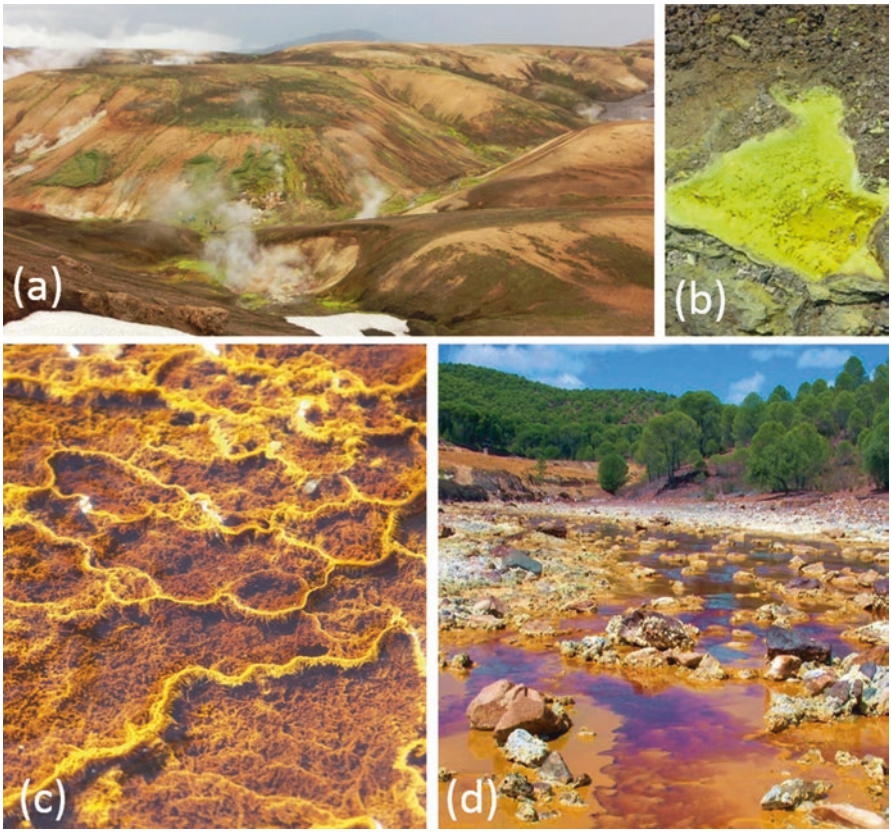

Fig. 2.2 Extreme acidic environments. (**a**) Seltun acidic geothermal area, SW Iceland, (**b**) elemental sulfur forming from gases venting the Soufriere Hills volcano on Montserrat, West Indies, (**c**) terraces formed by iron precipitates in Río Tinto, SW Spain, (**d**) Río Tinto, SW Spain, at Salinas site

influential in shaping eukaryotic microbial diversity patterns at pH extremes also remains underexplored.

Most aquatic acidic habitats have two major origins, one associated to volcanic activities and the other to metal and coal mining (Johnson 1998) (Fig. 2.2). In the first case, acidity is mainly generated by the biological oxidation of elemental sulfur produced as a result of the condensation reactions among sulfur containing volcanic gases. These can result from the generation of sulfuric acid by the microbial oxidation of reduced forms of sulfur (reviewed by Johnson and Aguilera 2016). Both hydrogen sulfide and sulfur dioxide are common in many volcanic gasses. Condensation of these two gasses produces elemental sulfur ($2H_2S + SO_2 \rightarrow 3S^0 + 2H_2O$) which can occasionally be seen as prismatic sulfur particles forming around the peripheries of volcanic vents (Fig. 2.2a, b). Dissimilatory oxidation of sulfide, sulfite (from SO_2), elemental S, and other forms of sulfur with

oxidation states of <+6, by chemolithotrophic archaea and bacteria, generates sulfuric acid (e.g., $S^0 + 3\ H_2O + 1.5\ O_2 \rightarrow 2\ H_3O^+ + SO_4^{2-}$). In the second case, metal and coal mining expose sulfidic minerals to the combined action of water and oxygen, which facilitate microbial attack (Aguilera et al. 2010; Vera et al. 2013). The most abundant sulfidic mineral, pyrite, is of particular interest in this context. In low pH environments, the main oxidant of this mineral is ferric iron, which attacks pyrite liberating ferrous iron and oxidizing the reduced sulfur moiety (oxidation state −1) to thiosulfate ($FeS_2 + 6\ Fe^{3+} \rightarrow 7\ Fe^{2+} + S_2O_3^{2-} + 6\ H^+$). This is an acid-generating reaction that does not involve oxygen. For the reaction to continue, the ferrous iron generated needs to be re-oxidized to ferric, which does require oxygen and is also acid-consuming ($Fe^{2+} + 0.25\ O_2 + H_3O^+ \rightarrow Fe^{3+} + 1.5\ H_2O$) (Fig. 2.2c, d). Both habitats vary greatly in their physicochemical characteristics and, as a consequence, in their microbial ecology (Table 2.1). Acidic environments associated to mining operations are very recent on the geological and evolutionary scale, although some metal mining activities have a relatively long history.

On the other side, in the acidic habitats related to mining activity, the extreme conditions found in the environment are the product of the metabolic activity of chemolithotrophic microorganisms, mostly iron- and sulfur-oxidizing bacteria that can be found in high numbers in their waters (Johnson 2009). Their iron-oxidizing microorganisms are responsible for the solubilization of sulfidic minerals, mainly pyrite, and the correspondent high concentration of ferric iron, sulfate, and protons in the water column. Most of these chemolithotrophic prokaryotes are autotrophic. Thus, in addition to promoting the extreme conditions of the habitat they are primary producers (González-Toril et al. 2003). Acidophilic chemolithotrophs, especially *Acidithiobacillus ferrooxidans* and *Leptospirillum* spp., accelerate the rate of

Table 2.1 Physicochemical parameters measured at different acidic environments

Acidic origin	Location	pH	Fe (mM)	Cu (mM)	As (μM)	Cd (μM)	Zn (mM)	Cr (μM)
Acidic mine drainage	Río Tinto (SW Spain)	2.3	52.4	100.3	48.6	43.9	120.6	13.1
Acidic mine drainage	La Zarza (SW, Spain)	1.9	47.7	0.70	30.6	62.6	1.85	8.5
Acidic rock drainages	Pachacoto River (Perú)	2.8	6.8	12.5	0.7	1.8	12.8	2.9
Acidic rock drainages	Bjørndalen (Svalbard)	2.8	15.7	0.03	3.6	0.6	1.1	0.6
Acidic volcanic	Río Agrio (NE, Argentina)	2.4	5.6	1.5	0.3	0.04	0.75	0.5
Acidic geothermal	Seltun (SW, Iceland)	2.9	21.4	117.8	0.1	0.2	78.2	27.8
Acidic geothermal	Hveradalir (SW, Iceland)	3.4	28.5	5.7	0.02	0.07	30.6	2.9

The table shows the average values for pH and concentration of different metals measured in the water at each location

pyrite oxidation. At the same time, low pH facilitates metal solubility. Therefore acidic water tends to have high concentrations of heavy metals.

Despite these extreme environmental conditions, most acidic environments showed an unexpectedly high degree of eukaryotic diversity. Thus, chlorophyta such as *Chlamydomonas*, *Chlorella*, and *Dunaliella* are frequently found in acidic environments, as well as the photosynthetic protist *Euglena mutabilis* (Aguilera et al. 2006, 2007a; González-Toril et al. 2015). Within the decomposers, fungi are very abundant and exhibit great diversity, including yeast and filamentous forms. In fact, until now, only four eukaryotic organisms were known to grow near pH 0: one algae, *Cyanidium caldarium*, and three fungi, *Acontium velatum*, *Cephalosporium* spp., and *Trichosporon cerebriae* (Schleper et al. 1995).

2.4 Acidophilic Fungi Diversity

Among acidophilic eukaryotic organisms, algae and protozoans have received more attention than fungi and yeasts, although fungi have long been recognized as active participants in acidification of sulfide-rich environments (Armstrong 1921; Gross and Robbins 2000). Additionally, most studies related to these organisms have been focused on biodiversity, and little is known about their physiology or their interactions with other species. Most fungi living in acidic habitats should be regarded as acid tolerant rather than strictly acidophilic because they are also able to grow under neutral or even alkaline pH (Gross and Robbins 2000). Although field studies on acidophilic fungi are usually carried out only in soil samples, up to 81 fungal species have been described (Gross and Robbins 2000). Molecular analysis have shown that acidophilic basidiomycetes phylotypes had more than 97% sequence identity to known taxa, whereas the phylotypes of the acidophilic Zygomycota/Chytridiomycota had less than 93% sequence identity to sequences available in the GenBank database (Gadanho and Sampaio 2006). Some of those phylotypes were allocated at the base of the fungal clade, being their closest relatives situated at the base of the fungal radiation.

Generally, fungi occur over a wide pH range (pH 1.0–11.0) and have been detected in acid habitats like volcanic springs, acid mine drainage, or acid industrial wastewaters (Gross and Robbins 2000). Many of them are primarily acid tolerant, but truly acidophilic species have also been detected. From a stream carrying acid mine drainage 189 species of fungi including yeast as well as filamentous fungi were isolated (Cooke 1976). Two classes of fungi, Dothideomycetes and Eurotiomycetes, have been isolated from the highly acidic (pH 0.8) and metal-rich acid mine drainage from Richmond Iron Mountain, California (Baker et al. 2004, 2009). The presence of *Geotrichum* sp. and *Aspergillus* sp. in Sar Cheshmeh Copper Mine is also reported (Orandi et al. 2007). Additionally, near hundred strains of yeast have been isolated from the Río Tinto Basin, one of the largest acidic ecosystems reported until now (Oggerin et al. 2014). Fifty-two percent are able to grow in media amended with river water (pH 2.3). They belong to five genera of

basidiomycetes (*Rhodotorula*, *Cryptococcus*, *Tremella*, *Holtermannia*, and *Mrakia*) and two ascomycetes (*Candida* and *Williopsis*). In addition, over thousand strains of hyphomycetes have been isolated from the Tinto ecosystem and most of them characterized phenotypically. Around 50% of the isolated filamentous fungi are able to grow in the extreme acidic conditions of the river. Of this, 19% belong to the genus *Penicillium* and the rest have been identified as members of the *Scytalidium*, *Bahusakala*, *Phoma*, and *Heteroconium* genera or showed dark sterile mycelia (probably dematiaceous hyphomycetes). In addition, some isolates have been identified as strains of the ascomycete genera *Lecythophora* and *Acremonium* and the zygomycete genus *Mortierella*. Besides, fungi were the dominant group in Carnoulès sediments (France) and in the Richmond Mine (Iron Mountain, Los Angeles, CA, United States) biofilms (Baker et al. 2004; Volant et al. 2016).

Species related to Opisthokonta fungi, mainly affiliated within the Ascomycota *Helotiales* and *Dothideomycetes*, have been identified in Los Rueldos (NW Spain), an abandoned mercury underground mine, as well as the genus *Paramicrosporidium* and the Zygomycota genus *Mucoromycotina* (Mesa et al. 2017). Fungi detected in water samples in this area mainly belonged to the groups *Pezizomycotina*, LKM11 clade, and *Nucletmycea*. The environmental fungal clade LKM11 belongs to a group of fungi located near the phylogenetic root of the fungal kingdom, Rozellomycota. The clade is primarily comprised of *Rozellida*, a group of parasites with algal and fungal hosts (Masquelier et al. 2010; Auld et al. 2016). Phylogeny reconstruction indicated that the LKM11 group shared high similarity with *Paramicrosporidium* fungi, which are endonuclear parasites of free-living amoebae (Corsaro et al. 2014). Many of the fungi detected using molecular techniques have sequences that probably correspond to novel genera (Amaral-Zettler et al. 2002; Gross and Robbins 2000). Concerning metal tolerance Eurotiomycetes and Sordariomycetes isolates showed the highest resistance to toxic heavy metals, much higher than the concentrations detected in the river, while members of the Dothideomycetes showed a level of resistance to concentrations similar to those existing in the water column, and those from Basidiomycetes were in general less metal tolerant (Oggerin et al. 2014).

As mentioned before, three of the most acidophilic microorganisms described until now are fungi. The acidophilic bacteria *Thiobacillus thiooxidans* had been considered unique in its tolerance to acid until Starkey and Waksman (1943) demonstrated that two fungi, *Acontium velatum* and a *Dematiaceae* related species, were able to grow in a medium initially as acid as 2.5 N sulfuric acid solution saturated with copper sulfate, growing at pH values considerably below pH 1. Additionally, a fungus provisionally identified as *Trichosporon cerebriforme* was found to grow in 2.5 N sulfuric acid and 280 g CuS04 in solution (Sletten and Skinner 1948). Growth was evident in about 10 days. All these species were isolated from acid solutions employed in industrial plants.

Studies on yeast in acidic environments are even scarcer and also related to biodiversity description. Usually, those that formed pink colonies (*Rhodotorula* sp.), arthroconidia (*Trichosporon* sp.), and *Candida* are the most prominent. Among the ascomycetes, species belonging to the Hemiascomycetes and Euascomycetes have

been described in the Iberian Pyrite Belt (*Glomerella* sp. and *Lecythophora* sp.), as well as basidiomycetous yeasts distributed in the classes Hymenomycetes and Urediniomycetes (Gadanho et al. 2006). These species have also been described in natural acidic geothermal areas (Russo et al. 2008). Three novel asexual basidiomycetous yeast species have been recently described in the Iberian Pyrite Belt (*Cryptococcus aciditolerans* sp. nov., *Cryptococcus ibericus* sp. nov., and *Cryptococcus metallitolerans* sp. nov.) belonging to the order Filobasidiales and form a well-separated clade (Gadanho and Sampaio 2009). These *Cryptococcus* species are apparently specialists of acidic aquatic environments since they require low pH for growth, a property that has not been observed before in yeasts.

2.5 Acidophilic Fungi and Metal Immobilization

2.5.1 Ecological Role of Fungi in Extreme Acidic Environments

Fungi seem to play an important role in these environments because, together with other microorganisms, they form biofilms on the surface of rocks. These biofilms are the site of metal and mineral precipitation and provide a substrate for other microbial populations. Fungi can display metal resistance and can sequester specific metals, allowing less tolerant species to exist. Most of the eukaryotic microbial communities found in extreme acidic environments are distributed in extensive biofilms, mainly formed by microalgal species and fungi (Aguilera et al. 2007b). As in other habitats, monospecies biofilms are relatively rare and thus most biofilms are composed of mixtures of microorganisms. These biofilms are organized multicellular systems with a structural and functional architecture which influences metabolic processes, response to nutrients, predation, and other factors of the ecosystem. Moreover, it is important to study how biofilms in highly acidic conditions affect geochemical processes as metal immobilization and influence the ecophysiological rates of the microorganisms when compared to microorganisms growing in a planktonic form (Aguilera et al. 2008). This is even more important in extreme environments where forming a structured biofilm might protect the organisms from external stress conditions and allow them to resist more extreme conditions. Furthermore, analysis regarding the microcolonization sequence in Río Tinto showed an initial accumulation of amorphous particles composed of bacteria and inorganic grains of minerals. By the end of the second month, the organic matrix was also populated by fungi, bacteria, and a few eukaryotic heterotrophs such as amoebae and small flagellates. Diatoms only showed significant colonization in regions where mycelial matrices were first established (Aguilera et al. 2007b). This fact supports the idea that fungi provide a suitable substrate for less tolerant species to low pH and metals, allowing them to grow in such adverse environmental conditions. The diversity of eukaryotic microorganisms inhabiting extreme acidic systems includes microscopic

algae, which are primary producers; protozoans (ciliates, flagellates, rotifers, amoebae), contributing to primary or secondary production; and fungi, which act as decomposers and contribute to carbon recycling (Méndez-García et al. 2015). Fungi and protists confer structure to the biofilms and impact the community composition by grazing on resident bacteria and archaea (Baker et al. 2004).

The ecological role of fungi in acid environments or affected streams and lakes is not adequately studied (reviewed by Das et al. 2009). Extreme acidic waters are often very low in easily degradable organic carbon. The degradation of terrestrial organic carbon sources, such as leaf litter, is impaired by the absence of invertebrates that actively shred the leaves at pH values below 3.5 (Siefert and Mutz 2001). Under these conditions, fungi may become important as primary degraders of complex organic matter. At the same time, the fungi will contribute to oxygen consumption, thereby limiting oxidative stress for the SRB. Moreover, fungi can be directly involved in the reduction of ferric iron or sulphate (Ottow and von Klopotek 1969) which is an important electron transport process in acid mine drainage and contributes to biological alkalinity generation if appropriate solid products are formed.

2.5.2 Metal Resistance Mechanisms

Acidophilic fungi can display metal resistance and can sequester specific metals allowing less tolerant species to exist (reviewed by Das et al. 2009). Fungi can absorb metals in their cell wall or adsorb in extracellular polysaccharide slime. This capacity enables them to grow in the presence of high amounts of heavy metals. Fungi can also neutralize by excreting basic substances (Shiomi et al. 2004). Thus, fungi isolated from Río Tinto (pH between 2 and 2.5) are capable of growing in the presence of metal concentrations as high as 0.4 M (Duran et al. 1999a). In general, these isolates are more resistant to heavy metals than the reference systems obtained from type collections, exhibiting a characteristic polyresistance profile. Some of the fungi can sequester heavy metals with rather high efficiency, which is normally associated with metal resistance, showing also specific heavy metal sequestering. Preliminary data using *Penicillium* isolates suggested that the mechanism of specific copper sequestering (33% at 100 mM of Cu^{2+}) depends on active cell growth, involving metal transport and formation of cellular inclusions.

The high concentration of heavy metals in solution results toxic to numerous aquatic organisms (Bowman et al. 2018). Therefore acidophilic fungi require suitable mechanisms to develop in these extreme conditions. At low pH, the cellular components must be adapted to the high concentration of extracellular acidity and be able to maintain the cytoplasm near neutrality using different homeostatic mechanisms (Baker-Austin and Dopson 2007; Magan 2007). In addition, heavy metals may induce denaturation of proteins and disruption of cellular membranes, act as antimetabolites of essential cellular functions, and generate very reactive free radicals (Gadd 1993; Tiquia-Arashiro 2018). Thus, fungal survival and growth in these environments are possible through the development of several strategies including

the synthesis of metallothioneins, extracellular precipitation, biosorption to cell walls, impermeability, and intracellular compartmentation among others (Gad and Griffiths 1978; Brown and Hall 1990; Mehra and Winge 1991; Gadd 2008). The best understood mechanism that fungi have developed to survive in the presence of toxic heavy metals are their sequestering on the cellular envelops or active transport to eliminate metals from the intracellular media. Moreover, it has been detected the capacity of different acidophilic fungi to specifically sequester toxic metals intracellularly, resulting in the base of a methodology to eliminate and recover valuable metals from industrial contaminated wastewaters (Duran et al. 1999a, b). Some of the best examples of microbial metal tolerance are also found in the genus *Penicillium*, underlining the fact that metal responses may be strain specific. As noted above, *P. ochro-chloron* can grow in saturated $CuSO_4$ and it is frequently isolated from industrial effluents (Stokes and Lindsay 1979), whereas *P. lilacinum* comprised 23% of all fungi isolated from soil polluted by mine drainage (Tatsuyama et al. 1975).

Moreover, it has been described that ferrous iron oxidation carried out by *Thiobacillus ferrooxidans* was stimulated by the basidiomycetous *Rhodotorula mucilaginosa*. Recent studies have shown that biogenic formation of jarosite, in natural acidic environments, usually related to bacterial activity, is also induced by acidophilic fungi. *Purpureocillium lilacinum*, a fungal strain isolated from Río Tinto, specifically precipitates hydronium-jarosite. The mineral starts to nucleate on the fungal wall of both living and dead cells as well as on the extrapolymeric substances. This may act as heterogeneous crystallization nuclei for a metabolism independent process of jarosite precipitation, possibly promoting local ion oversaturation for mineral crystallization when suitable physicochemical conditions are present and helping to shape and control the geochemical properties of the environment (Oggerin et al. 2014).

Understanding the evolution and adaptive mechanisms of microorganisms to thrive in extreme environments will increase our basic knowledge of evolutionary processes and allow a better evaluation of the potential ecological consequences of environmental changes.

2.6 Conclusions and Future Perspectives

Knowledge of the phylogenetic and physiological diversities of acidophilic microorganisms has expanded greatly in the past 25 years. Data from biomolecular studies of extremely acidic sites, however, suggest that a large number of extremophilic fungi in general and particularly acidophilic ones still await isolation and characterization. There is a great deal of interest in acidophiles, not only from the standpoint of understanding how these microorganisms can thrive in conditions that are hostile to most life forms, but also due to their importance in environmental pollution and in biotechnology. To date little is known regarding the role of acidophilic fungi in shaping the varied ecosystems that occur in acidic environments and less about

whether these microorganisms can support microenvironmental conditions that increase the survival of other members of the microbial community, or the interaction between different organisms enhances colonization of others. Acidophilic fungi have to play an even more important role in the development of microbial communities in extreme environments by providing a suitable architectural structure, mechanical stability, and protection against external conditions, and be able to selectively accumulate metals from the surrounding water.

Chapter 3
Ecology of Thermophilic Fungi

Tássio Brito de Oliveira and Andre Rodrigues

3.1 Introduction

One fascinating property of microorganisms is their ability to adapt to extreme environments, in which factors such as pH, temperature, pressure, and salt concentration exceed the values that most living beings can survive. Among these factors, temperature alone can influence the function of the majority of biomolecules and the maintenance of biological structures. In fact, most of the currently known organisms can only sustain growth within a narrow temperature range. However, the existence of thermally stable environments has allowed the selection or the persistence of microorganisms that not only resist but also require high temperatures to survive: the thermophilic organisms.

Among the thermophilic microbes, fungi that sustain growth at high temperatures have attracted interest not only of biologists and ecologists but also for their wide applications in biotechnology and industry. While biologists investigate the adaptations of thermophilic fungi to their heated environment (Cooney and Emerson 1964; Crisan 1973), applied microbiologists explore these adaptations for economical purposes (Johri et al. 1999; Gomes et al. 2016; Singh et al. 2016). Regardless of the approach, the taxonomy and systematics of these fungi as well as their interactions with the environment are usually not considered in these fields. Here, our goal was to provide a taxonomic background of thermophilic fungi for users that explore these fungi but want to keep up-to-date with name changes of this group of microorganisms. Thus, we review the 46 currently known thermophilic fungal species

belonging to 23 genera. A second goal of this work is to discuss the various concepts of thermophilic fungi and how this depicts their ecology and lifestyles in the natural substrate. We go further and also explore biogeography and the mechanisms for adaptations to thermophily based on the current knowledge. Although several works reviewed the applications of thermophilic fungi (Cooney and Emerson 1964, Johri et al. 1999, Maheshwari et al. 2000, Gomes et al. 2016, Singh et al. 2016), here, we bring an updated background on the taxonomy and ecology.

3.2 Thermophilic Fungi

In general, thermophilic organisms can be classified as either moderate thermophilic or hyperthermophilic. The former exhibits growth temperatures ranging from a minimum of 20 °C up to a maximum of 60 °C and with optimal growth above 40 °C. These moderate thermophiles include species from the domains Bacteria and Archaea and representatives from Eukarya (mostly filamentous fungi), whose maximum temperature limit has been recorded to be 62 °C (Tansey and Brock 1972). On the other hand, the hyperthermophiles are organisms able to grow at temperatures between 65 and 110 °C. They contain several representatives from the domains Bacteria and Archaea, but do not include organisms from the domain Eukarya (Vieille and Zeikus 2001).

Although the first report of a thermophilic fungus, named *Mucor pusillus* (currently named as *Rhizomucor pusillus*), dates back to more than a century ago, the ability of fungi to grow at high temperatures was unknown at that point (Lindt 1886). Only a few years later that a second fungus (*Thermomyces lanuginosus*), isolated from potato disks, was described and its ability to grow at temperatures above 50 °C was demonstrated for the first time (Tsiklinsky 1899). In fact, the early systematic studies on thermophilic fungi are attributed to Miehe (1907) who described two important species, *Malbranchea pulchella* var. *sulfurea* (currently *Malbranchea cinnamomea*) and *Thermoascus aurantiacus*. However, it was only decades later when the first definition of thermophilic fungi was proposed (Apinis 1953).

Apinis was the first to use the term “thermophilus” to define all fungal species with good growth in the range of 35–40 °C (Apinis 1953). Thereafter, Crisan (1959) stated that all fungal species with regular growth at 40 °C or above are considered thermophiles. Then, Apinis (1963) proposed a classification using the cardinal points, classifying thermophilic fungi as having optimum temperatures for growth between 40 and 50 °C and a maximum up to 60 °C, but unable to grow at 20 °C. In the following year, Craveri et al. (1964) suggested a broad interpretation of thermophily in which a thermophilic fungus would be regarded as having the minimum growth temperature higher than 25 °C.

Considering that the end points (maximum and minimum) are easily demonstrated in comparison to the optimum growth, Cooney and Emerson (1964) proposed a less elaborate definition, separating these fungi into two subgroups:

thermophilic and thermotolerant. These authors considered thermophilic fungi as those with a maximum growth at 50 °C or above and a minimum growth temperature at 20 °C or above, separating them from the thermotolerant fungi, which could grow up to 50 °C and below 20 °C. Although this classification was generally used in the literature for many years, authors found several exceptions that do not fit to these criteria. As an example, *Aspergillus fumigatus* is a thermotolerant fungus able to grow at temperatures above 50 °C and below 20 °C (Mouchacca 2000a). Mostly because of these exceptions and the several different systems for distinguishing between thermophilic and thermotolerant fungi, many thermotolerant fungi are continuously classified as thermophilic (Mouchacca 2000a, 2007; Oliveira et al. 2015).

Evans (1971), noticing that the Cooney and Emerson definition was becoming artificial and obscure, delimited the heat-tolerant fungi in several groups. Briefly, group 1 (strong thermophiles) constitutes the obligate thermophiles, while species in groups 2 (weak thermophiles) and 3 (strong thermotolerants) form a transitional stage between true thermophily and general thermotolerance, the latter term embracing those species included in group 4 (thermotolerant in general). Then, Evans (1971) suggested that strains of certain fungi are transitional between the two groups: thermophilic and thermotolerant.

Alternatively, a few new definitions of thermophily in fungi came out in the last decades. Maheshwari et al. (2000) proposed a simpler classification, mostly used as a working model in applied research, where thermophilic fungi are defined as those species with an optimum growth temperature of 45 °C or above. Later, Morgenstern et al. (2012) used the criterion that a thermophilic fungus is that the one which grows faster at 45 °C than at 34 °C. The most recent definition was suggested by Oliveira et al. (2015), where thermophilic fungi are those with optimum growth ranging from 40 to 50 °C, separating them from thermotolerant species by the inability of growing below 20 °C. The inability to grow at low temperatures implies that thermophilic fungi are the only species that require higher minimum growth temperature (≥20 °C) to exclude the gap presented for thermotolerant species (e.g., *A. fumigatus*).

3.3 Taxonomy

Thermophilic fungi comprise a paraphyletic group and, although they are distributed among taxonomically distinct lineages, they constitute an ecologically well-defined group. The first species reported as thermophilic was named *Thermomyces lanuginosus* (Tsiklinsky 1899). However, this species was relocated into different genera over the years, such as *Humicola*, *Monotospora*, and *Sepedonium*, before it has finally been relocated to *Thermomyces*. Likewise, many of the thermophilic fungi described until the last decades have been successively reclassified and renamed. The outcome of such name changes was the chaotic nomenclatural state of several members of this group as pointed by Mouchacca (2000b) and Oliveira et al. (2015).

Recently, an important step towards the stabilization of scientific names in fungal taxonomy was taken. A nomenclature code for fungi was proposed by mycologists resulting in the new *International Code of Nomenclature for Algae, Fungi and Plants* (ICN, McNeill et al. 2012). The development of this code was based on the "One fungus = One name" movement, seeking to stabilize fungal nomenclature by designating one name for pleomorphic fungal species (Taylor 2011; Wingfield et al. 2012). After that, Oliveira et al. (2015) published a full list of thermophilic fungal species and their nomenclatural status to date.

Eukaryotes can grow only up to 62 °C (Tansey and Brock 1972), and growth at this temperature is represented by a small number of fungal species. A large contribution on the taxonomy, biology, and economic importance of thermophilic fungi was given by Cooney and Emerson (1964) in their monograph. Eleven thermophilic species were documented with few being new to science (*Rhizomucor pusillus*, *R. miehei*, three varieties of *Chaetomium thermophilum* and *Chaetomium virginicum*, *Thermoascus aurantiacus*, *Melanocarpus albomyces*, *Malbranchea cinnamomea*, *Mycothermus thermophilus*, *Thermomyces lanuginosus*). Currently, the total number of fungal species described is approximately 120,000 (Hawksworth and Lücking 2017). From that, according to the last review on the taxonomy of thermophilic fungi, only 44 species are thermophilic, belonging to 20 genera (Oliveira et al. 2015). Thus, according to the authors, there are representatives of Mucoromycota (*Rhizomucor* and *Thermomucor*), Ascomycota (*Acremonium*, *Arthrinium*, *Canariomyces*, *Chaetomidium*, *Chaetomium*, *Humicola*, *Malbranchea*, *Melanocarpus*, *Myceliophthora*, *Myriococcum*, *Rasamsonia*, *Remersonia*, *Scytalidium*, *Sordaria*, *Thermoascus*, *Thermomyces*, and *Thielavia*), and one Basidiomycota (*Thermophymatospora*, Oliveira et al. 2015).

However, since the publication of the review by Oliveira et al. (2015) a few new species were described, renamed, or reclassified. A new *Rasamsonia* species from compost in China was described, *R. composticola* (Su and Cai 2013). The taxonomy of the genus *Myceliophthora* was re-evaluated through multilocus phylogenetic analysis (Marin-Felix et al. 2015). Four species, *Myceliophthora guttulata*, *M. hinnulea*, *M. heterothallica*, and *M. thermophila*, were reclassified to the new genus *Thermothelomyces* and *M. fergusii* to the new genus *Crassicarpon* as *C. thermophilum*. As described by Natvig et al. (2015), the species previously known as *Scytalidium thermophilum* is distantly related to the type species of the genus *Scytalidium*, *S. lignicola*, and could not be assigned to any existing genus. Then a new genus and combination was proposed, *Mycothermus thermophilus*. The thermophilic species in the phylum Basidiomycota, *Thermophymatospora fibuligera*, was renamed to *Ganoderma colossus*, following the new rules for fungal taxonomy (for more details, see Oliveira et al. 2015). Considering the recent changes, there are a total of 46 thermophilic species belonging to 23 genera (Table 3.1).

Thermophily is not a monophyletic character, because it is found in taxa in different phylogenetic lineages in the fungal tree of life. A recent phylogenetic analysis showed the paraphyletic nature of heat tolerance in fungi (Morgenstern et al. 2012). It is clear that this ability had multiple origins in the kingdom Fungi. However, in Chaetomiaceae (Sordariales), thermophily probably had a single origin and then

Table 3.1 Classification of accepted thermophilic fungal species (sensu Oliveira et al. 2015) according to the current literature

Phylum	Order	Genus	Species
Mucoromycota	Mucorales	*Rhizomucor*	*R. miehei*

multiple losses subsequently occurred within the family, whereas multiple independent gains seem to be more likely in Trichocomaceae (Eurotiales) (Morgenstern et al. 2012; van Noort et al. 2013).

Overall, most representatives belong to the phylum Ascomycota, particularly in Sordariales and Eurotiales, orders that comprise the largest number of thermophilic species. There are also representatives in the orders Hypocreales and Microascales. In Mucoromycota, thermophily is restricted to the Mucorales order and in Basidiomycota to the order Polyporales (Table 3.1). The phylogenetic position of a few species is still unclear, such as species from the genera *Arthrinium*, *Malbranchea*, *Myriococcum*, and *Scytalidium*.

3.4 Ecology, Evolution, and Biogeography

Thermophilic fungi are cosmopolitan and they may occur either as propagules or as active mycelia in both natural and human-made environments. Their growth and activity are mainly regulated by the temperature and availability of nutrients. The evolution of thermophily in the kingdom Fungi is not clarified; however, a few speculations had come to light.

Some authors suggest that the heat tolerance in fungi evolved from mesophilic ancestors associated with nests of birds able to thermoregulate their nests, as those found in Australia (Megapodiidae) (Cooney and Emerson 1964; Rajasekaran and Maheshwari 1993). These birds use decaying plant material to stimulate the growth of microorganisms and warm up their nest. Fungi play an important role in this system; their exothermic metabolism raises the nest temperature to approximately 45 °C, similar to the heating process in natural composting (Seymour and Bradford 1992; Tiquia et al. 1996, 2002; Tiquia 2005). In contraposition, some authors suggested that thermophily arose as an adaptation to seasonal changes and high daytime temperatures rather than as an adaptation for the occupation of new high-temperature niches (Powell et al. 2012).

It is generally believed that their wide distribution is due to the propagules, which are easily transported by air, such as dispersal spores (sexually or asexually produced), resting spores, chlamydospores, and sclerotia (Thakur 1977; Rajasekaran and Maheshwari 1993; Le Goff et al. 2010). Thermophilic fungi have been recovered even from Antarctic soils (Ellis 1980a; Satyanarayana et al. 1992). Their

widespread occurrence could well be explained by their wide dissemination machinery. These fungi occur mainly from man-made environments, such as composting systems, due to the production of aerosols carrying mycelia or reproductive propagules when revolving the piles (Le Goff et al. 2010). Most species do not show any geographical restrictions. According to Salar and Aneja (2006), soils in tropical countries do not appear to have a higher population of thermophilic fungi than soils in temperate countries as believed earlier. It is likely, however, that inoculum density in tropical soils and piles of plant material is higher than in temperate soils.

Thermophilic fungi are common in habitats wherever decomposition of organic matter takes place. According to several reports, they have been found in a variety of environments (Table 3.2). The habitats for the recovery of such fungi are not exotic like those of prokaryotes. The temperature, humidity, and atmosphere of these environments are favorable substrates for fungal development (Salar and Aneja 2006). There are no records of thermophilic fungi in many countries; however, this lack of information is not likely due to the absence of these fungi but most likely for lack of investigations in these sites.

Thermomyces, *Chaetomium*, and *Mycothermus* are the most recurrent genera in different environments (Table 3.2). Among them, *Thermomyces lanuginosus* and *Mycothermus thermophilus* (syn. *S. thermophilum*) are not only present but also often found as the most abundant (Pan et al. 2010; Powell et al. 2012; De Gannes et al. 2013; Langarica-Fuentes et al. 2014a, b, 2015; Oliveira et al. 2016). On the other hand, some species have not been recorded since they were identified for the first time, such as the Basidiomycota *G. colossus*.

Thermophilic fungi are usually found in self-heating environment. The composting system, where the temperature rises due to the exothermic metabolism of microorganisms, is by far the most suitable environment for their growth and dispersal. In a pressmud composting system, Oliveira et al. (2016) observed that the relative load of thermophilic species increases, from the thermophilic stage, over the reduction of mesophilic ones.

According to Paterson and Lima (2017), because of the increase in the average global temperature caused by climate change, it is expected that more fungi that tolerate or prefer higher temperatures can be found in areas where crops are being grown. They could turn into pathogens and infect crops, as they are adapted to similar substrates, and would have little competition for this new niche against other fungi at such higher temperatures.

3.5 Ecological Roles

Lignocellulosic biomass consists of cellulose (32–50%), hemicellulose (19–25%), and lignin (23–32%) polymers, as well as a small part of organic acids, salts, and minerals (Pandey et al. 2000; Hamelinck et al. 2005). In nature, biomass-degrading microbes play a crucial role in plant biomass decomposition and in nutrient cycling (Plecha et al. 2013). The complexity of lignocellulosic biomass influences multiple microorganisms to produce equally a vast complex of enzymes, which act synergically. The breakdown of lignocellulosic biomass involves the formation of long-chain polysaccharides, mainly cellulose and hemicellulose, and the subsequent hydrolysis of these polysaccharides into readily soluble saccharides, their 5- and 6-carbon monomers (Zhou and Ingram 2000; Sandgren et al. 2005).

Many microorganisms can degrade cellulose and other plant cell wall fibers, and fungi are known to be natural plant decomposers. There is a close relationship between the niche occupied by a microorganism and the characteristics of its intra and extracellular enzymes. It is expected that thermophilic microorganisms produce extracellular enzymes capable of tolerating temperatures corresponding to at least the optimum temperature for their growth, i.e., above 45 °C. Thus, these fungi are suitable to secrete a wide variety of lignocellulolytic enzymes, which act under this special environmental condition, significantly contributing to biomass decay in nature.

Many reports showed the ability of thermophilic fungi to produce a wide range of enzymes involved in biomass decomposition and nutrient recycling (Table 3.3). These fungi have a high capacity to secrete enzymes with a variety of mechanisms of action and substrate specificity. Most strains produce various enzymes in large amounts which are released in the environment and act in a synergistic manner (Dashtban et al. 2009). A plethora of studies screened various thermophilic fungi to find new and promising strains able to produce enzymes of biotechnological interest. Most of these studies employed agricultural residues to stimulate the production

of enzymes to target biotechnological process. From this perspective, we can perceive their ecological roles on biomass decomposition in nature.

Some thermophilic fungi such as *Thermomyces lanuginosus*, *T. dupontii*, *Rhizomucor pusillus*, and *R. miehei* cannot use cellulose as a carbon source (Table 3.3). However, the inability to hydrolyze a particular polymer, such as cellulose, does not mean that the fungus does not have an enzymatic system for the hydrolysis of another polymer. For instance, *T. lanuginosus* does not degrade cellulose, but it is able to use xylan as a carbon source and grow faster on this polymer than on medium with simpler sugars (Mchunu et al. 2013; Oliveira et al. 2015). Likewise, thermophilic pectinolytic fungi are not always high producers of hemicellulolytic enzymes. On the other hand, organisms that do not depolymerize the organic matter can grow as a commensal, using sugars released by other organisms.

Pereira et al. (2015) evaluated the production of cellulases and xylanases from heat-tolerant fungi by solid-state fermentation using lignocellulosic materials as substrate. *Thermothelomyces thermophila* (syn. *M. thermophila*) was the best producer of endoglucanase (357.51 U g^{-1}), β-glucosidase (45.42 U g^{-1}), xylanase (931.11 U g^{-1}), and avicelase (3.58 U g^{-1}). Martin et al. (2010) evaluated the production of polygalacturonase from *Thermomucor indicae-seudaticae* using a mixture of carbon sources; the highest production (108 U g^{-1}) was obtained in a mixture consisting of 40% orange bagasse, 40% wheat bran, and 20% sugarcane bagasse (Martin et al. 2010). *Mycothermus thermophilus* was able to produce high amounts of cellulases in a medium containing a mixture of rice straw and wheat bran (1:3) such as endoglucanase (64.7 U g^{-1}), avicelase (23.5 U g^{-1}), β-glucosidase

(160 U g^{-1}), and FPase (3.48 U g^{-1}). This fungus was also able to produce xylanase (199.2 U g^{-1}, Jatinder et al. 2006).

The majority of fungi growing on plant residues in nature usually produce both cellulolytic and xylanolytic enzymes due to the close association of cellulose and xylan in plant cell walls. However, so far *T. lanuginosus* was found to be a non-cellulolytic hyperproducer of xylanases. Alam et al. (1994) obtained high amount of xylanases (1889.6 U g^{-1}) and pectinase (673.2 U g^{-1}) in solid-state fermentation using wheat bran and no cellulose activity was detected. In the same study, the species *T. aurantiacus* was demonstrated to be able to produce cellulose (705.7 U g^{-1}), xylanase (306.5 U g^{-1}), and cellulase (215.8 U g^{-1}).

Considering the increased number of available genomes, new rational approaches, as genome mining, have been applied as an alternative to find target and new enzymes from thermophilic fungi. For instance, *T. lanuginosus* had its genome sequenced to obtain additional information for a better assessment in the industry (Mchunu et al. 2013). Zhou et al. (2014) reported the existence of a large number of genes coding for proteolytic, amylolytic and lipolytic enzymes including also xylanase and β-glucanase in the genome of *R. miehei*.

A genomic study of *T. thermophila* and *Thielavia terrestris* suggested that they were capable of hydrolyzing all the major polysaccharides present in the plant biomass (Berka et al. 2011). *Thielavia thermophila* has the highest number of hemicellulolytic enzymes and accessory enzymes observed to date; it contains 8 genes encoding endoglucanases, 7 cellobiohydrolases, 9 β-glucosidases, 25 lytic polysaccharide monooxygenases (LPMOs), and other enzymes of the group including xylanase, arabinases, mannanase, pectinases, and esterases (Karnaouri et al. 2014). Oliveira et al. (2018) evaluated 13 thermophilic species and listed the presence of peptidase-coding genes in their genome. All species have putative peptidase-coding genes, ranging from 241 to 347.

3.6 Fungal Adaptations to Thermophily

Sustaining growth at high temperatures involves adaptation of the cytoplasmic membrane, proteins, and DNA to temperatures above mesophilic range. These adaptations provoked great interest from both biological and evolutionary perspectives. However, it is in biotechnology that this interest is significantly explored, considering that the thermoresistance mechanisms of biomolecules of these microorganisms may be interesting models for bioengineering or to directly use in bioprocesses.

In general, all the features observed in thermophilic fungi are similar to those of mesophiles. Thermophilic fungi do not appear to have any specific organelles, structural modifications, or developmental patterns, which are not seen in their mesophilic counterparts (Singh et al. 2016). However, the adaptation of a particular

microorganism allowing it to survive and grow at elevated temperatures involves crucial aspects as modifications of existing structures.

Crisan (1973) discusses four hypotheses that help explaining the ability of thermophiles to grow at high temperatures: (i) lipid solubilization, (ii) rapid resynthesis of essential metabolites, (iii) macromolecular thermostability, and (iv) ultrastructural thermostability. Only the latter two still appear to be of major importance. The importance of macromolecular thermostability is questionable since the existence of a single, thermostable, essential macromolecule, common to all thermophiles, has not been demonstrated. On the other hand, the author concluded that the hypothesis of ultrastructural thermostability appears to be the most promising to explain the existence of thermophilism in a variety of different organisms.

To date, no fungi have been identified with a growth above 62 °C. This may be related to the greater thermolability of their membrane systems than to the thermostability of enzymes or other cellular structures. The adaptation of thermophilic microbial membranes corresponds to the process named homeoviscous adaptation, which consists of the replacement of unsaturated fatty acids with saturated fatty acids. With these shifts, membrane acquires the balance between density and fluidity necessary for the maintenance of physical and functional integrity at elevated temperatures. The saturated fatty acids generate a stronger hydrophobic environment than the unsaturated ones, aiding in the stability of the membrane. This adaptation occurs in the Bacteria and Eukarya domains, while the latter is so far found only in the kingdom Fungi (Adams 1993).

The thermophilic fungi have experienced genome size reduction compared to the closest mesophilic species (van Noort et al. 2013). This process involves loss of protein-coding genes, transposable elements, and reductions in the size of introns and intergenic regions. Oliveira et al. (2018) found that the number of peptidase-coding genes in the genome of thermophilic fungi is reduced, when compared to peptidases from phylogenetically related mesophilic species, in contrast with the observations for cellulolytic enzymes, which reflects an increased wood degradation capacity (van Noort et al. 2013).

Although most of the studies exploring enzymes from thermophilic organisms are focused on their production and characterization, only a few focused in comparing the differences between enzymes from thermophilic and mesophilic species (Niehaus et al. 1999; van Noort et al. 2013; Oliveira et al. 2018). Some differences in the sequence, structure, function, dynamics, and thermodynamic properties were observed when making such kind of comparison (Niehaus et al. 1999; Oliveira et al. 2018).

Oliveira et al. (2018) evaluating the peptidases from thermophilic fungi found that they contain a larger proportion of Ala, Glu, Gly, Pro, Arg, and Val residues and a lower number of Cys, His, Ile, Lys, Met, Asn, Gln, Ser, Thr, and Trp residues when compared to the mesophilic ones. The authors also found that peptidases from thermophilic fungi had a reduction in the number of internal cavities. They suggested two possible evolutionary scenarios for these changes: in the course of genome reduction, (i) they have lost peptidases with large number of cavities and kept only those that are compactly folded or (ii) the enzymes were optimized to contain fewer.

In contrast to the reductionist genome tendency, the duplication of intriguing genes may provide insights into the evolution of thermophily, such as identifying the genes responsible for hyphal melanization, which are involved in resistance to high temperatures, desiccation, and UV radiation (van Noort et al. 2013).

3.7 Conclusions and Future Perspectives

Thermophily in fungi evolved several times in nature; however, they are an ecological well-defined group. Distributed worldwide, these fungi occur in several habitats, but they develop when high temperatures allow their growth and survival. Over the years, many concepts were employed to characterize these organisms, but here we showed some concepts that may be ecologically relevant. Moreover, the taxonomy of these fungi changed in recent years prompting to the several name changes reported in this review. As the search for fungi continues in unusual niches (Cantrell et al. 2011) including several self-heated environments, it is possible that new thermophilic fungi may be discovered. These taxonomic novelties may reveal new mechanisms on how eukaryotic life may thrive in high temperatures.

Thermophilic fungi are efficient in biomass degradation, what makes them target species to prospect for enzymes of biotechnological interest. They have evolved adaptations to high temperatures, and the knowledge of such characters might help to better understand their biology and make a better use of them to our welfare. Also, the increasing number of available genomes of thermophilic fungi brings new perspectives to their exploitation, such as genome mining. Nowadays, there are 46 known species and the use of molecular techniques (i.e., metagenomics) could increase our knowledge regarding their diversity and distribution. Moreover, the find of new species is linked to the discovery of new molecules with intrinsic properties.

Chapter 4
New Perspectives on the Distribution and Roles of Thermophilic Fungi

Miriam I. Hutchinson, Amy J. Powell, José Herrera, and Donald O. Natvig

4.1 Introduction

The goal of this chapter is twofold. First, we briefly review the history, basic biology, evolution, and industrial relevance of thermophilic fungi. Second, we address ongoing questions concerning the ecology of these organisms. In the past two decades, several excellent reviews have considered one or more of these topics (Oliveira and Rodrigues, this volume; Maheshwari et al. 2000; Mouchacca 2000a, b; Salar and Aneja 2007; Salar 2018). Here, we give particular attention to topics for which there has been some difference of opinion. These include a discussion of the definition of thermophily as it pertains to fungi and an evaluation of the types of microhabitats that are most relevant to the growth and distribution of these organisms. We argue that the microenvironments capable of supporting the growth of thermophilic fungi are widespread and often transient. In the latter context, we present the results of a recent previously unpublished survey of thermophilic fungi in diverse ecosystems of the western United States, Mexico, and Canada.

Definition. While thermophilic fungi do not grow at the extreme temperatures that are optimal for many thermophilic bacteria and archaea, they are the only eukaryotes demonstrated to grow at temperatures up to 60 °C (Tansey and Brock 1972). In practice, the term thermophilic, when applied to fungi, has sometimes been used quite loosely, and there is no universally accepted definition.

Cooney and Emerson (1964), who wrote the first monograph for thermophilic fungi, considered such fungi to be those that have "a maximum temperature for growth at or above 50 °C and a minimum temperature for growth at or above 20 °C." We have adopted a simpler working definition (Powell et al. 2012; Hutchinson et al. 2016). Namely, we consider a thermophilic fungus to be one that grows better at 45 °C than at 25 °C. One practical advantage of this latter definition is that it permits easy evaluation of fungal isolates.

Less consistent in the literature is the distinction between thermotolerance and thermophily. Cooney and Emerson considered thermotolerant fungi to be those with a maximum growth temperature near 50 °C while having a minimum growth temperature "well below" 20 °C. This definition is quite restrictive on the high end. Although it permits inclusion of the ubiquitous *Aspergillus fumigatus*, it excludes many fungi, for example, the model organism *Neurospora crassa*, that can grow at temperatures near or above 45 °C while having temperature optima below 50 °C. From a practical point of view, 45 °C is a temperature that is lethal or stress-inducing for most organisms, and we consider fungi that can grow at 45 °C to be thermotolerant.

History. The first reported thermophilic fungus, *Rhizomucor pusillus*, was isolated from bread by Lindt in the 1880s (Lindt 1886). Later, Tsiklinsky (1899) identified another thermophile, *Thermomyces lanuginosus*, growing on potatoes. In the early 1900s, Hugo Miehe (1907a, b; 1930a, b) published a series of papers derived from his investigations regarding the role of living organisms in the self-heating of stored hay. One result was the description of two new thermophiles, *Thermoidium sulfureum* (*Malbranchea cinnamomea*) and *Thermoascus aurantiacus*.

The study of these organisms languished for several decades before they were discovered to be part of the composting process associated with the production of rubber from the desert shrub Guayule (*Parthenium argentatum*). During World War II, the United States and allies lost access to rubber-plant plantations in the Pacific, which hindered the manufacture of rubber badly needed for the war effort. The US Department of Agriculture had a large-scale program aimed at developing Guayule latex as an alternative source of rubber. One of the experimental approaches involved chopping the shrub into pieces and composting it in piles. These "rets" were strongly thermogenic as a result of microbial activity, and the characterization of the organisms involved led to the identification of new and previously recognized thermophilic fungi (Cooney and Emerson 1964). The single publication by Allen and Emerson (1949) that resulted from the study of the effects of microbial activity on rubber quality did not detail the organisms involved in the process. The importance of the Guayule project in the "rediscovery" of thermophilic fungi as the basis for the studies that led to the Cooney and Emerson (1964) monograph of thermophilic fungi was recounted in the latter.

Industry. In recent decades, much of the attention given to thermophilic fungi has been in industry. This interest stems in large part from the ability of these fungi to yield thermostable enzymes, especially those that are cellulose-active. These enzymes function at temperatures high enough to exclude contaminants, and they accelerate reactions that convert cellulose into fermentable sugars for bioethanol

(Beckner et al. 2011; Rubin 2008; van den Brink et al. 2013). To understand the genetic mechanisms of thermophily and thermostability, the genomes of several fungal thermophiles have been sequenced (Berka et al. 2011).

4.2 Evolution

Of the more than 100 thousand described species of fungi, only approximately 50 species are thermophilic, representing a small fraction of the 2.2–3.8 million estimated fungal species (Salar and Aneja 2007; Hawksworth and Lücking 2017). Thermophilic fungi are known from two phyla, the Ascomycota and the Mucoromycota. In the Ascomycota, thermophiles are restricted to the orders Sordariales, Eurotiales, and Onygenales. Thermophiles in the Mucoromycota occur in the Mucorales (Salar 2018) and a recently created order, the Calcarisporiellales (Hirose et al. 2012; Morgenstern et al. 2012; Tedersoo et al. 2018). The order Mucorales contains two families with thermophiles, the Rhizopodaceae and the Lichtheimiaceae (Hoffmann et al. 2013). The Calcarisporiellales contains the thermophilic species *Calcarisporiella thermophile.* In the Sordariales, all known thermophilic species belong to the family Chaetomiaceae, which contains the greatest diversity of thermophilic fungi (Morgenstern et al. 2012). Among the Eurotiales, two families are considered to possess thermophilic members, the Trichocomaceae and the Thermoascaceae (Houbraken et al. 2014, 2016). A sole species of thermophilic fungus, *Malbranchea cinnamomea*, is found in the Onygenales (Morgenstern et al. 2012). Thermophilic Basidiomycota have been described by Straatsma et al. (1994) and Fergus (1971) but these species have either not been confirmed to be thermophilic or, as in the case of *Myriococcum thermophilum*, have been found to belong in the Ascomycota instead (Morgenstern et al. 2012; Koukol 2016).

Taxonomy for thermophilic fungi is in a state of considerable flux (Mouchacca 2000b; Oliveira et al. 2015; Natvig et al. 2015). This results in part from the fact that under the "One Fungus = One Name" convention recently adopted by *the International Code of Nomenclature for Algae, Fungi, and Plants*, the names for many thermophiles in the fungal kingdom need to be revised (Oliveira et al. 2015). This convention requires that the asexual and sexual nomenclature be unified and that a single name be assigned to a single species. In addition to name changes that have been required by changes in nomenclatural codes, in many cases, thermophilic fungi have simply been misclassified because of the failure to identify correct taxonomic affinities. The genus *Myceliophthora* provides examples of name changes required by new nomenclatural rules and by molecular phylogenetic studies that reveal true relationships (van den Brink et al. 2012). For example, the species recently recognized as *Myceliophthora heterothallica* was previously known under the teleomorphic names *Theilavia heterothallica* and *Corynascus heterothallicus*. To add to the confusion, as *T. heterothallica*, this species was once thought to be the teleomorph of *Chrysosporium thermophilum*, now recognized as *M. thermophila* (von Klopotek 1976; Hutchinson et al. 2016; van den Brink et al. 2012). A similar

case exists for *Rasamsonia*, a genus erected to accommodate teleomorphs of *Geosmithia* and *Talaromyces* species, which were improperly identified (Houbraken et al. 2012). As a final example, the genus *Mycothermus* was recently erected to accommodate fungal strains previously known as *Scytalidium thermophilum*, placed in a genus (*Scytalidium*) that is appropriate for organisms in a different fungal class (Natvig et al. 2015).

4.3 Ecology

Despite advances in industry and genetics, comparatively little is known about the natural role and distribution of thermophilic fungi. Although commonly isolated from compost, these fungi are known to exhibit a variety of lifestyles, including as animal and plant associates and as saprotrophs (Salar 2018). For example, the thermophilic species *Myceliophthora thermophila* was identified as an endophyte of foliar tissue from a desert tree, *Parkinsonia microphylla* (Massimo et al. 2015). Another thermophile, *Rhizomucor pusillus*, has been reported to cause human infections, especially in immune-compromised individuals (St-Germain et al. 1993; Andrey et al. 2017). Cooney and Emerson (1964) noted that thermophilic fungi often remain unrecognized in culture when moderate incubation temperatures are used. As such, it may be that many thermophilic fungi remain undescribed.

A debate exists regarding how broadly distributed are the habitats in which thermophilic fungi can thrive. One hypothesis suggests that most thermophilic fungi are specialists of insulated compost-like substrates and that the presence of these fungi in soil and other non-compost substrates represents dispersal of aerial propagules (Maheshwari et al. 2000). Support for this idea has been presented for *Thermomyces lanuginosus*, which though common in soil was not competitive with mesophilic and thermotolerant fungi in soil microcosm experiments performed under fluctuating temperature regimes, unless temperatures were maintained above 40 °C. In addition, spores of *T. lanuginosus* failed to germinate in soil under conditions favorable for growth (Rajasekaran and Maheshwari 1993).

On the other hand, it is possible to wonder if understanding the role of thermophilic fungi in soil requires consideration of specific microhabitats and substrates suitable for growth. The proportion of physiologically active microorganisms in soil can be small compared to the total microbial biomass, and the level of activity for a microorganism or microbial group is dependent on substrate availability (Blagodatskaya and Kuzyakov 2013). Moreover, microcosm experiments performed with only mesophilic "soil" fungi demonstrate that the performance of one species relative to another is substrate dependent (e.g., Deacon et al. 2006). Therefore, while previous studies have reported thermophiles from diverse compost or pseudo-compost materials such as animal nests, manure compost, mushroom compost, and self-heating hay bales (Fergus and Sinden 1969; Tansey 1971, 1973, 1975, 1977; Tiquia 2005), it is likely that even a small 5-cm mass of leaf litter can be sufficiently insulated, moist and solar-heated to encourage growth of thermophilic fungi

(Subrahmanyam 1999). Indeed, recent studies of arid ecosystems (where sizeable composts are rare, if not absent), including the Sevilleta Long-Term Ecological Research (LTER) site in New Mexico, have demonstrated that thermophilic fungi are common in certain microhabitats (Powell et al. 2012). We recovered isolates from a variety of substrates including soil, biological soil crusts, leaf litter, and herbivore droppings. While these and other previous studies have shed light on microhabitats and distributions, the extent to which thermophilic fungi exhibit habitat specificity is unclear, as is the prevalence of thermophilic fungi on a regional scale.

Microhabitats Suitable for the Growth of Thermophilic Fungi Are Common in Diverse Ecosystems. Although the early studies of thermophilic fungi examined substrates that were self-heating as a result of microbial activity (Miehe 1907a, b; Cooney and Emerson 1964), soil and other substrates can achieve temperature and moisture conditions suitable for thermophiles as a result of solar gain (Tansey and Jack 1976; Powell et al. 2012). In reality, soil, litter, and herbivore droppings in temperate ecosystems often reach temperatures at or above those suitable for thermophilic fungi. In an experiment designed to follow the succession of thermophiles in a natural setting, we monitored temperatures in the droppings of three herbivores (elk, oryx, and rabbit) over a period of approximately 1 year (Fig. 4.1) at the Sevilleta National Wildlife Refuge. Even during winter months, daytime temperatures were often near or above 40 °C. In warmer months, daytime temperatures often reached 60–75 °C, temperatures at which fungal growth has ceased. In a single 24-h period, temperatures could swing from 15 °C to above 60 °C (Fig. 4.1). Droppings in this environment therefore represent an extreme microhabitat with dramatic and rapid changes in temperature and moisture. Thermophilic fungi are common in this microenvironment, and they participate in decomposition along with a complex community of bacteria, non-thermophilic fungi, and microfauna.

4.4 A Survey of Thermophilic Fungi from Across the Western United States

In a previously unpublished study, we surveyed thermophilic fungi in soils, plant litter, and herbivore droppings from a wide range of latitudes, elevations, and distinct climatic regions across sites from central Mexico to southern Canada. One goal was to evaluate the extent to which these fungi are common in locations where the opportunities for natural compost are rare. A second goal was to evaluate whether there exist geographical, latitudinal, or substrate differences in the distributions of major thermophile groups. Our sampling focused on soil, litter, and herbivore droppings. In addition, deep-frozen (−80 °C) rhizosphere soil samples collected from under blue grama grass (*Bouteloua gracilis*) were tested for the presence of thermophilic fungi.

Experimental Approach. Samples were collected in two phases. From May through June of 2008, 10 samples of rhizosphere soil were collected from each of five stands of *Bouteloua gracilis* in western North America as part of a separate

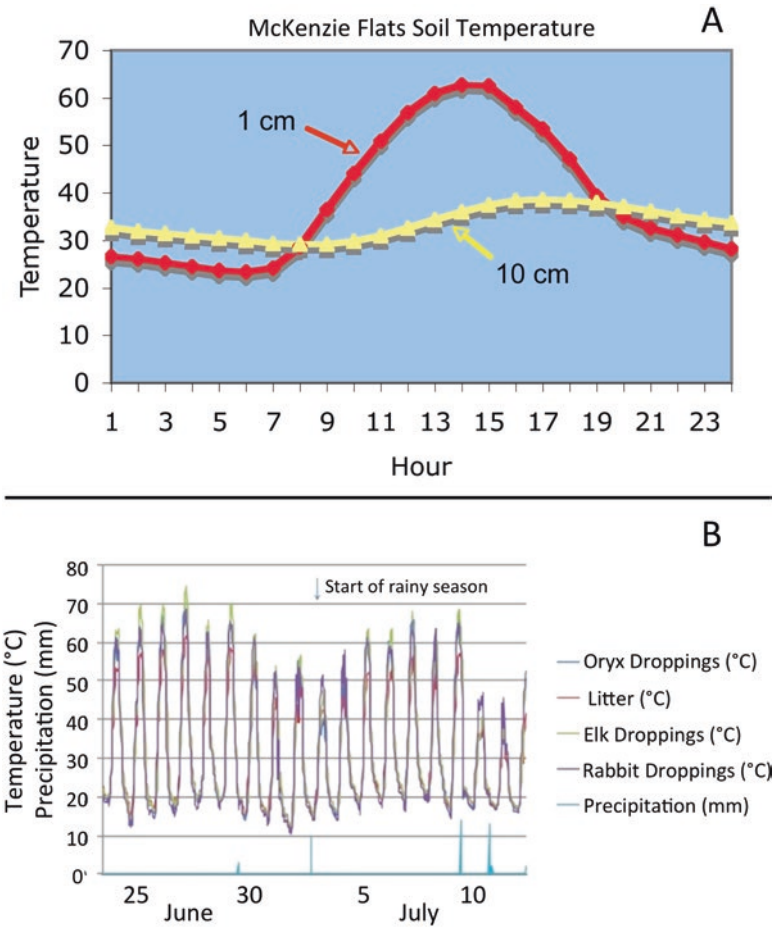

Fig. 4.1 Extreme microenvironments are common in temperate ecosystems. (**a**) Variation in soil temperature for a typical 23-h period (1:00 AM to midnight) in July at the Sevilleta National Wildlife Refuge in central New Mexico (adapted from Fig. 1 in Powell et al. 2012, copyright © Mycological Society of America, https://msafungi.org/, reprinted with permission from Taylor & Francis Ltd., http://www.tandfonline.com on behalf of the Mycological Society of America). (**b**) Dramatic swings in internal temperatures for herbivore droppings and litter in the foothills of the Los Pinos mountains in central New Mexico over 19 days surrounding the transition to the monsoon season in 2013. The temperature swings were frequently from 12 °C to 15 °C in early morning to over 70 °C at midday. The high temperatures were driven by solar gain. Air temperatures did not exceed 35 °C. Temperatures were measured with a small thermocouple and recorded on a Campbell Scientific CR1000 datalogger

study of root-associated fungi (Herrera et al. 2010). Soils were transported from the field on ice within 48 h and ultimately stored at −80 °C. These samples were plated in January of 2013. In a second effort, soil, herbivore droppings, and leaf litter samples were collected from each of 10 locations in the western United States

Fig. 4.2 Locations of soil, litter, and herbivore dropping samples employed for the thermophile survey presented here. Details of the samples are given in Table 4.1

between March 2012 and May 2013 (Fig. 4.2, Table 4.1). These samples were stored at 4–5 °C for no more than 4 days before plating.

All samples were plated onto malt extract agar (MEA) with 50 μg/mL ampicillin (to exclude bacteria) and incubated up to 10 days at 50 °C (see Bustamante 2006). Approximately 0.5–1.0 g of substrate was used for each plate. Rhizosphere soils from the Herrera et al. (2010) study were plated in replicates of 3. Resulting colonies from all cultures were then sub-cultured to obtain axenic isolates.

A cetyl trimethylammonium bromide (CTAB) DNA extraction procedure modified from Winnepenninckx et al. (1993) was used to isolate DNA from cultures, using methods previously described (Hutchinson et al. 2016). DNA was amplified by PCR of the ribosomal internal transcribed spacer (ITS) region using the fungal-specific primers ITS4 and ITS1F (White et al. 1990; Gardes and Bruns 1993). Each reaction consisted of 6.5 μL ExTaq polymerase (Takara, Mountain View, CA), 1 μL of each (5 μM) primers, 2 μL of 2% bovine serum albumin (Sigma-Aldrich, St. Louis, MO), 2 μL milliQ purified water, and 1 μL of template DNA, for a total of 13.5 μL. The following thermocycler settings were used: 95 °C for 5 min, 30 cycles at 94 °C for 30 s, annealing at 50 °C for 30 s, and extension at 72 °C for 45 s, followed by a final extension of 72 °C for 7 min. After PCR, reactions were purified by an enzyme procedure using the ExoSAP-IT kit (Affymetrix, Santa Clara, CA) and manufacturer's specifications.

Amplicons were Sanger sequenced with a BigDye Terminator v3.1 Cycle Sequencing kit (Applied Biosystems) in 10 μL reactions containing 0.5 μL BigDye Terminator v3.1, 2 μL of 5X Sequencing Buffer (Life Technologies/Applied Biosystems, Carlsbad, CA) 1 μL of 3 μM primer, and 5.5 μL of milliQ water. A BigDye STeP protocol was used with the following parameters: 96 °C for 60 s followed by 15 cycles of 96 °C for 10 s, 50 °C for 5 s, and 60 °C for 1 min 15 s; then 5 cycles of 96 °C for 10 s, 50 °C for 5 s, and 60 °C for 1 min30 s; and a final 5 cycles of 96 °C for 10 s, 50 °C for 5 s, 60 °C for 2 min/s (Platt et al. 2007).

Chromatogram files for the forward and reverse reads were edited and assembled into contigs using Sequencher v5.1 (Gene Codes, Ann Arbor MI). To determine the overall species richness among the isolates, ITS sequences were assembled into Operational Taxonomic Units (OTUs) using UPARSE 9.0 (Edgar 2013). OTU cutoffs were set to 97% identity. To obtain taxonomic information, the resulting OTUs were then queried at National Center for Biotechnology Information (NCBI) GenBank with Basic Local Alignment Search Tool Nucleotide (BLASTN) searches using the option to exclude uncultured and environmental samples.

Phylogenetic Analyses. ITS sequences were aligned in MUSCLE implemented through the European Bioinformatics Institute web interface (Edgar 2004; Li et al. 2015). Alignments were then visualized and trimmed in AliView v1.2.1 (Larsson 2014). Reference sequences from GenBank were included as a comparison to the newly acquired sequences, and type strains were selected as references when possible (Tables 4.2 and 4.3). Trees were constructed with the Randomized Axelerated Maximum Likelihood (RaxML) program v7.3.2 using 1000 bootstrap replicates (Stamatakis 2006). Because ITS sequences align poorly across distant phylogenetic groups, we built separate trees for each of the three orders to which the sequences were classified. Trees were visualized and edited with Mesquite v2.75 (Maddison and Maddison 2010).

Results. Thermophilic and thermotolerant fungi were recovered from every substrate type and nearly every location. Notably, propagules of thermophilic fungi from the rhizosphere soil were also able to survive storage at −80 °C for nearly 5 years. Sixty-two total isolates were recovered. After excluding duplicates from the same sample, 55 isolates were characterized at the sequence level, resulting in 14 putative OTUs, 10 genera, and 13 known species. The identity of each of the OTUs is summarized in Table 4.2, and relationships among the isolates are shown in Fig. 4.3. Most isolates fell into the fungal orders Eurotiales (34 isolates) and Sordariales (17 isolates). Only 4 isolates belonged to the Mucorales, and no isolates from the Onygenales were identified. The lack of isolates from the Onygenales may owe to the types of substrates and media used, as this group of fungi is known to be keratinophilic (Sharpton et al. 2009). The most common species was *Thermomyces lanuginosis*, represented by 16 isolates, followed by *Aspergillus fumigatus*, represented by 8 isolates, and *Chaetomium thermophilum var. dissitum,* represented by 6 isolates.

Several of the isolates were from species viewed as thermotolerant rather than thermophilic. Mouchacca (2000a) suggests that *A. fumigatus*, *A. nidulans*, and *C. jodhpurense* have been erroneously reported as thermophiles when they actually

OTU 14	1	*Rhizopus microsporus* isolate VPCI 128/P/10	Mucorales	Rhizopodaceae	KJ417570.1

possess lower temperature optima than true thermophiles. Additionally, *Thielavia gigaspora* is a thermotolerant species previously isolated in Egypt (Moustafa and Abdel-Azeem 2008). Mouchacca (2000a) also reported *Rhizopus microsporus* as a misattributed thermophile, but (Peixoto-Nogueira et al. 2008) demonstrated that isolates grow optimally at 45 °C. Overall, thermotolerant species represented 29% of all of our isolates. Excluding the thermotolerant species, there were 25 isolates from the Eurotiales and 14 from the Sordariales.

Independent-samples Welch's t-tests were employed to compare elevation and latitude specificity for thermophilic isolates in the Eurotiales and Sordariales. Because the Mucorales were comparatively rare, they were not included in statistical analyses. For elevation, there was no significant difference between the distributions of Eurotiales and Sordariales ($M_{EUROTIALES}$ = 2038.28 m, SD = 900.51; $M_{SORDARIALES}$ = 1765 m, SD = 823.66; t(29) = 0.96, p = 0.05). For latitude, again,

[a]Type strain

there was no significant difference between the distributions of Eurotiales and Sordariales ($M_{EUROTIALES}$ = 38.79°, SD = 16.35; $M_{SORDARIALES}$ = 41.44°, SD = 28.92; $t(18) = -0.32$, $p = 0.05$).

In terms of substrate preference, thermophilic samples in Eurotiales were most frequently isolated from litter (44%), while for samples in the Sordariales, the top sources were droppings (35.71%) and top soil (35.71%). Overall, the most thermophilic isolates originated from litter substrates (35.9%), followed by droppings (30.7%), soil (20%), and finally rhizosphere, which represented 12.8% of the samples.

For the soils collected in 2008 and stored at −80 °C, there appeared to be a latitudinal gradient in terms of the success of platings. Just over half (62.5%) of soils collected in Saskatchewan, Canada, were positive for thermophiles, compared to 80% of soils from Custer, South Dakota; 86.7% from Socorro, New Mexico; 93.9% from Janos (Chihuahua), Mexico; and 89.7% from Ojuelos (Jalisco), Mexico. With the exception of the soils from Janos (which showed a higher percentage than

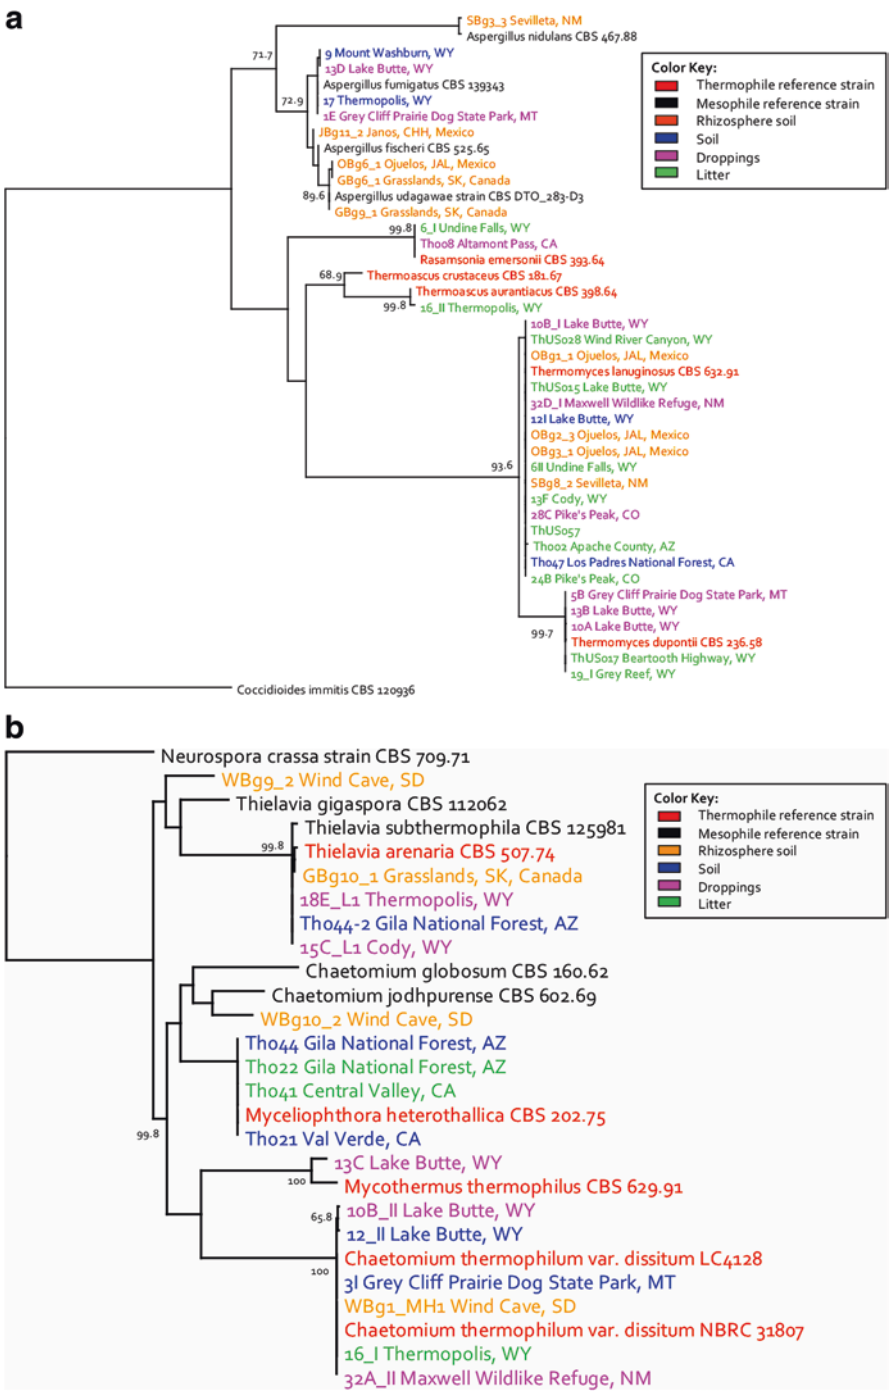

Fig. 4.3 Ribosomal RNA ITS gene trees for three orders of thermophilic fungi recovered from a recent survey (collection sites are presented in Fig. 4.2 and Table 4.1): Eurotiales (**a**), Sordariales (**b**), Mucorales (**c**). Trees were rooted with *Coccidioides immitis*, *Neurospora crassa*, and *Pilobolus crystallinus*, respectively. New isolates are color coded by substrate type, while reference strains are colored by temperature optimum. Bootstrap values (1000 replicates) are displayed for all nodes receiving 65% or greater support. All new isolates form well-supported clades with previously identified species, and represent diverse substrate types and locations

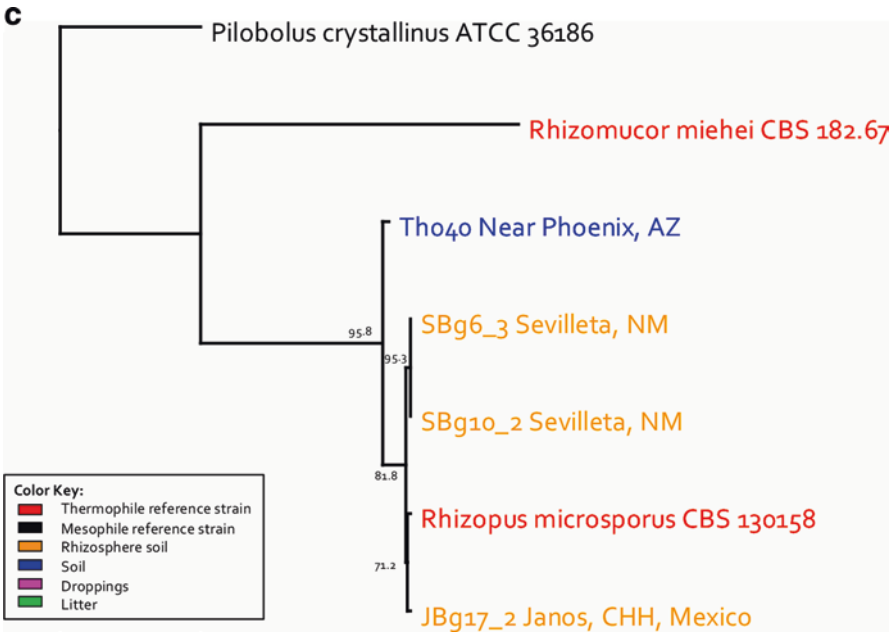

Fig. 4.3 (continued)

Ojuelos to the south), plating success declined with increasing latitude. In pairwise comparisons, plating success for Saskatchewan was an outlier, and significantly different from all other locations except South Dakota according to a Pearson's N-1 chi-square test [$\chi^2_{\text{SOUTHDAKOTA}}(1,N=54)=2.00, p=0.16; \chi^2_{\text{NEWMEXICO}}(1,N=54)=4.20$, $p = 0.04$; $\chi^2_{\text{JALISCO}}(1,N = 63) = 6.60$, $p = 0.003$; $\chi^2_{\text{CHIHUAHUA}}(1,N = 57) = 8.63$, $p = 0.01$]. No other pairwise comparisons were significantly different.

Discussion. Our results indicate that thermophilic fungi are readily isolated from various substrates, from elevations as low as 40 m above sea level to as high as 3951 m and from a great range of latitudes between Mexico and Canada. We observed no correlation between phylogeny and environment. Specifically, isolates from the Eurotiales and Sordariales did not differ significantly for substrate preference, elevation, or latitude. Even within a single OTU cluster, constituent sequences were derived from diverse locations and substrates. For example, OTU1 (*Thermomyces lanuginosus*) represents isolates from as far south as Ojuelos, Jalisco, to as far north as the Beartooth Highway in Wyoming. This cluster also consisted of multiple isolates from every substrate type and of elevations from 315 m to above timberline at 3951 m. Indeed, at the resolution of OTUs at the 97% level, there appears to be no specificity of thermophilic fungi to a particular habitat. It is possible, however, that the 97% cutoff is too generous and blurs the finer distinctions among the isolates. To develop a better sense of the phylogenetic relationships between the isolates, one might also collect data for functional DNA regions that are less variable and more reliable at predicting deeper levels of taxonomy.

Studies show that members of the Chaetomiaceae (Sordariales) are proficient in decomposing cellulosic biomass, so they are thought to associate with plant-based substrates in nature (Ames 1963; Mehrotra and Aneja 1990). They have been previously isolated from herbivore droppings, leaf litter, and even from live plants (Kerekes et al. 2013; Richardson 2001; Abou Alhamed and Shebany 2012). Chaetomiaceae are also prevalent in composts (Cooney and Emerson 1964; Kane and Mullins 1973; Straatsma et al. 1994). For example, using an ITS barcoding approach, Neher et al. (2013) showed *Chaetomium* species to be dominant members of the fungal OTUs across all of the compost recipes they tested, especially in the earlier stages of composting. As discussed previously, composts have been proposed as the primary habitats for thermophilic fungi, with the suggestion that specimens found on other substrates are likely inactive propagules dispersed from compost (Rajasekaran and Maheshwari 1993). However, soil is also sufficiently rich in cellulose as it is one of the top sources of complex carbon polymers (Kögel-Knabner 2002; López-Mondéjar et al. 2016). Thus, it is perhaps unsurprising that many thermophilic species in the Chaetomiaceae have been identified from soil (Tansey and Jack 1976; Pan et al. 2010; Powell et al. 2012). Mesophilic Cheatomiaceae have been demonstrated to be both present and active in the soil. Using Stable Isotope Probing with ^{13}C cellulose substrate, Eichorst and Kuske (2012) showed that species of *Chaetomium* actively decay cellulose added to soil. It is reasonable to believe that thermophilic members of the Chaetomiaceae do the same.

Species in the order Eurotiales are also commonly associated with decaying plant material. For example, the well-known fungus *Aspergillus fumigatus* is cited as one of the most frequent species recovered from composts and other plant debris (Taylor et al. 2015). *A. fumigatus* also shows a pan-global distribution, which Pringle et al. (2005) have suggested may be due to the role of humans in expanding composting processes. Another member of the Eurotiales, the thermophilic fungus *Thermomyces lanuginosus* also shows seemingly ubiquitous distribution. In our present study, it was the most frequently isolated taxon and derived from a variety of substrates and locations. Langarica-Fuentes et al. (2014) also found that along with *Talaromyces thermophilus* (another species in the Eurotiales), *T. lanuginosus* accounted for 65% of sequences obtained via 454′ barcoding of the fungal community in the middle and center of an in-vessel compost system. Similarly, it was the top isolate in studies of thermophilic fungi from soils in India (Maheshwari et al. 1987; Rajasekaran and Maheshwari 1993). Still, Rajasekaran and Maheshwari (1993) were unable to detect actively growing *T. lanuginosus* in soil with immunofluorescence assays. However, Hedger and Hudson (1974) reported that *T. lanuginosus* shows commensal interactions with cellulolytic fungal thermophiles (*Chaetomium thermophile* and *Humicola insolens*) and subsists on the sugar byproducts from cellulose decomposition. Thus, it may be that this species performs best in a consortium with cellulolytic thermophiles and requires other fungal partners to grow. If there is adequate cellulose in a given substrate, cellulose degrading fungi can likely support commensal fungi, thus providing a niche in soil for species such as *T. lanuginosus*.

Soils undergo diurnal temperature fluctuations to upwards of 70 °C, so soil is a suitably hot substrate for thermophilic fungi (Powell et al. 2012). Leaf litter and

herbivore droppings also experience similar swings in temperature (Fig. 4.1). In addition, thermophilic fungi are more readily isolated from soil after precipitation events, indicating that they are responsive to changes in the soil environment (Powell et al. 2012). Taken together, these factors suggest that thermophilic fungi can inhabit many microhabitats, including soil, provided that they have access to moisture and appropriate temperatures.

4.5 Conclusions

Much remains to be learned about the ecology of thermophilic fungi. Although it has long been known that these fungi can be isolated from soil, herbivore droppings, and other substrates, most studies have focused on composted plant materials in either natural or anthropogenic settings. In contrast, our surveys have shown that nearly all ecosystems provide thermophilic fungi with at least transient access to decomposing plant material, and sufficiently high temperature and moisture (see Fig. 4.1). Our results suggest that such transient microenvironments might be the primary habitats. At the level of resolution provided by ribosomal ITS sequences, there is little evidence for habitat specialization or geographical restrictions among thermophiles. Thermophiles in the Ascomycota are distributed across three orders, with several phylogenetic lineages within each order. We found members of most lineages across wide latitudes, elevations, substrate, and ecosystem types, ranging from desert shrublands and grasslands to montane forests to northern grasslands.

4.6 Future Perspectives

Thermophilic fungi have provided many contributions to science, both in their utility to industry and in the advancement of basic understanding in biology. Information on the distribution of thermophilic fungi, and a better grasp on their natural diversity and roles in the environment, will help further the field of microbial ecology and will aid in bioprospecting new, potentially useful organisms for biotechnology. Although next-generation sequencing methods can detect thermophilic fungi in environmental samples, many thermophiles have close mesophilic relatives, and as a result, the assessment of thermophily often requires evaluation based on growth in the laboratory rather than on sequence analysis alone. Accordingly, it is likely that fungal thermophiles are overlooked in environmental sequencing data. Similarly, culture-based methods of community analysis often employ only temperatures suitable for mesophiles, and temperatures optimal for the growth of thermophiles or psychrophiles are not considered. Moreover, it is possible that certain fungal thermophiles are unculturable and are only detected as DNA in environmental surveys. These circumstances thereby result in a need for a unified, comprehensive approach to appraising and understanding not only the biology of thermophilic fungi, but also the ecology of non-thermophilic microbes that share environments with thermophiles.

Chapter 5
Ecology and Biotechnology of Thermophilic Fungi on Crops Under Global Warming

Robert Russell M. Paterson and Nelson Lima

5.1 Introduction

More extreme climates will occur under climate change. These are likely to affect detrimentally the ability to grow crops where temperature increase will cause most problems and the most likely change is high temperatures, as is well known (http://unfccc.int/paris_agreement/items/9485.php) (Paterson and Lima 2010a, 2011, 2017a; Paterson et al. 2013). The changes will affect negatively the diseases of crops with fungal maladies being particularly important (Paterson and Lima 2010a; Paterson and Lima 2011; Paterson et al. 2013; Paterson and Lima 2017a).

Climate change affects the plant disease triangle comprising the environment, plant host and pathogen (Paterson and Lima 2017a). Some fungi can produce mycotoxins on crops (Medina et al. 2015) (Paterson and Lima 2010a; Paterson and Lima 2011; Baranyi et al. 2015) and the infection process is similar to that for fungal plant pathogens not producing mycotoxins. An alternative route for mycotoxin contamination is via stored crops where there may be greater control from, for example, keeping the commodity dry.

Mycotoxins are low-molecular-weight fungal secondary metabolites some of which have statutory limits imposed on crops by trading blocks and nations. These compounds have toxicities and so are biologically active. However, secondary metabolites also include antibiotics and other drugs of which fungi are well-known

producers, for example, penicillin, cephalosporin and statins. Production of mycotoxins is highly influenced by climate change (Magan et al. 2011), affecting the succession of fungi and mycotoxins on crops towards those that grow and are produced respectively at higher temperatures (Paterson and Lima 2010a,2011), where a progression of temperatures is observed. This only occurs with *A. flavus* and aflatoxins, after which there are no conventional fungi that produce well-known mycotoxins. All these fungi do not grow, or not well, above 35 °C. Higher temperatures are obtained readily currently and will become common under global warming (Paterson and Lima2017a). In countries such as Pakistan (Paterson and Lima 2011) and Australia (Guardian, UK newspaper 8 Jan 2018), astonishingly high temperatures are recorded at ca. 45–50 °C, or more.

Interestingly, the increase in temperature anticipated from climate change may lead to thermotolerant and thermophilic fungi (TTF) (Salar 2018) with new biotechnological properties. For example, fungal enzyme activity is responsible for some plant diseases, especially those involved in wilts and rots, and many of the same enzymes have utility in industrial processes, for example, cellulases, ligninases, pectinases and amylases. New high-temperature enzymes may be obtained from novel thermophilic plant pathogenic fungal species.

The distinction between mesophilic, thermotolerant and thermophilic is imprecise and fungi capable of simply growing above 45 °C have been considered thermophilic. If growth up to 45 °C is considered as mesophilic, where do the thermotolerant fungi fit? Morgenstern et al. (2012) usefully consider thermophilic species as those which grow faster at 45 than 34 °C. 'Thermotolerant' can then be applied to fungi which grow at or above 40 °C, distinguishing them from most mesophiles, but with optima below this threshold.

Salar (2018) appears to support the following classifications for fungi: Thermophilic have optima for growth greater or equal to 45 °C; thermotolerant have maxima less than or equal to 50 °C, with a minimum 'considerably' less than 20 °C; A novel category referred to as thermophilus includes all fungi growing at elevated temperatures, hence including TTF; thermoduric are those with reproductive structure surviving ca. 80 °C but have with normal growth temperatures of 22–25 °C; transitional thermophiles are those that grow below 20 °C but withstand near 40 °C. It is unclear how helpful so many definitions are, some of which overlap. Redefinitions may be required as global warming continues and higher temperatures become the norm.

The increase in fungal disease of crops because of climate change has been anticipated in various studies (Paterson and Lima 2010a, 2011, 2017a; Paterson et al. 2013). The magnified level of maladies could occur from more virulent fungi and/or less resistant crops. Increase in virulence would result from the new conditions favouring the pathogen over the plant. Alternatively, strains of the fungi may be selected for under the novel climate as it is well known that fungi are mutable and are likely to change more than a particular crop could become resistant to the disease within a particular period of time. The fungus could mutate more readily into a virulent strain from, for example, higher levels of UV irradiation from the sun's rays penetrating the atmosphere than from the destruction of the ozone layer (Paterson

and Lima 2011; Paterson et al. 2013). Finally, different fungal taxa with higher growth temperatures could become novel pathogen crops in the manner previously described for mycotoxigenic fungi.

The scope of this chapter commences with the premise that fungi are changing from those that grow at low temperatures to those that are thermophilic. This indicates a significant change in biodiversity. These changes will have a large impact on biotechnology in that novel fungi will be increasingly studied with useful properties. However, there will also be losses of biodiversity with a potentially negative biotechnological impact. Naming fungi correctly is essential; otherwise inventories for biotechnology will become misleading. These points are illustrated uniquely using mycotoxigenic fungi and plant pathogens. The field of bioprospecting is also covered. No other work combines these aspects in a unified report.

5.2 Fungal Succession as Illustrated by Mycotoxigenic Fungi

What evidence is there that mycotoxigenic fungi succeed one another when the growing conditions change (Paterson and Lima 2011), which would be an indication of what will occur with other fungi under climate change? In fact, there is a great deal of evidence from crops in Europe where novel mycotoxins are becoming problematic whereas others were predominant previously (Paterson and Lima 2017a).

Conventional mycotoxigenic fungi are mesophilic, although *Aspergillus flavus* and *A. parasiticus* may be thermotolerant marginally, the two most important and dangerous aflatoxin-producing fungi. Temperatures are likely to increase well beyond these ranges and especially in the tropics, although these high temperatures will appear eventually in non-tropical climates if climate change is not addressed. Which fungi and conventional mycotoxins (e.g. aflatoxin, ochratoxin A, deoxynivalenol and fumonisins) will succeed? Paterson and Lima (2010a) suggested that *A. flavus* may become extinct because of climate change, which would be advantageous to crop production as they would have low levels of aflatoxin. Furthermore, there is less relevance in studying conventional fungi and mycotoxins if they become increasingly rare on crops. Paterson and Lima (2011) discuss how mycotoxin contamination is predictable if the same fungi are involved under climate change but becomes unpredictable should novel fungi dominate.

The ecology of fungi under climate change towards high temperatures is interesting. Existing fungi, currently at low concentrations, may dominate when temperature change conforms to the growth optima of these fungi. Alternatively, species from higher temperature regions may be introduced to the more temperate regions as invasive species.

Of greatest significance is that aflatoxigenic fungi will be replaced by TTF. The succession of *A. flavus* and aflatoxin fungi has been reported frequently (Paterson and Lima 2017a), with additional examples from fusaria. The increased frequency of aflatoxin detection indicates an increase in the fungi responsible and represents a

biochemical diagnostic for the fungi (Paterson and Kozakiewicz 1997). And vice versa, the decreased detection of the previous mycotoxins acts to indicate fewer producing fungi and a similar principle could be employed with other fungi that produce secondary metabolites on crops. This method could compliment culture-independent PCR methods (Paterson 2012).

Increased aflatoxin B1 contamination in Europe was associated with hot weather, contributing to increased *A. flavus* on crops in Italy (Paterson and Lima 2011; Giorni et al. 2007), and *A. flavus* colonized maize by outcompeting *Fusarium* species during the hot and dry episodes in the same country in 2003 (Giorni et al. 2008). Increased aflatoxin M1 in milk in 2012 related to more aflatoxins than normal in animal feed from southeast Europe (Alfonso and Botana 2015). A survey (EFSA 2007) correlated aflatoxin contamination of crops in southern Europe with a recent subtropical climate, and a model for *A. flavus* growth and aflatoxin B1 production indicated that aflatoxin contamination will increase in maize from climate change, where there was an increase in aflatoxin risk in many countries at plus 2 °C. Furthermore, *A. flavus* colonized ripening maize by outcompeting *Fusarium* species (Magan et al. 2011). Extreme temperatures of >35 °C resulted in a change from *Fusarium verticillioides* and contamination with fumonisins of maize to *A. flavus* and aflatoxins (Giorni et al. 2007). No aflatoxin contamination was detected in Serbian maize in 2009–2011, but prolonged hot and dry weather in 2012 correlated with 69% of samples being contaminated (Kos et al. 2013), with an implied increase in the producing fungi. Increases in aflatoxins in maize in Hungary may be from climate change (Dobolyi et al. 2013), and aflatoxin-producing *A. flavus* isolates in several maize fields were isolated in 2012–2013, whereas before none were found: Aflatoxin B1 levels in cereals and animal feed above the EU limit in 4.8% of samples were observed in Hungary (Borbély et al. 2010), and aflatoxins were also detected in maize kernels in Hungary in 2012 (Baranyi et al. 2015) indicating a climate change event.

This succession has been observed with the fusaria that grow optimally at higher, although mesophilic, temperatures (Paterson and Lima 2017a). The displacement of the formerly predominant species, *Fusarium culmorum* and *Microdochium nivale*, by the more virulent plant pathogen *F. graminearum*, as a result of warm European summers, has been reported (FAO 2008). *F. graminearum* was the most abundant *Fusarium* on wheat in the Netherlands in the early 2000s, whereas *F. culmorum* was dominant in the 1990s (Waalwijk et al. 2004). The fungus has increased on wheat in the UK, while *F. culmorum* is less important (Edwards 2009) and similarly for Germany (Miedaner et al. 2008). *F. poae* was highest in Poland followed by *F. tricinctum*, *F. avenaceum*, *F. culmorum* and *F. graminearum* (Logrieco and Moretti 2008): a significant increase in *F. graminearum* has now been observed (Stępień and Chełkowski 2008). T-2 and HT-2 toxin contamination are more prevalent on oats and barley in the UK related to *F. langsethiae* detection in grains (Edwards 2009) and by implication climate change. In addition, this species has become prevalent on barley in recent years in northern France (Moretti and Logrieco 2015) and produces toxins (Magan et al. 2011). High temperatures favour growth of the fumonisin producer *F. verticillioides* in maize (FAO 2008). A more toxigenic 3-acetylated

deoxynivalenol chemotype of *F. graminearum* replaced the 15-acetylated deoxynivalenol chemotype in Canada (Ward et al. 2008), indicating that lower taxonomic ranks of species are involved. Minnesota, USA, has witnessed the emergence of a novel *Fusarium* taxon called the 'Northland population', which does not produce deoxynivalenol or nivalenol (Paris et al. 2015). Hence, TTF are likely to succeed other mycotoxigenic fungi in the future as temperature increases, and these previously mentioned results are extremely useful for predicting what will happen to fungi in general under climate change.

5.3 Threat Posed by Existing Mycotoxins from Global Warming

Perhaps surprisingly, the only conventional mycotoxin-producing TTF are those that manufacture patulin (Fig. 5.1). There is also a group of potentially patulin-producing TTF. Hence, patulin may become more prevalent in the future through global warming, which requires monitoring. The concentration of patulin in apple products is subject to regulations and is produced in apples by *Penicillium expansum* (Wright 2015). More commodities will require assessing for patulin contamination which are currently only analysed for the other conventional mycotoxins, because of patulin production from TTF and global warming. New commercial markets will be formed in mycotoxin analysis and mycotoxin remediation which may be considered as forms of biotechnology.

It is worthwhile summarizing the toxicity of patulin: The probable primary biochemical lesions and the early cellular events leading to toxic cell injury or cellular deregulation caused by patulin, involve initial non-protein sulfhydryl depletion, leading to (a) an event cascade of altered ion permeability and/or intercellular communication, (b) oxidative stress and (c) cell death, involving inhibition of macromolecular biosynthesis (Paterson and Lima 2010b). The International Agency for Research on Cancer has since 1986 maintained that patulin is not a carcinogen, because of the lack of studies demonstrating its carcinogenicity, but this classification may change in the future as science progresses (Pfenning et al. 2016).

Byssochlamys, *Paecilomyces* anamorphs and *Thermoascus* were considered as patulin-producing fungi or suspected producing fungi. However, from recent nomenclatural changes, *Byssochlamys fulva* is now considered as *Paecilomyces fulvus* and *Byssochlamys nivea* is *Paecilomyces niveus* (Frisvad 2018). Contamination of canned goods can occur with these fungi as they survive high temperatures used in the industry. Species identification is difficult and the taxonomy has been

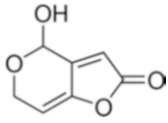

Fig. 5.1 Chemical structure of patulin

subjected to a number of revisions to delineate which taxa produce patulin (Samson et al. 2009), although more work is required particularly on the effect of high temperature on patulin production. Frisvad (2018) considered that a high percentage of fungi listed as producing patulin were designated predominantly from (a) misidentifications of the fungus or toxin and/or (b) carry-over in the analytical equipment, which is remarkable. Can this be ascribed to these reasons in all cases? There are major faults in the procedures and in the literature reporting them, if this is the case. Correct identifications can effectively only be carried out by a small number of taxonomists under current systems, although the need to identify the fungi and mycotoxin production is from a much wider group of scientists. Other interpretations, such as only a few strains of a species having the capacity, or mutation of the fungi from environmental and/or cultural conditions, cannot be dismissed (Paterson and Lima 2015a). Also, subtle changes in growth conditions may allow expression of the patulin pathway in some laboratories but not others and preservation methods may have inhibited expression of the pathway. Contamination of cultures is another possibility. It indicates that the current (chemo) taxonomies cannot be applied universally (Paterson et al. 2017, 2018). A fundamental criterion is that scientific methods should be repeatable by other scientists in other laboratories and so simpler methods are required which can be used in most laboratories and by various taxonomic skill levels. The correct naming of fungi forms the basis of many aspects of biotechnology.

Paecilomyces variotii sensu *lato* is a common fungus in the air, subtropical soil, tropical soil, compost and wood, and is frequently in foods such as rye bread, margarine, peanuts, peanut cake, cereals and heat-treated fruit juices (Houbraken et al. 2006). Strains of *P. variotii* produce patulin, although the species may represent a complex of *P. divaricatus*, *P. formosus*, *P. saturatus* and *P. variotii*. *P. brunneolus* may form another species within the complex, but is very similar to *P. variotii*. However, only *P. saturatus* is listed as producing patulin (Samson et al. 2009). A single representative of *P. brunneolus* grew more at 30 than 37 °C, whereas it is the reverse for *P. variotii*, perhaps indicating that *P. variotii* is a TTF and *P. brunneolus* is not. A chemotaxonomic revision of these fungi is required in relation to patulin production under high temperature which might stimulate patulin production. Furthermore, *P. variotii* is claimed as the anamorph of *Byssochlamys spectabilis*. *P. variotii* appears as the earliest name applied to this species and a new combination into *Byssochlamys* may be required if *B. spectabilis* is not proposed for protection. The case has not been reported upon by an ICTF-recognized working group and remains undecided (Hawksworth 2015). Frisvad (2018) states that *B. variotii* is now named *P. variotii*, which may confuse the non-expert.

B. nivea is a well-recognized name for a patulin-producing species (Samson et al. 2009) although it appears that the designation has been superseded by *P. nivea* (Frisvad 2018). Also, Frisvad (2018) stated that *B. variotii* is now correctly named as *P. variotii* as mentioned previously and the situation appears confusing. At least one strain grew at 46 °C (Zhang et al. 2016) and so is a TTF. The optimum temperature for *P. variotii* growth is 50 °C and the maximum is 55 °C (Table 5.1): this patulin-producing species (Maheshwari et al. 2000) is a valid candidate to succeed

Table 5.1 Patulin production and potential production of some thermophilic and thermotolerant fungi (Maheshwari et al. 2000)

Fungus	Temp. optimum (°C)	Temp. maximum (°C)	Comment
Paecilomyces variotii	50	55	Of this species complex, *P. saturatus* may be the patulin-producing species
Byssochlamys nivea	–	At least 46 (Zhang et al. 2016)	Well-known patulin producer
Thermoascus aurantiacus	49–52	61	IDH positive; patulin to be confirmed
Byssochlamys verrucosa	20–53	–	*B. verrucosa* is more related to *Thermoascus*. IDH positive; patulin to be confirmed

mesophilic mycotoxigenic fungi in nature. *B. nivea* (now *P. nivea*) is also a valid candidate as it is at least thermotolerant and produces patulin. Patulin (Fig. 5.1)-producing fungi mentioned herein (Table 5.1) would be considered thermophilic but also grow within the thermotolerant range and a precise study of the optima and maxima of these fungi is merited. Patulin, produced by TTF, could become more prevalent on crops and even displacing aflatoxin in the future under climate change. Interestingly, this mycotoxin was considered as a potential antibiotic, also indicating how novel biotechnologically relevant compounds could arise under climate change.

The isoepoxydon dehydrogenase (idh) gene of the patulin metabolic pathway was detected in *B. verrucosa*, which is an indicator of the ability to produce patulin in fungi (Paterson et al. 2003), although patulin was not detected (Hosoya et al. 2014). This could reflect that the mycotoxin was produced below the detection limits of an analytical system, or that appropriate growth conditions were not employed, rather than the fungus being incapable of producing the compound. Testing patulin production at high temperatures would be appropriate. The temperature optimum or optima lie within a range that extends to 52 °C, which is thermophilic. Hence this species is a possible candidate for a conventional mycotoxin producer that could replace the mesophilic mycotoxigenic fungi, if patulin production was confirmed. However, *B. verrucosa* is more related to *Thermoascus* than *Byssochlamys* by analyses of the ITS, and partial β-tubulin DNA region (Samson et al. 2009).

Thermoascus aurantiacus is a well-defined species which again possessed the idh gene, although patulin was undetected (Hosoya et al. 2014). *Thermoascus* has been isolated from various foods including maize and could become prominent under climate change. The incidences of spoilage by these fungi are increasing which may be climate change related. The species has a temperature optimum between 49 and 52 °C and a maximum of 61 °C. To reiterate, no other TTF produce other conventional mycotoxins.

5.4 Secondary Metabolites from Thermophilic Fungi That May Contaminate Crops

A list of potential mycotoxins and other secondary metabolites from TTF are given in (Paterson and Lima 2017a) and Table 5.2. Some examples include gliotoxin from *A. fumigatus*; estatin A and B from *Myceliophthora thermophile*; and talathermophilins from *Talaromyces duponti*. Other secondary metabolites will be discovered from TTF which could provide novel pharmaceuticals or become novel mycotoxins. Fungal diseases of crops in general have similarities to mycotoxin contamination by fungi of crops, and this will now be illustrated by a fungal disease of oil palm called basal stem rot.

5.5 *Ganoderma boninense* Oil Palm Disease

Palm oil has many uses including (a) a component of many foods and cosmetics, (b) cooking, (c) pharmaceuticals and (d) biodiesel (Paterson and Lima 2018). It contributes significantly to the economies of many countries and Malaysia and Indonesia particularly, as these are the highest producers by far. However, the production of palm oil contributes to climate change predominantly because of deforestation and burning of peat to grow OP. Equally, the growth of OP is affected negatively by climate change and diseases of the palm will be affected. Levels of disease are likely

Table 5.2 Secondary metabolites from thermophilic fungi (Paterson and Lima 2017a)

Fungus	Temp. optimum (°C)	Temp. maximum (°C)	Secondary metabolites	Habitat
Aspergillus fumigatus	37	65	Gliotoxin, fumigatins, fumigaclavines, fumiquinazolines, fumitremorgins, verruculogens, helvolic acids	Composts, tree bark, crops
Myceliophthora thermophila	45–50	55	Estatin A and B	Wood pulp
Talaromyces duponti	45–50	60	Talathermophilins, thermolides	Guayule shrub, fermented straw, compost
Thermomyces lanuginosus	45–50	60	Thermolides, bacterial-like hybrid macrolactones	Compost, moist oats, cereal grains, mushroom compost, hay, leaf mould peat, garden compost, various plant substances

to increase under climate change (Paterson and Lima 2010a), with novel fungi causing more maladies, or even mutated strains becoming involved (Paterson et al. 2013). The novel fungi may have beneficial properties for biotechnology consistent with the theme of this chapter.

Oil palm and fungal diseases of oil palm have adapted to the tropical climates in which the plant grows. There is considerable concern about the sustainability of oil palm and one of the major issues is an increase in disease from an increase in climate change (Rival 2017; Corley and Tinker 2016; Paterson et al. 2013; Paterson and Lima 2018). The most important disease in Malaysia and Indonesia is basal stem rot caused by *G. boninense* (Fig. 5.2), the growth optimum of which is approximately 32 °C (Paterson et al. 2013), although more stains require testing. The species responsible have not been satisfactorily determined and there may be novel taxa of the genus more adapted to higher temperatures. This will be explained in more detail to indicate which novel species could become a fungal disease.

There are many other wood-rotting fungi within the plantations that could cause the rot disease (Naidu et al. 2015; Paterson et al. 2000; Treu 1998). *G. boninense* has adapted sequentially to jungle/forest trees, coconut/rubber and OP (Flood et al. 2000a). The fungus reproduces sexually, allowing genetic variation to occur: It produces millions of spores for propagation, even from one basidiome, thereby permitting further variation. Evolution in *Ganoderma* and increasing complexity in population structure will occur where interactions with oil palm are longest, when pathogens are evolving and adapting to environmental changes (Merciere et al. 2017). Rapid evolution of taxa adapted to the novel conditions of CC can be

Fig. 5.2 The white rot fungus *Ganoderma* on oil palm (https://www.google.com/search?q=oil+palm+ganoderma+disease+and+symptom+photo&source=lnms&tbm=isch&sa=X&ved=0ahUKEwjkvMztiazaAhVDLVAKHbQFBa4Q_AUICigB&biw=1094&bih=547&dpr=1.25#imgrc=-yc-jvH7ZylSeM)

anticipated. The variation within the genus associated with OP can be appreciated when (a) *G. boninense*, *G. zonatum*, *G. miniatocinctum* and *G. tornatum* (Rashid et al. 2014) and (b) *G. ryvardense* (Corley and Tinker 2016) may cause the disease and these species, or other related taxa, may become dominant in the future. The taxonomy of *Ganoderma* remains unresolved and species concepts are reviewed frequently (Paterson and Lima 2015b; Zhou et al. 2015). The situation is complicated by the plant disease website Plantwise (https://www.plantwise.org/KnowledgeBank/Datasheet.aspx?dsid=24924) where BSR is associated initially with *G. boninense*, but the name *G. orbiforme* is used when the distribution map is consulted: *G. orbiforme* is not considered a synonym of *G. boninense* (Wang et al. 2014) and forms a separate species. Nevertheless, authentic *G. orbiforme* may also be involved in BSR. The indigenous, or introduced, *Ganoderma* in Malaysia and Indonesia in existence with oil palm are capable of adapting to CC more quickly than can the oil palm.

A related malady is the enigmatic upper stem rot which is poorly studied. OP with upper stem rot will tend to remain standing longer than those with BSR as they are more stable (Flood et al. 2000b) making the rot appear less serious: it is important only in deep peat and inland valley soils and appears sporadically in Malaysia and Indonesia. Interestingly, there are conflicting reports of the cause being *Phellinus noxius*, another basidiomycete white rot fungus (Paterson 2007), with *G. boninense* perhaps a secondary infection (Corley and Tinker 2016). Contrary reports suggest that *G. boninense* causes the disease: *Ganoderma* was confirmed in all cases of upper stem rot examined in Sumatra, sometimes with a *Phellinus* sp. *P. noxius* could become a more important disease of OP under CC if conditions favour this fungus.

Thermophilic fungi will be increasingly important as temperature increases under CC (Paterson and Lima 2017a) as mentioned above. *G. collosum* is a thermophilic white rot (Paterson 2007) *Ganoderma* which grows optimally at 40 °C and up to 45 °C. The fungus has been shown to degrade date palm, but has not been tested against OP (Adaskaveg and Gilbertson 1995). Hence, there already exists a palm-degrading *Ganoderma* adapted to high temperatures. Other palm-degrading fungi could also adapt to causing disease in stressed OP from the consequences of CC (Naidu et al. 2017). A question this current chapter asks is what other properties will these TTF have of interest to biotechnology apart from those already discussed.

5.6 Increased Thermophilic Fungi to Impact Biotechnology

One of the main subjects of this chapter is that the climate change conditions may select for fungi with novel biotechnological potential as best illustrated with mycotoxigenic fungi. Increases in plant disease may occur and new mycotoxins may appear which will require novel methods for diagnoses, consequently contributing to the bioscience industries. More and/or different equipment will be required which will boost profits for analytical equipment companies, although there will be lost

profits from a reduced need to analyse for fungi or mycotoxins which will no longer be relevant. The toxicity of novel mycotoxins will require assessments which will lead to technological developments implying more resources being expended in these areas.

Improved analytical methods related to biotechnology for patulin will be required if it becomes more prevalent, many of which will be HPLC related. In addition, molecular biology procedures will be employed to identify the fungi isolated from the crops where patulin contamination occurs. Analytical methods will need development based on first principles for each potential toxin in the case of novel mycotoxins from TTF. HPLC, MS and NMR will all be required for these new compounds. Novel toxicity testing and bioassays may be required. New immuno-affinity columns (IAC) may be produced, for example, allowing a new market for diagnostic companies. However, IAC for patulin may not be possible as the molecule is too small to allow the correct immune response in the production animals. This requires weighing against the reduced requirement for equipment to detect the mycotoxins present currently.

When the TTF grow and produce mycotoxins on crops, methods will be required to control these sources of food contamination. Control of current mycotoxins might be possible using biocontrol microorganisms applied to the crop (Chulze et al. 2015). Similarly, novel biocontrol microorganisms may be developed to control TTF as they become problematic. These biocontrol organisms will need to be effective at the new extreme temperatures.

With the possibility of patulin contamination becoming more prevalent, it is useful to consider biotechnological procedures to reduce levels and degrading the molecule may be possible employing patulin-degrading microorganisms (Zhu et al. 2015).

As novel mycotoxins emerge, so might new pharmaceuticals from the TTF, especially if bioprospecting projects are undertaken. Novel fungi with new properties may be found. Refocusing on TTF because of their potential to infect crops may yield promising new (high-temperature) enzymes, organic acids and pharmaceuticals, or fungi that can produce existing ones more efficiently. The search for novel pharmaceuticals, enzymes and organic acids, for example, is often associated with bioprospecting (Paterson and Lima 2017b). The change in climate to thermophilic temperatures implies that novel fungi will almost certainly occur adapted to the novel conditions. In addition, mutations may occur allowing fungi to adapt and thrive under the hot temperatures.

There are few bioprospecting projects that are exploring the current fungi found in particular regions or niches (Stierle and Stierle 2017), but these could usefully be increased. Pingal (2017) discussed a project based in Iwokrama rainforest in Guyana. Novel fungi could be discovered under CC if a new project was established and as proposed in the current chapter. But first a new survey of existing fungi is required, and similarly for the Sarawak rainforest in Malaysia (Shaw 2017) and other biodiverse regions. Unfortunately, useful fungi could become extinct because of CC. These fungi may have yielded new antibiotics, for example, which are

especially important in the current era of resistant diseases (Paterson and Lima 2017c) and may represent a missed opportunity.

TTF are often studied for high-temperature enzyme production but are also known to produce secondary metabolites with antimicrobial activities and can be used for composting activities (Singh et al. 2016). Houbraken et al. (2014) investigated the taxonomy of TTF which had biotechnological properties and Maheshwari et al. (2000) discussed TTF enzymes. TTF are seen as having the potential to contribute significantly towards a more sustainable world and represent an understudied group. This may lead to them being investigated for their properties and lead to new enzymes and metabolites. Crops could be modified to withstand higher temperatures from climate change by transforming genes from TTF as (Kumar et al. 2016).

Another negative impact of climate change may be that some useful fungi will become less prevalent or extinct as climate changes. This may provide the impetus for increasing bioprospecting surveys (Paterson and Lima 2017b) before these fungi effectively disappear. The environments that require surveys are fields where crops are grown and which are analysed for mycotoxins and the rainforests and plantation floors where OP are grown or intended to be grown. Thermophilic fungi that cause basal stem rot in oil palm disease under climate change may possess highly active high-temperature ligninolytic enzymes capable of converting plant material into biofuel or animal feed.

5.7 Conclusions

Climate change will create a new environment for biotechnology and for microorganisms such as fungi. Surveys of hot regions (e.g. the tropics) that grow important crops are required to determine which TTF are present and if they can produce any of the important mycotoxins. PCR of metabolic pathway genes may be useful for this purpose (see above). Also, the presence of the TTF on crops may be higher than is currently appreciated, because seldom are high temperatures employed to isolate fungi from foodstuffs. The presence of TTF in currently temperate countries requires investigation to anticipate which fungi will succeed those isolated under mesophilic conditions. When assessing the mycoflora, higher incubation temperatures are recommended of at least 42.5 to as much as 65 °C. The succession of fungi on crops because of global warming will not cease after temperatures increase beyond the mesophilic range. It is likely that patulin will increasingly become a threat under climate warming as discussed herein. The new environmental conditions may allow isolation of novel fungi with useful properties for biotechnological advancement. However, what will we have missed in the mean time?

5.8 Future Perspectives

The anticipated outcomes of climate change are likely severe. However, there may be some positive aspects such as greater availability of fungi able to grow at high temperatures and producing novel (high-temperature) enzymes and pharmaceuticals. Efficient lignin degraders could be discovered capable of degrading by-products from plants much quicker than is possible currently, permitting efficient conversion to biofuels and animal feeds. The most dangerous mycotoxin, aflatoxin, may be less common on crops. Nevertheless, these are oases in an outlook which is bleak, if climate change is not addressed and deaccelerated as outlined in the Paris climate conference. Negative consequences for fungi include the extinction of potentially useful fungi present in the environment under current conditions. The presence of the aflatoxin is likely to increase, and other mycotoxins will be in higher concentrations before the possible reduction of aflatoxin on crops. Patulin may become a major problem. Crop diseases are likely to increase particularly in the tropics. Finally, the effects of climate change on biotechnology will be profound, although it remains unclear if the pros will outweigh the cons. This is not the case concerning the overall consequences of climate change, which remain severe.

Acknowledgments This study was supported by the Portuguese Foundation for Science and Technology (FCT). It was within the strategic funding of UID/BIO/04469/2013 unit, COMPETE 2020 (POCI-01-0145-FEDER-006684) and BioTecNorte operation (NORTE-01-0145-FEDER-000004), which was funded by the European Regional Development Fund within Norte2020—Programa Operacional Regional do Norte. RRMP received gratefully the IOI Professorial Chair in Plant Protection for 2018 at the Universiti Putra Malaysia.

Chapter 6
Soil Microfungi of Israeli Deserts: Adaptations to Environmental Stress

Isabella Grishkan

6.1 Introduction

It is now well established that the development and functioning of soil microbial communities are strongly affected by environmental factors at different geographic scales (Caruso et al. 2011; Fierer et al. 2009; Makhalanyane et al. 2015). For that reason, diversity and distribution of soil fungi in stressful habitats is an important topic to study because it can shed light on the mechanisms of survival and adaptation of microorganisms in extreme environmental conditions. Deserts represent such stressful habitats where severe climate and limited resources greatly influence biota formation (Sterflinger et al. 2012).

Numerous mycological studies have been conducted in desert soils all over the world (Abdullah et al. 1986; Bates et al. 2012; Ciccarone and Rambelli 1998; Conley et al. 2006; Grishkan and Nevo 2010a; Halwagy et al. 1982; Mouchacca 1993; Mulder and El-Hendawy 1999; Ranzoni 1968; Romero-Olivares et al. 2013; Zhang et al. 2016). It has been shown that both taxonomic and functional diversities of soil fungi in the arid zone are highly dependent on water availability, temperature regime, and organic matter content (Zak 2005 and references therein). Because of high spatiotemporal heterogeneity in resource availability, fungal species richness in the desert soils may be greater than expected based solely on consideration of abiotic conditions (Wicklow 1981; Zak et al. 1995).

Deserts cover more than 60% of Israeli territory (Atlas of Israel 1985). Such massive distribution of the desert area in the country offers an excellent opportunity to study soil fungi and their adaptive strategies on a broad environmental scale: from the semiarid to extremely arid regions, with annual rainfall ranging from 300 mm to 25 mm, respectively. The gradient also covers a range of altitude and

vegetation diversity, and such combinations of different climatic, microclimatic, and edaphic factors can principally govern the structure of soil microfungal communities (Grishkan and Nevo 2010b).

6.2 Site Description and Edaphic Characteristics

Our most comprehensive studies devoted to desert soil mycobiota were conducted in three regions of the Negev Desert—Nahal (Wadi) Shaharut (southern Negev), Makhtesh Ramon (central Negev), and Wadi Nizzana (western Negev)—as well as along the altitudinal and latitudinal gradients of the Arava Valley (Fig. 6.1).

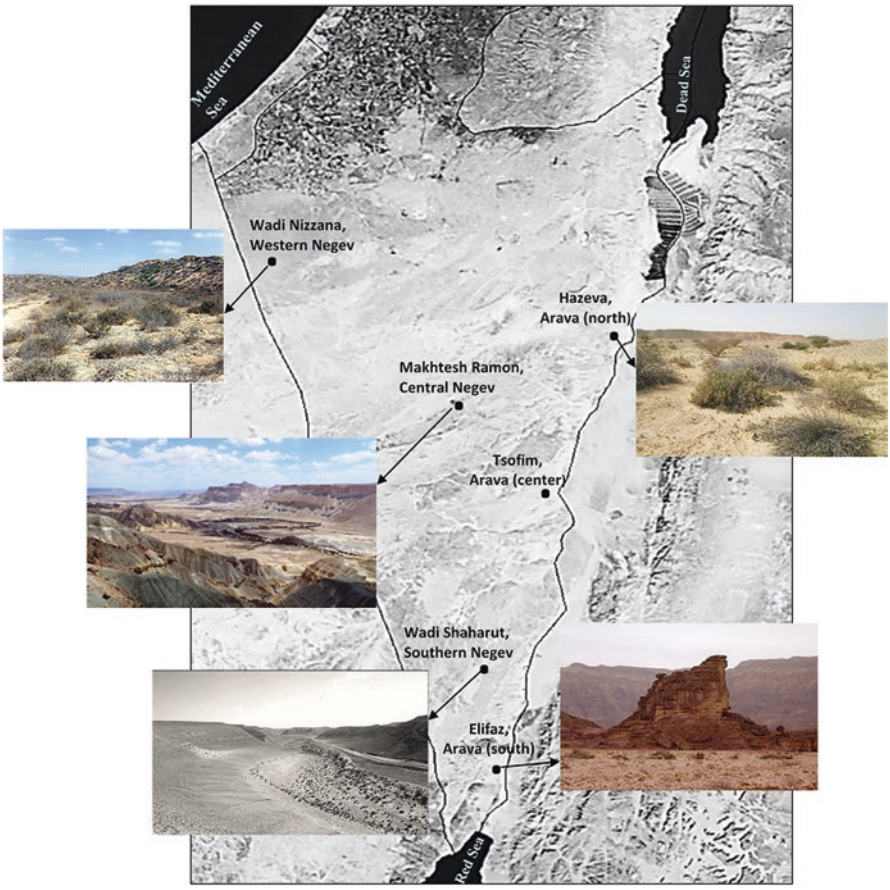

Fig. 6.1 Map of the southern part of Israel showing the locations of study sites at the Negev Desert and the Arava Valley

The main Israeli desert, Negev, occupies at least 55% of the country at its southern part. The world "*negev*" means "dryness" in the original Hebrew connoting also "south" (Hillel 1982). In the arid regions of the Negev, annual rainfall ranges from more than 200 mm in the north of the central part to about 30 mm in the extreme south (Bitan and Rubin 1991). The distribution of rainfall within the rainy season (November–April) is highly irregular with wide fluctuations from year to year. Most of the Negev area consists of marine sedimentary rocks, mainly limestones and chalks. The landscape is represented by rocky hills and mountains, wadis, plateaus, coarse sediments, and sands. The typical soil of the Negev is loess—a buff-colored, fine-granulated, wind-borne shallow deposit of desert dust (Singer 2007).

Wadi Shaharut is located in the extremely arid region of southern Negev, with an average annual rainfall less than 40 mm (Bitan and Rubin 1991). The mean daily temperature of the coldest month (January) is 9–11 °C and of the warmest months (July–August) is 36–38 °C. The wadi has two opposite slopes—south facing (SFS, dips about 35°) and north facing (NFS, dips about 30°)—separated by about 150 m at the valley bottom (VB). The slopes consist of limestone and are characterized by various sediments, mainly stony debris (Dan et al. 1976). Very sparse dwarf shrubs (*Zygophyllum dumosum* and *Reaumuria hirtella*) cover the middle and upper parts of the NFS. In the VB, occupied by coarse desert alluvium soil, sparse shrub vegetation is accompanied by *Tamarix* sp. trees.

Makhtesh Ramon (MR) is a unique geological feature located at the southern boundary of the Negev Highlands. This landform is the world's largest erosion cirque or makhtesh (the Hebrew word for "mortar" or "crater") (Garfunkel 1978). The cirque is 40 km long and 2–10 km wide and is extended in north-eastern–south-western direction, with rims about 900–1000 m above sea level. The climate in the region is extremely arid, with only sporadic rainfall from 85 mm per year on the northern rim to 56 mm per year in the central cirque (Ward et al. 2000). The mean temperatures of the coldest month (January) and warmest month (July) are 8–13 °C and 24–31 °C, respectively (Atlas of Israel 1985). Desert lithosols on sandstone, hard limestone, and chalk are characteristic of the area (Dan et al. 1976); on the north-facing slope of the cirque southern rim (NFS), the sand is enriched by ferric and manganese compounds giving the surface a reddish-brown tincture.

The MR area is considered a transition from the Irano-Turanian phytogeographic region (steppe vegetation) in the north to the Saharo-Arabian region (true desert) in the south (Zohary 1962). Adjacent to the northern part of the cirque steppe zone is covered mainly by the dwarf shrub *Artemisia herba-alba*. The outside southern south exposed desert zone is occupied by sparse shrub vegetation (mainly *Z. dumosum*, *Capparis aegyptia*, and *Haloxylon persicum*) with occasional *Tamarix* trees. A south-facing slope of the northern rim of the cirque (SFS) is covered by very sparse *Z. dumosum* and the geophyte *Bellevalia desertorum*. On the NFS, vegetation is entirely absent.

Wadi Nizzana is located within the Hallamish dune field at western Negev. Long-term mean annual precipitation is about 95 mm, and annual potential evaporation is ~2600 mm (Evenari 1981). The mean temperatures are near 27 °C during the hottest month of July and 12 °C during the coldest month of January (Rosenan and Gilad

1985).Most of the dunes have a mobile crest covered by very sparse vegetation (<5%). The lower flanks of the dunes and the sandy interdunes have 10–20% vegetation cover (Kadmon and Leschner 1994) and are almost entirely covered by biological soil crusts (BSC) represented by four types of cyanobacterial crusts and one type of moss-dominated crust. Significant differences characterized their species composition, biochemical and physical parameters, and wetness duration (Kidron et al. 2010). Within the interdunes, fine-grained flat patches (usually less than 50 × 50 m) are scattered. These sediments, known as playas, are comprised of high (50–80%) amounts of fines (silt and clay), which leads to low porosity (Blume et al. 1995), and therefore to low water infiltration, promoting runoff generation (e.g., Kidron and Vonshak 2012). Because of low infiltration, the playa surfaces experienced high evaporation rates which results, in turn, in an almost absolute absence of plants and in high accumulation of salts at a relatively low depth of >10 cm (Blume et al. 1995; Yu and Steinberger 2012). The playa surfaces mostly lack BSC (Kidron and Vonshak 2012), and only ~20–25% of the surfaces which have slightly concave contours and therefore receive lower amounts of runoff are covered by 0.5-cm-thick crusts.

Another Israeli desert, Arava, is located in the southeastern part of the country and belongs to the longitudinal Syrian-African Rift Valley. This desert, which is more than 160 km in length, extends from the Dead Sea in the north to the Gulf of Eilat (Gulf of Aqaba) in the south. The elevation of the valley varies from about 400 m below sea level at the Dead Sea area to 210 m a.s.l. in the region of Arvat Yafruq, in the center of the valley, and then decreases southward to sea level at Eilat (the Red Sea) (Goldreich and Karni 2001). The climate of the Arava region is defined as hyperarid (Goldreich and Karni 2001), with an annual precipitation of 15–50 mm (Ginat et al. 2011). Mean annual maximal temperature during the hottest month of July is 39.5 °C, and mean annual minimal temperatures during the coldest month of January are 7.8 °C and 13.6 °C in Sapir (near the center of the valley) and Sedom (near the Dead Sea), respectively (Goldreich and Karni 2001). Annual potential evaporation is ~3200 mm. The major part of the Arava Valley floor consists of stony coarse alluvial soil, mainly on gypseous chalk formations (Singer 2007). The very sparse vegetation of the Arava Valley is represented by dwarf shrubs such as *Nitraria retusa, Traganum nudatum, Haloxylon salicornicum, Anabasis articulata*, and *Z. dumosum* accompanied by rare *Acacia* trees (Danin 1983).

Some edaphic parameters of the studied soils in the central, southern Negev, and the Arava Valley are presented in Table 6.1. They provide insight into hostility and stressfulness of these desert environments for living organisms as a whole and fungi in particular. In the majority of localities, gravimetric moisture content was very low even in winter; in Wadi Shaharut, the driest periods were found not only in the summer, but also in the winter, due to strong windy weather. Summer temperatures in the uppermost soil layers (0–1 cm) of the open sun-exposed localities during the afternoon hours exceeded 50 °C. The soils in the studied areas are slightly alkaline, with pH in most cases lower in shrubby as compared to open localities and with opposite variations in low organic matter content.

Table 6.1 Selected edaphic parameters (mean ± SD) in different sites of the Negev Desert and Arava Valley

In the crusted sandy profiles at Wadi Nizzana, alkaline pH gradually increased with depth, while at the playa, it gradually decreased through the profiles (Table 6.2). Contrarily to the sandy habitats, substantial increase with depth in the values of electric conductivity characterized the playa profiles attesting for high salinity and limited water infiltration. As for organic matter content (OM), except for the sandy BSC, all other values were very low, less than 0.3%. Notably, a small peak of OM was registered at 10–20 cm of the sandy sediments which is probably a result of root concentration (mainly of annuals) at this depth. Even following medium rain events

(20 mm), water infiltration at non-crusted and crusted playa formations was limited to the upper 20 cm and 30 cm, respectively, whereas in all sandy habitats it reached >30 cm (Grishkan and Kidron 2016).

6.3 Sampling Design and Methodology

In the studied desert areas, the sampling was designed in order to cover maximal regional, local, and seasonal environmental variability. At Wadi Shaharut, the Makhtesh Ramon area, and along the Arava Valley, soil samples were collected from the upper soil layers of 0–2 cm from sun-exposed bare open localities and wherever it was possible—under the nearby shrub canopies. Six samples were taken from each locality at each sampling area during summer and winter; at Wadi Shaharut, samples were taken in each of four seasons.

At Wadi Nizzana, we aimed to study the vertical distribution of microfungal communities through depth in two different soil formations—crusted sandy dunes and playas. Samples were collected in summer in soil profiles from the layers of 0–0.2, 0.2–1, 1–5, 5–10, 10–20, 20–30, 30–40, and 40–50 cm. Four samples, 5 m apart, were taken in each sandy crust type (cyanobacterial and moss-dominated) and the playa (non-crusted and crusted) from each layer.

Soil microfungi were isolated using the soil dilution plate method (Davet and Rouxel 2000). This method, in spite of certain limitations and biases (e.g., Jeewon and Hyde 2007), "is simple and rapid, gives reasonable results, and yields excellent comparative data" (Bills et al. 2004, pp. 284–285), and remains a useful approach in studying the ecology of fungal communities (e.g., Schmit and Lodge 2005).

In the course of the studies, the following characteristics of microfungal communities were examined: (a) general species composition; (b) contribution of major groupings with different life-history strategies, such as mesic *Penicillium* spp., thermotolerant *Aspergillus* spp. and teleomorphic Ascomycota (producing morphologically expressed sexual fruit bodies), and xeric melanin-containing microfungi, to community structure; (c) dominant groups of species in different localities; (d) diversity characteristics—species richness, heterogeneity, and evenness; (e) quantitative parameter—density of microfungal isolates; and (f) the influence of main edaphic factors (soil moisture, temperature, pH, and organic matter content) on microfungal community structure and diversity level. Detailed descriptions of the isolation and identification procedure and data analyses are given in the corresponding articles (Grishkan et al. 2007; Grishkan and Nevo 2010a; Grishkan and Kidron 2016). Besides the analysis of culturable soil mycobiota in the Israeli deserts at community level, this chapter also contains information on the genetic structure of the populations of an ascomycetous fungus, *Aspergillus nidulans* in the soil of Wadi Shaharut (southern Negev) (Hosid et al. 2010a, b).

6.4 Composition and Structure of Mycobiota

The soils of Israeli deserts are inhabited by comparatively rich diversity of culturable microfungi—more than 420 identified species representing 135 genera. The data showed once again that, in spite of climatic hostility, desert soils which are characterized by high spatiotemporal heterogeneity in resource availability can maintain diverse microfungal biota (Wicklow 1981; Zak et al. 1995). An analogous pattern was found along the precipitation gradient in Israel for another group of soil microorganisms, bacteria, which the overall taxonomic diversity at the species level in the arid site was high and similar to that found in the humid Mediterranean, Mediterranean, and semiarid sites (Tripathi et al. 2017). The following features characterized the structure of microfungal communities in the soil of Israeli deserts.

6.4.1 Dominance of Melanin-Containing Fungi

Expectedly, melanin-containing species dominated the majority of topsoil microfungal communities in the studied desert regions (Fig. 6.2). These species are well-known stress-tolerant microorganisms resistant to solar and UV radiation, high temperature, desiccation, oligotrophic conditions, and chemical and radioactive pollution (Grishkan 2010 and references therein). A dominance of dark-colored microfungi was found in almost all mycologically studied desert soils (e.g., Abdullah et al. 1986; Christensen 1981; Ciccarone and Rambelli 1998; Grishkan et al. 2015; Halwagy et al. 1982; Mulder and El-Hendawy 1999; Ranzoni 1968; Zak 2005).

Importantly, composition of this dominant group in different localities was heterogeneous. Melanin-containing fungi with large thick-walled and multicellular conidia dominated communities in the most microclimatically and edaphically stressful localities of the MR area (Fig. 6.2a), significantly increasing their contribution in the most climatically stressful summer season, and overwhelmingly prevailed in all localities and in all seasons at Wadi Shaharut, southern Negev (Fig. 6.2b). These species were mainly represented by *Alternaria atra, A. alternata*, and *A. phragmospora*, accompanied by *A. chlamydospora* (Wadi Shaharut) and *Monodyctis fluctuata* (the Arava Valley) (Fig. 6.2). Such species (from the genera *Alternaria* and *Ulocladium*) were the most widespread in the soils of the Atacama Desert, which is known as one of the driest locations on Earth (Conley et al. 2006). Likewise, these fungi, belonging to the order Pleosporales, were found to predominate in the biological soil crusts studied by the culture-independent molecular approaches at the Colorado Plateau, in the semiarid grassland in central New Mexico, and in the southwestern deserts of the USA (Bates et al. 2010, 2012; Porras-Alfaro et al. 2011) as well as in the crusted sand of the Tengger Desert, China (Zhang et al. 2016).

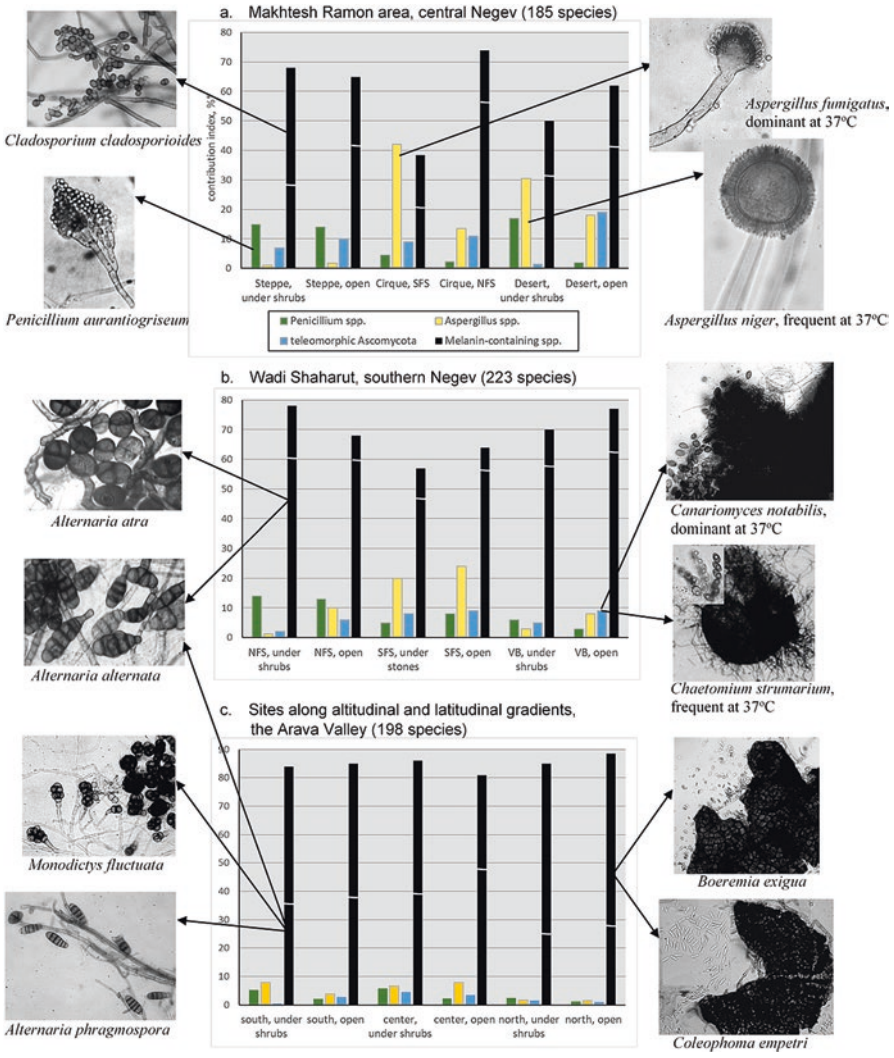

Fig. 6.2 Contribution of main microfungal groupings to local communities in the soil of different sites of the Negev Desert and the Arava Valley, Israel (the area below the white line on the bars of melanin-containing fungi indicates contributions of species with large multicellular spores)

The multicellular spore morphology should be considered an important adaptive feature of desert soil mycobiota and is similar to one of the survival adaptations of annual plants in the desert. Gutterman (2002) reported on two main adaptive strategies in seed dispersal of desert annuals: mass production of tiny dustlike seeds (escape strategy) and production of relatively large lignified seeds in smaller numbers (protection strategy). The main core of soil microfungi in most Negev and Arava localities follows the protection adaptive strategy possessing an ability to

successfully survive under extreme temperatures, drought, and UV radiation. In nature, isolated species with dark, many-celled conidia also inhabit stressful and highly fluctuable plant surface (Ellis 1971, 1976; Ellis and Ellis 1997). In laboratory conditions, Durrell and Shields (1960) showed that the survival time of thick-walled multicellular conidia of *Stemphylium ilicis* under the same irradiation was 30-fold longer than for thin-walled one-celled conidia of *Aspergillus niger.* Thus, dark-colored, many-celled conidia carry out both dispersal and resting functions, which are vital in climatically and microclimatically stressful desert habitats.

By contrary, in the shrub localities of the Makhtesh Ramon area (central Negev), species with one-celled conidia prevailed (such as *Cladosporium cladosporioides* in the steppe communities) (Fig. 6.2a). Similar prevalence of dark-colored species with comparatively small one-celled conidia was characteristic of the SFS open localities of the northern Wadi Keziv, Upper Galilei (Grishkan et al. 2003a).

In the soils of Arava Valley, another group of melanin-containing species frequently and abundantly occurred. These species—*Boeremia exigua, Coleophoma empetri*, and *Phoma medicaginis*—produce comparatively small (5–15-μm-long) light-colored conidia inside the dense multilayered picnidial fruit bodies (Fig. 6.2c). Similar to the melanized fungi with large many-celled spores, these picnidial fungi are known also as phylloplane-inhabiting species (Ellis and Ellis 1997; Sutton 1980), and thick-walled dark-brown or black spherical fruit bodies provide them with protection against extremely stressful and highly fluctuating environmental conditions.

Picnidial species significantly increased their contribution at the northern part of the Arava Valley located at 190 m below sea level. The increase in abundance of picnidial fungi in the soil of this area is apparently caused by the weakening of abiotic stress (decrease in the level of UV radiation) and the consequential weakening in the competition with melanin-containing species with large many-celled spores dominating the microfungal communities in proximate areas. A similar prevalence of other dark-colored microfungi with small one-celled conidia, *A. niger* and *C. cladosporioides*, was characteristic of the sand of the hypersaline Dead Sea shore (Grishkan et al. 2003b)—an extremely stressful environment but receiving very low UV radiation because of its location at more than 400 m below sea level.

Notably, in soil profiles of Wadi Nizzana (western Negev), melanized fungi with large multicellular conidia prevailing at the uppermost layers in both the crusted sandy and playa habitats substantially contributed also to the communities at 10–50 cm of the non-crusted playa profiles, as well as in the deepest layers of the crusted playa profiles (Fig. 6.3). It indicates that melanin which is known to protect fungal cells from various kinds of stresses, together with many-celled spore morphology, can help microfungal species also to survive, although in very low amounts, under severe stress of strongly limited aeration and high salinity characteristic of playa formations.

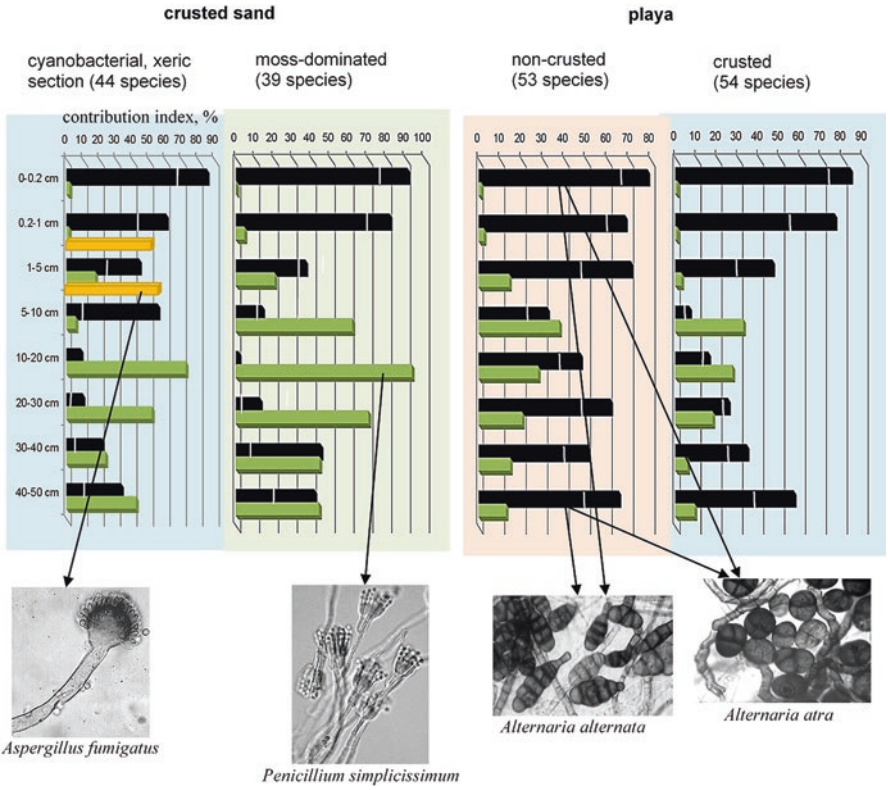

Fig. 6.3 Vertical dynamics of contribution of main microfungal groupings to communities in different sandy and playa profiles at Wadi Nizzana, western Negev (melanin-containing species, *Penicillium* spp., *Aspergillus* spp.; the area left from the white line on the bars of melanin-containing species indicates contribution of species with large multicellular spores)

6.4.2 *Different Distributional Patterns of* Aspergillus *and* Penicillium

According to the number of species, *Penicillium* and *Aspergillus* are the richest genera in Mycota—354 species (Visagie et al. 2014) and 339 species (Samson et al. 2014), correspondingly. They are also known as two main soil genera (e.g., Domsch et al. 2007) and were numerously represented in the soil of Israeli deserts—43 and 39 species of penicillii and aspergilli, respectively. *Penicillium* and *Aspergillus* are taxonomic relatives belonging to the same family—Trichocomaceae—but they display different, even opposite, life-history strategies and geographical trends: mesophilic *Penicillium* is characteristic of cool-temperate mycobiotas, while *Aspergillus*, consisting of many thermotolerant and thermophilic and osmotolerant and osmophilic species, is more widely distributed in warm xeric regions (e.g., Christensen 1981; Klich 2002; Domsch et al. 2007). Likewise, in the soil of Israeli deserts, these

genera displayed opposite spatial and seasonal distributional tendencies. *Penicillium* spp. formed a minor group in all topsoil communities studied being remarkably more abundant in the soil under shrubs and correlating significantly and positively with moisture and organic matter content in the Negev localities, whereas for *Aspergillus* spp. these correlations were reverse (Grishkan et al. 2007; Grishkan and Nevo 2010a).

Importantly, aspergilli composed the basic core of thermotolerant mycobiota isolated at 37 °C in all localities and seasons. Thermotolerant communities were dominated by *A. fumigatus*; *A. niger* was the second most abundant *Aspergillus* species prevailing in the winter thermotolerant communities at Wadi Shaharut (Grishkan 2018). *A. fumigatus* is known as one of the most frequent and abundant thermotolerant species in a variety of desert regions (e.g., Abdullah et al. 1986; Bokhary 1998; Christensen 1981; Halwagy et al. 1982; Mouchacca 1993; Oliveira et al. 2013; Powell et al. 2012; Ranzoni 1968). This species also dominated microfungal communities isolated at 45 °C from the soil of the Arava Valley. Moreover, *A. fumigatus* overwhelmingly prevailed in the mesophilic communities of the extremely hot sun-exposed SFS localities in Makhtesh Ramon (summer and winter) and Wadi Shaharut (only summer) (Fig. 6.2).

A different picture was observed in the depth-wise distribution of the two main soil genera at Wadi Nizzana (Grishkan and Kidron 2016). *A. fumigatus* prevailed only at 1–10 cm depth of the most xeric section of the cyanobacterial crusts, while the middle layers of all studied sandy crust profiles (10–20 cm) harbored microfungal communities overwhelmingly dominated by one or two *Penicillium* species (Fig. 6.3). The increase in abundance of penicillii might be associated with the penetration of massively produced very small fungal spores during water infiltration and their deposition mainly at 10–20 cm depth. It is likely that at these depths, mesic penicillii met the appropriate abiotic conditions (lower temperatures, a small increase in organic matter content) for successful survival and competition with the stress-selected melanized microfungi prevailing in the topsoil communities.

6.4.3 Sexual Reproduction as an Adaptive Strategy of Desert Mycobiota

In the soils of Israeli deserts, ascomycetes with morphologically expressed sexual stage comprised the one fourth of the species. A significant part of teleomorphic Ascomycota belonged to the genus *Chaetomium*—28 species. This genus is known as cellulolytic (e.g., Domsch et al. 2007), but is also considered characteristic of desert soils (Christensen 1981) and was abundantly recorded in the Dead Sea coastal sand (11 species, Grishkan et al. 2003b). Our study on the relationship between ecological stress and sex evolution in soil microfungi (Grishkan et al. 2003c) showed a highly significant increase in the proportion of sexuals in mycobiota with an increasing salinity/aridity stress southward in Israel. This trend was explained by

the high adaptive plasticity of perfect fungi in a highly stressful environment, which is associated with sexual reproduction. Importantly, most of the isolated ascomycetes had thick-walled, dark brown or black perithecia, and almost all of them also produced large (10 μ and more) dark-colored ascospores, thus displaying morphological adaptations to stressful environmental conditions. Among the surveyed sites, the proportion of teleomorphic ascomycetes climaxed in the highly stressful Dead Sea coastal area (33% species, 18.5% isolates—Grishkan et al. 2003b). In the desert soils, the contribution of sexual species was less significant, but together with aspergilli, they formed the main part of the thermotolerant mycobiota—54 teleomorphic species were isolated at 37 °C, and 35 of them only at 37 °C. Apparently, melanin-containing species with protective many-celled spore morphology that dominated mesophilic microfungal communities cannot develop at high temperatures because none of their isolates were grown in the laboratory at 37 °C. At the same time, thermotolerant teleomorphic species led by *Canariomyces notabilis*, *Chaetomium strumarium*, and *Ch. nigricolor* could not only survive but also germinate and be active during a long period of high temperatures in deserts.

6.5 Density of Isolates as a Quantitative Characteristic of Microfungal Communities

Expectedly, the density of microfungal isolates (expressed in colony-forming units—CFU—per gram of dry soil) in all studied locations exposed a highly significant positive correlation with organic matter content displaying maximum values in shrub localities (Fig. 6.4a–c). Seasonally, summer was the least abundant season on microfungal density, except in the NFS locality in Makhtesh Ramon and the open SFS locality in Wadi Shaharut. In these most edaphically stressful environments, the summer increase in CFU number was caused by a more abundant development of xeric melanin-containing *Alternaria* species (Makhtesh Ramon) or thermotolerant *A. fumigatus* (Wadi Shaharut), which comprised, respectively, more than 70% and nearly 45% of all isolates obtained from these localities in this season.

In soil profiles at Wadi Nizzana, density of microfungal isolates abruptly decreased with depth (Fig. 6.4d). Similar reduction in fungal biomass was also found in other parts of the world (e.g., Bissett and Parkinson 1979; Rodriquez et al. 1990; Pandey et al. 1991; Fierer et al. 2003) and was attributed mainly to the depth-wise decline in carbon availability and diminishing aeration. Obviously, a sharp decline in isolate density which expressed a highly positive linear relationship with organic matter (OM) content was expected at the boundary between the OM-enriched crust and the underlying sandy soil. At the playa, the decline in the CFU numbers was apparently associated with the reduction in water availability, as found during periodical moisture measurements.

Depth-wise decrease in isolate density was much more remarkably expressed in the playa soils (and especially in the non-crusted playa) than in the sandy profiles. Likewise, the CO_2 evolution rate and microbial biomass were lower in the playa

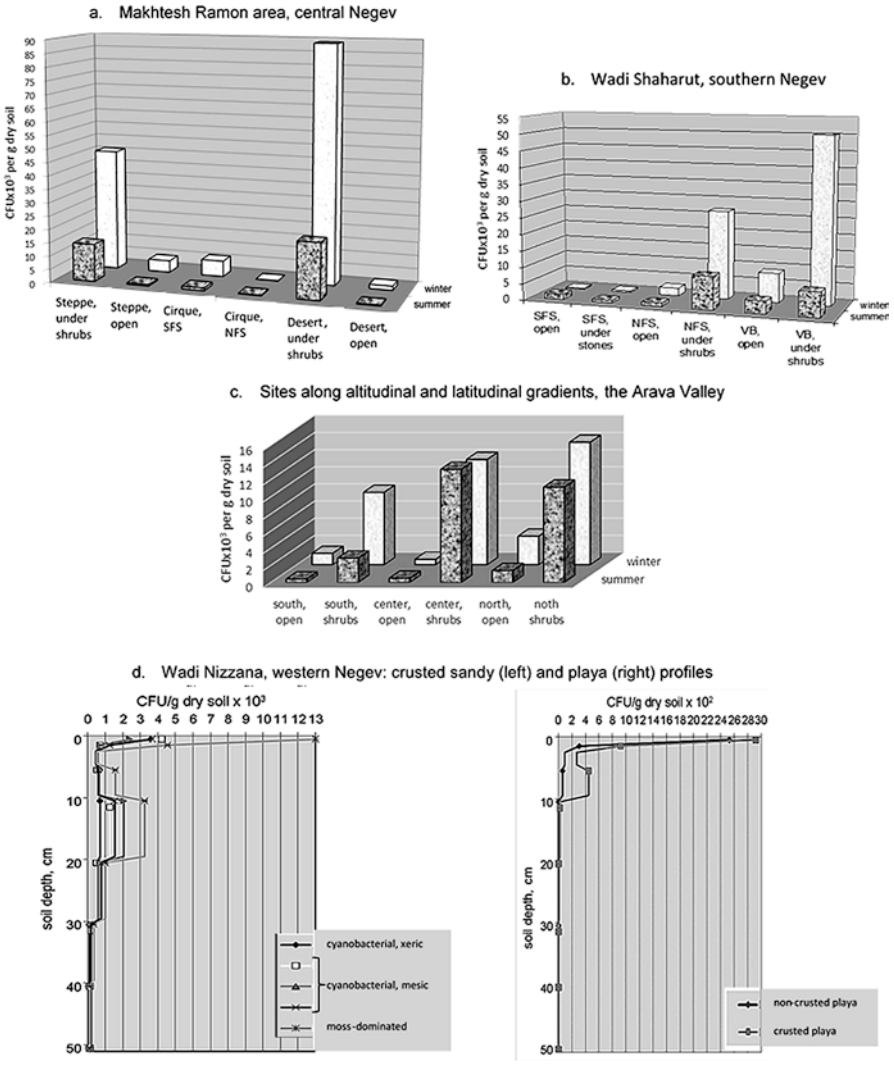

Fig. 6.4 Spatial and seasonal dynamics of density of microfungal isolates (in CFU—colony-forming units) in the soil of different localities at the Negev Desert and the Arava Valley

(Yu and Steinberger 2012). Apparently, diminishing water infiltration and aeration as well as high salt accumulation in the playa soil create harsh environmental conditions for survival and development of fungi as well as for their passive migration by water (Trevors et al. 1990; Breitenbeck et al. 1988; Abu-Ashour et al. 1994). This may explain the fact that the crusted playa profiles, which occupy slightly convex surfaces and therefore facilitate deeper infiltration, harbor 1.5-fold more microfungal isolates at the 5–10-cm layer than the non-crusted playa habitats at the 0.2–1-cm layer (Fig. 6.4d).

Density of microfungal isolates is considered a non-reliable quantitative characteristic because of the impossibility to distinguish between colonies arising from either active mycelium or resting spores (Parkinson 1994). However, sharp spatial and seasonal differences in isolate densities revealed in the studied desert soils cannot be simply ignored. These differences may indirectly indicate significant variations in fungal biomass associated with spatiotemporal variability of edaphic and microclimatic conditions.

6.6 Effect of Different Environmental Aspects on the Characteristics of Microfungal Communities

The unique geographical position of the Arava Valley, with its northern part located below sea level, gave an opportunity to test the influence of different environmental aspects—locality position along altitudinal and latitudinal gradients, locality type (open and under shrubs), and season (summer and winter)—on the characteristics of microfungal communities. The analysis (Table 6.3) showed that locality type

Table 6.3 Data of two-way unbalanced ANOVA analysis (by XLSTAT, http://www.xlstat.com) for the effect of locality type, locality position, season, and interactions between them on different parameters of microfungal communities at Arava Valley

strongly influenced most measured parameters of microfungal communities followed by locality position along altitudinal and latitudinal gradients. The latter aspect highly significantly affected the abundance of melanin-containing fungi with large multicellular spores which lost their dominant position in the area located 190 m below sea level to the species with picnidial fruit bodies. Importantly, cluster analysis based on the relative abundance of species also revealed that, in the majority of cases, the communities from the same locality type (open or under shrubs) were more similar to each other than the communities from different localities at the same sampling area. A similar pattern was revealed in our study devoted to soil microfungi along the precipitation gradient in northern and central Negev (Grishkan et al. 2006). It indicated that, in most cases, the crusted and shrub localities, separated only by a few meters or less, differed in microfungal community structure much more significantly than crusted or shrub localities at a distance of tens of kilometers. This observation again confirms the fact that microclimatic and edaphic factors play an essential role in the development of soil microfungal communities, and their composition and structure can be a sensitive indicator of changing environmental conditions at a microscale.

6.7 Genetic Divergence and Mode of Reproduction in Populations of *Aspergillus nidulans* from the Soil of Wadi Shaharut, Southern Negev

Aspergillus nidulans is a fungus easily generating in culture with two morphologically distinct kinds of sporulation: sexual (teleomorphic state, producing ascospores) and asexual (anamorphic state, producing conidia). The genetic divergence of *A. nidulans* was studied on regional and local scales using 15 microsatellite (SSR) markers (Hosid et al. 2010a). Three populations of the fungus isolated from the soil of the northern Mediterranean and the desert canyons were found to be genetically distinct. The estimated genetic divergences corresponded to geographical distances and ecological differences between the canyons (Fig. 6.5). On a regional scale, SSR polymorphism tended to increase with severity of ecological conditions being maximal in the desert population of the fungus.

Testing the reproductive structure of the populations of *A. nidulans* indicated the presence of sexuality in the northern populations and predominant clonality in the desert population (Hosid et al. 2010b). The predominantly clonal character of the desert population of the fungus was explained by the assumption that for relevant multilocus systems of a fungus, only several haplotypes could survive in the rather constant, extremely stressful desert conditions. Additionally, the very low density of *A. nidulans* populations in the soil of Wadi Shaharut, which reduced the probability of finding a sexual partner, might favor predominant clonality via selfing.

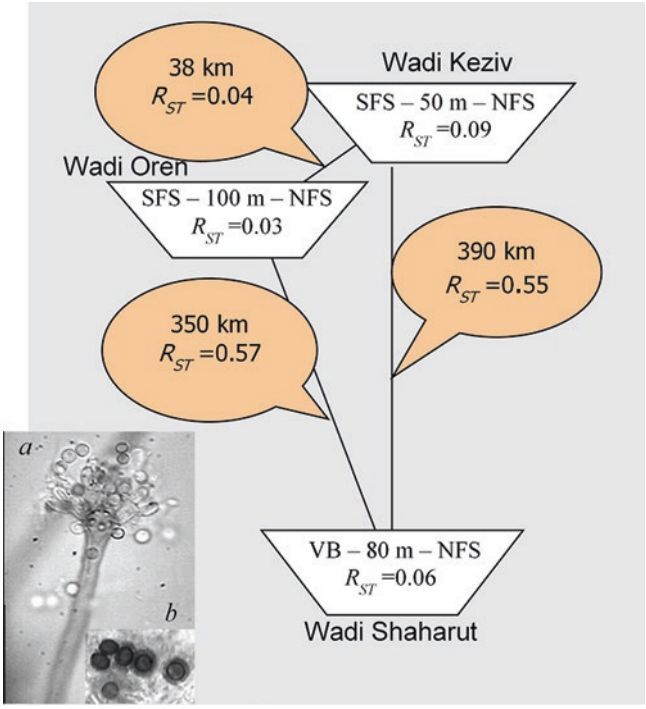

Fig. 6.5 Genetic distances between populations and subpopulations of *Aspergillus nidulans* (*a*, asexual conidial sporulation; *b*, sexual ascospores) from the northern Mediterranean (Wadi Oren and Wadi Keziv) and Israeli desert (Wadi Shaharut) regions (adopted from Hosid et al. 2010a)

6.8 Conclusion

This study showed that comparatively rich soil mycobiota of the Israeli deserts has developed under highly stressful climatic and edaphic conditions. The mycobiota displayed remarkable adaptive strategies to harsh desert stresses reflected in diverse phenotypic and biological traits: (a) melanin-containing fungi with large, thick-walled, and multicellular conidia dominated the majority of topsoil communities and lost their dominant position either to the species with picnidial fruit bodies in the less UV-radiated area located 190 m below sea level or to thermophilic *A. fumigatus* in the extremely hot localities (e.g., SFS of Makhtesh Ramon); (b) melanized species with protective spore morphology prevailed also in the deep layers of bare playa profiles characterized by high salinity and strongly limited water infiltration; (c) mesic *Penicillium* spp. dominated in the middle depths of sandy and playa profiles due to the ability of their abundantly produced small spores to penetrate during water infiltration; (d) aspergilli (mainly *A. fumigatus*) and teleomorphic perithecial ascomycetes comprised a basic part of thermotolerant mycobiota; (e) relatively small spatiotemporal variations characterized the structure of microfungal

communities in most hostile environments, but the density of microfungal isolates fluctuated drastically, with highly positive dependence on organic matter content; and (f) genetic structure and reproductive mode of the *A. nidulans* population from southern Negev were substantially distinct as compared to the northern Mediterranean populations of the fungus.

The conducted studies described only a culturable fraction of fungal communities in the soils of Israeli deserts, but nevertheless, this fraction is known to constitute a significant and essential part of soil mycobiota both taxonomically and functionally (see Domsch et al. 2007). We plan to continue our mycological investigations using culture-independent molecular approaches. It will substantially increase the magnitude of fungal diversity in the desert soils and enrich our knowledge about fungal adaptations and survival strategies in such extreme environment with highly severe climatic and microclimatic conditions and very limited availability of nutrient resources.

Chapter 7
Extremotolerant Black Fungi from Rocks and Lichens

Claudio Gennaro Ametrano, Lucia Muggia, and Martin Grube

7.1 Introduction

In contrast to the majority of fungi, which live more or less comfortably inside of hosts or substrates, some lineages have specialised to thrive on exposed surfaces. With little competition on nutrient-deprived conditions, such a stressful lifestyle also requires adaptations to fluctuations of hydration, among other challenges. Fungi in these situations also need to shield their cell content from excessive radiation using various kinds of pigments in their cell walls. The symbiotic thalli of lichen-forming fungi are one example on how to cope with conditions of exposed surfaces. Lichen-forming fungi develop diverse forms of characteristically compacted mycelial morphologies to filter light to sheltered photosynthetic algae. Another large group of fungi does not depend on symbiotic partners, but it is characterised by dark pigments, and unlike lichens, these fungi may tolerate much higher levels of air pollution. These 'black' fungi, as they are commonly called, are the focus of this chapter. We provide an overview of the current understanding of diversity and taxonomy of black fungi and review their phenotypic traits. As we previously recognised ecological and evolutionary links of black fungi with the lichen symbiosis, we also discuss first results from co-culture experiments of black fungi with algae. Finally, we also review first insights gained from -omics approaches.

The phenotypes of black fungi have evolved in different lineages of ascomycetes. Under the extremes of abiotic conditions, the typical morphology is usually restricted to vegetative mycelia with insufficient diagnostic characters for species

recognition. Hence it is practically impossible to identify the species directly in the environment or with a stereomicroscope. Diagnostic phenotypic characters are often expressed under controlled laboratory conditions, even though species commonly lack sexual structures. Analyses of DNA sequence data are the only way to prove the relationship of species with similar morphology and to place these fungi in a phylogenetic framework. Molecular approaches showed both that many lineages exist which have not been named so far while described taxa turned out to be polyphyletic (e.g. Ertz et al. 2014). DNA data are still of limited use to recognise species as little is known about the genetic variation within species, but they clearly showed that black fungi are phylogenetically more diverse than previously thought and that they primarily belong to two lineages of ascomycetes, the early diverging clades of Dothideomycetes and Eurotiomycetes in Ascomycota (Fig. 7.1).

7.2 Phylogenetic Relationships of Black Fungi Within Dothideomycetes and Eurotiomycetes

With more than 19,000 species, Dothideomycetes is the class with the largest number of species in Ascomycota (Kirk et al. 2008; Schoch et al. 2009a, b). Representatives of Dothideomycetes generally pursue a wide diversity of lifestyles, a diversity which is also scattered across many different clades (Egidi et al. 2014; Muggia et al. 2016). Within Dothideomycetes, the order Capnodiales is particularly rich in extremotolerant species. They comprise fungi isolated from rocks of Antarctic dry valleys (Onofri et al. 2007a, b, Selbmann et al. 2005; Egidi et al. 2014), high-altitude rocks of the Alps (Selbmann et al. 2014), hot deserts (Muggia et al. 2015) and black yeasts from marine salters (Gunde-Cimerman et al. 2000). Different lifestyles can be found even within genera. For example, the genus *Rachicladosporium* (Capnodiales) includes both rock inhabitants and plant pathogens (Egidi et al. 2014). The environmental versatility of closely related fungi suggests that they keep a shared set of traits, which facilitates adaption to new habitats. Ruibal et al. (2009) and Egidi et al. (2014) show that many of the rock-inhabiting fungi, isolated from both mild and extreme climates, are found in the family Teratosphaeriaceae (Capnodiales), such as *Friedmanniomyces endolithicus*, *Elasticomyces elasticus* and *Recurvomyces mirabilis*. While these species seem to be widespread extremotolerant fungi, *Cryomyces antarcticus* seems to be an endemic extremophile confined to Antarctica so far (Ruibal et al. 2009).

Black fungi in Eurotiomycetes are mainly found in the order Chaetothyriales (Gueidan et al. 2011). Chaetothyriales are mostly known as saprophytic and pathogenic fungi—with a wide variety of hosts (Geiser et al. 2006; Teixeira et al. 2017), but they also comprise a relevant number of species living on rocks (Sterflinger et al. 1999; Ruibal et al. 2005), for instance, species from the genera *Knufia*, *Bradymyces*, *Cladophialophora*, *Capronia* and *Strelitziana* (Ruibal et al. 2008; Réblová et al. 2016). It has been suggested that rock-inhabiting species in

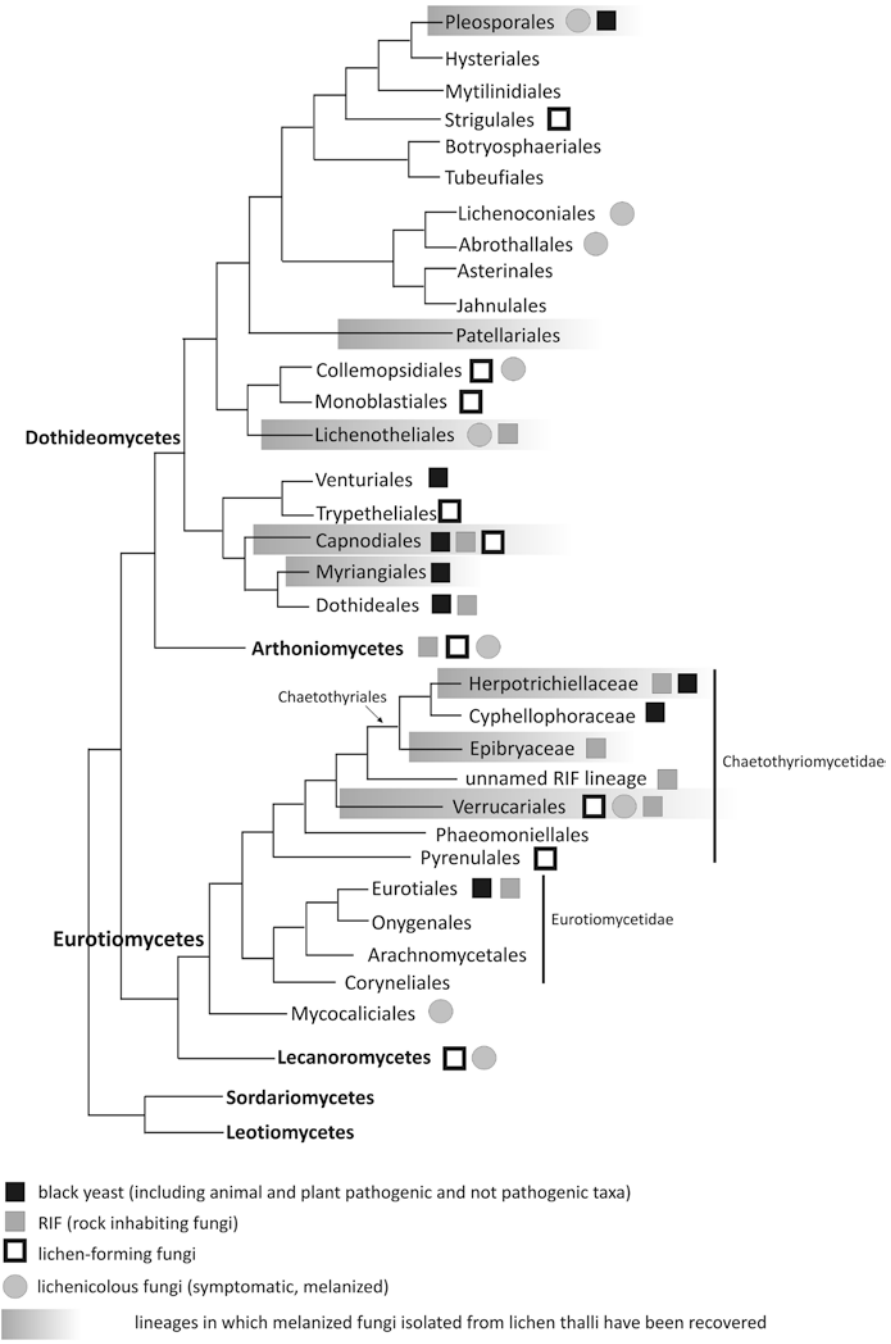

Fig. 7.1 Schematic representation of the major lineages in Dothideomycetes and Eurotiomycetes (Ascomycota) in which black fungi with different lifestyles are found. Lineages in which black fungi have been isolated from lichen thalli are shaded in grey. The phylogeny was graphically reconstructed merging information from most recent phylogenetic studies of Hyde et al. (2013), Gueidan et al. (2014), Chen et al. (2015), Liu et al. (2017) and Teixeira et al. (2017)

Eurotiomycetes are ancestral to present lineages of pathogenic and lichenised fungi in Chaetothyriales and Verrucariales (Gueidan et al. 2008), because they appear particularly diverse in early diverging lineages of these orders.

It is impossible to give a precise number of extremotolerant black fungi. As mentioned above, the characterisation of many black fungi suffers from ambiguous diagnostic characters and the lack of sexual reproductive forms (e.g. Crous et al. 2004; Muggia et al. 2008; Taylor 2011). Molecular phylogenetic studies alone cannot always resolve species delimitation problems of black fungi; thus authors considered the species as complexes containing (so far) cryptic species (Hyde et al. 2013; Egidi et al. 2014; Muggia et al. 2015). An integrative, or polyphasic, taxonomic approach is required to circumscribe closely related lineages. This has been demonstrated with the species complex of *Aureobasidium pullulans*, where a redefinition of its varieties by Zalar et al. (2008) initiated more detailed analyses that resulted in species descriptions for the former varieties (Gostinčar et al. 2014).

7.3 Important Features of Extremotolerant Fungi

7.3.1 Plasticity of Growth

The typical growth forms of polyextremotolerant black fungi and their ability to switch among them is a key adaptation to cope with stressful environmental conditions. Filamentous mycelia are able to explore the surrounding environment for nutrients. Substantially different mycelial organisations can be formed by the same strain on rock surfaces and on culture media. The hyphae of rock-inhabiting mycelia are often short celled, and mycelia may become compact to form microcolonies. These slow-growing forms may also build ‘skins’ and ‘shells’ made of extracellular matrix and minerals on the surface of the cell wall (Gorbushina 2007). Apparently, the compact shape of fungal microcolonies also protects black fungi against heat and desiccation, by optimising the volume/surface ratio, according to Gorbushina (2007). Moreover, colonial growth can form extensive biofilms, which are highly resistant to antifungals (Kirchhoff et al. 2017). Many species of black fungi, especially in Dothideales, can also switch between filamentous and yeast growth forms (pleomorphism) depending on the circumstances of the habitat. Transitions exist to completely budding forms, which are often called black yeasts. This ability is termed phenotypic plasticity, which has been recently studied in *Aureobasidium pullulans* by Slepecky and Starmer (2009). In addition, variation known as non-genetic heterogeneity exists between individual cells within genetically uniform mycelia, which grow under the same conditions. When single cells of black fungi become detached from the surface, they commonly develop budding forms (Staley et al. 1982; Gorbushina et al. 1993). Even neighbouring cells in a hyphal thread may differ in vitality according to microscopic analysis, and hyphal outgrowths may occasionally grow internally in neighbouring dead cells of the same hyphal segment

(Grube, unpublished observations). The non-genetic phenotypic heterogeneity results from differences in gene expression, which occur either stochastically or as a result from the relative position of cells in a mycelium (Hewitt et al. 2016). We think that this type of variation is a so far neglected factor of fungal adaptation to stressful environments.

7.3.2 Melanisation

A characteristic phenotypic trait of all black fungi is the presence of melanins in the cell walls. Melanins are a group of polymeric secondary compounds that have been interpreted as 'fungal armour' (Gómez and Nosanchuk 2003; Keller 2015), as they act as protective agents against a wide range of environmental stresses (Sterflinger 2006). The term 'melanins' indicates a black pigment of biological origin but provides little information about the chemical structure of the polymeric molecules. Melanins are produced by a wide range of organisms, including plants, animals and certain species of bacteria (Swan 1974). The polymer structures are still insufficiently characterised because the linkages among the precursors—as building blocks—and the composition are variable. Therefore, melanins are classified according to their precursors and biosynthetic pathways (Eisenman and Casadevall 2012). Eumelanins, the most common type of melanins, are produced during the oxidation of tyrosine (and/or phenylalanine) to 3,4-dihydroxyphenylalanine (DOPA) or dopaquinone which further undergoes cyclisation to 5,6-dihydroxyindole or 5,6-dihydroxyindole-2-carboxylic acid (Butler and Day 1998). Pheomelanins are initially synthesised like eumelanins, but DOPA undergoes cysteinylation into cysteinyl-dopa, which further polymerises into various derivatives of benzothiazines (Plonka and Grabacka 2006). Allomelanins, the least studied group of polymers, are produced through polymerisation of 1,8-dihydroxynaphthalene (DHN). In this pathway, the precursor molecule is acetyl-coenzyme A (acetyl-CoA) or malonyl-CoA. The first step, formation of 1,3,6,8-tetrahydroxynaphthalene, is catalysed by a polyketide synthase (PKS). Subsequently, a sequence of reactions produce the intermediary compounds scytalone, 1,3,8-trihydroxynaphthalene, vermelone and DHN, which is then polymerised to yield melanin (Butler and Day 1998; Langfelder et al. 2003; Plonka and Grabacka 2006). Most melanins characterised from ascomycetes are DHN-melanins (allomelanins) but DOPA-melanins (eumelanins) occur as well (Eisenman and Casadevall 2012); however the latter are more typical for basidiomycetes (Butler and Day 1998).

The best known function of melanins is to protect against UV radiation, which is of particular importance for the rock-inhabiting fungi thriving on bare rock surfaces in open environments. The melanins accumulate in the cell walls of spores and hyphae. Singaravelan et al. (2008) showed by in vitro experiments how physiological stress caused by UV radiation enhanced the synthesis of melanin as an adaptive response in *Aspergillus niger*. A significantly higher concentration of melanin was measured in the conidia, which positively correlated with their germination capacity.

Further, in the phytopathogenic fungus *Bipolaris oryzae* the expression of 1,3,8-trihydroxy-naphthalene reductase (THR1) gene—essential for DHN-melanin production—is transcriptionally enhanced by increased doses of UV radiation (Kihara et al. 2004). Melanins accomplish the same function also in basidiomycetes: the pathogenic black yeast *Cryptococcus neoformans* shows a lower susceptibility to UV light damages when the cells are protected by melanins (Wang and Casadevall 1994). Both DOPA and DHN-melanins are efficient protectors also against ionising radiation (Pacelli et al. 2017). The radioprotective properties of fungal melanins derive from a combination of physical shielding and free radical quenching (Dadachova et al. 2008). Ionising radiation alters the oxidative-reduction potential of melanins and is correlated with a faster growth rate in melanised fungi, suggesting that melanins might also function as energy traps (Dadachova et al. 2007; Dadachova and Casadevall 2008).

Melanins accumulate within the cell wall of black fungi as electron-dense granules, which contain various functional groups such as carboxyl, phenolic, hydroxyl and amine. These functional groups provide multiple binding sites for metal ions. The maximum binding capacity of fungal melanins decreases from copper to calcium, magnesium and zinc, respectively (Fogarty and Tobin 1996). Binding mechanisms of fungal melanins have been studied mostly for Cu, which binds mainly at a phenolic hydroxyl group and at a carboxyl group, as in humic acids (Fogarty and Tobin 1996). Though fungal melanins can bind Cu, they show a higher affinity for Fe, if both ions are co-present in a solution: in this case Fe is able to partially substitute Cu (Senesi et al. 1987). The high affinity of fungal melanins to Fe and Cu has also been demonstrated in the lower, melanised cortex of parmelioid lichens and in the melanised apothecia of the lichen *Trapelia involuta*, respectively (Fortuna et al. 2017; McLean et al. 1998). The capacity of melanins to bind ions becomes biologically relevant especially when toxic metal ions are abundant in the environment around the fungal cells: when bound, their decreased concentration allows the fungi to grow also in contaminated environments. Moreover, binding and exposition of cations on the hyphal surface can protect fungi from antagonistic microbes, either reducing the availability of microelements or interfering with the activity of hydrolytic enzymes (Fogarty and Tobin 1996).

Though essential to aerobic life, high electronegativity renders oxygen (O_2) one of the most reactive elements on Earth. During its reduction to water, reactive oxygen species (ROS) are generated as by-products and cause oxidative stress (Turrens 2003). Also other abiotic stresses, such as desiccation, freezing, heavy metals and other xenobiotic compounds, are likely to induce oxidative stress in fungi (Jamieson 1998; Lushchak 2011). ROS (e.g. superoxide radical, hydrogen peroxide and hydroxyl radical) cause severe cell damage, and living organisms have developed both enzymatic and non-enzymatic defence mechanisms. In fungi (both basidiomycetes and ascomycetes), melanins have a relevant redox buffer function and act as non-enzymatic defences against oxidative stress, as known for example in *Inonotus obliquus*, *Phellinus robustus*, *Aspergillus carbonarius*, *Paecilomyces variotii* (Shcherba et al. 2000), *Cryptococcus neoformans* (Jacobson and Tinnell 1993),

Exophiala dermatitidis, *Alternaria alternata* (Jacobson et al. 1995) and *Aspergillus nidulans* (Goncalves and Pombeiro-Sponchiado 2005). The redox buffering capacity of melanins has been studied mostly in pathogenic fungi identifying melanin as a virulence factor, as one of the most common reaction to pathogens is the production of ROS by leukocytes. Moreover, in pathogenic black fungi melanins have also been claimed to generate appressorium turgor, which is essential to penetrate animal/plant tissues (Sterflinger 2006).

Melanins seem also to confer resistance to osmotic stresses, and fungi isolated on saline media are almost exclusively melanised (Gunde-Cimerman et al. 2000). In this context, the action mechanism of melanins has not been fully elucidated, though Plemenitaš et al. (2008) hypothesised that the dense, shieldlike layer of melanin granules accumulated in the cell wall may reduce loss of osmoprotective substances during salt stress. Therefore, the reduction of cell permeability carried out by melanins would lead to an increased efficiency of the cells to counteract the osmotic stress.

7.3.3 Oligotrophy, Unusual Carbon Sources, Desiccation and Temperature Tolerance

On bare rock surfaces with limited nutrient resources and discontinuous presence of liquid water, fungi must be able to exploit a wide range of carbon sources deposited by dust, water or in the form of volatile organic compounds (VOCs; Prenafeta-Boldú et al. 2001, 2006). There have also been studies using C^{14}-labelled CO_2 and HCO_3^- (Mirocha and DeVay 1971; Palmer and Friedmann 1988), which suggest the capacity of some fungi and black fungi to directly fix carbon dioxide. Yet, these studies still need confirmation and additional work to find out the possible pathways of CO_2 incorporation. Lacking Calvin cycle metabolism, they would need to incorporate carbon via any other potential pathways of carbon uptake (Bar-Even et al. 2012). So far studies mostly focused on the spectrum of organic compounds efficiently usable by these fungi. For example, aerobic metabolism of a large spectrum of L and D forms of monosaccharides, disaccharides and alcohols has been investigated (Sterflinger 2006). Ethanol can be usually degraded, whereas the oxidation of methanol is rare; the use of meso-erythritol is also often reported and several rock-inhabiting fungi are even able to degrade simple and polycyclic aromatic hydrocarbons (Prenafeta-Boldu et al. 2006; Sterflinger 2006; Nai et al. 2013). *Knufia petricola* (Chaetothyriales, Eurotiomycetes), in particular, was proposed as a model organism for further analysis of the physiology of rock-inhabiting black fungi (Nai et al. 2013). This fungus indeed tolerates and grows on media containing monoaromatic compounds, confirming its capacity to utilise recalcitrant carbon sources eventually spurned by other microorganisms (Nai et al. 2013). Further, one of the most striking evidences that fungi are capable of exploiting unusual carbon sources is the black mould *Racodium cellare* (Dothideomycetes, Capnodiales).

Its metabolism seems to benefit volatiles released by wine barrels as carbon source and it is also able to grow using other VOCs (Tribe et al. 2006). Another black fungus associated with alcoholic vapours is *Baudoinia compniacensis*, which is frequently found near distilleries (Scott et al. 2007).

The ability to degrade aromatic compounds appears more typical for black fungi in Chaetothyriales, and in particular to the members of the family Herpotrichiellaceae. This family has been mainly studied for its role in human pathogenesis, but many species have been isolated from hydrocarbon-rich environments as well, such as soil contaminated by hydrocarbon, fuel tanks, washing machines, soap dispensers, indoor moist environments or rotten wood (Prenafeta-Boldu et al. 2006; Badali et al. 2011; Zalar et al. 2011; Isola et al. 2013). These and other recent works highlighted a possible connection between neurotropism (affinity of a pathogen for brain tissues) and the metabolism of aromatic hydrocarbons in the environment (Moreno et al. 2018a).

In this context, hydrocarbon assimilation may represent an additional virulence factor, as the brain contains monoaromatic catecholamine neurotransmitters (e.g. dopamine). Moreover, neurotransmitter catabolism compounds and other substances detected in the human brain are also found as products of lignin degradation (Prenafeta-Boldu et al. 2006). Because some pathogenic fungi have been isolated from environmental sources too, it has been hypothesised that hydrocarbon-rich environments could represent a possible pathogen reservoir. However, the environmental *Cladophialophora psammophila*, congeneric with the notorious human pathogen *C. bantiana*, lacks pathogenicity (Badali et al. 2011). Isola et al. (2013) confirm this finding with isolates of *Exophiala* species, where several pathogens and hydrocarbons associated with black fungi have been found mostly in ecologically divergent lineages of *E. xenobiotica*. With the shared adaptive traits of pathogens and extremotolerant or hydrocarbon-growing black fungi, reciprocal segregation in specific niches is not always complete. Opportunistic pathogens may still have the ability to grow outside the host, while some environmental strains could occasionally become pathogenic in immunocompromised hosts. *E. mesophila*, indeed, is the first reported clinical strain able to grow on alkylbenzenes as well (Blasi et al. 2016), and environmental *Fonsecaea erecta* is able to infect and survive in animal host tissue (Vicente et al. 2017). The ability to thrive in polluted environment and to use aliphatic and aromatic hydrocarbon as energy and carbon source in an otherwise extremely oligotrophic environment is of particular interest for the application in bioremediation of polluted environmental matrices and gas effluent biofilters (Kennes and Veiga 2004; Blasi et al. 2016).

Black fungi also share few other characteristics which make them surviving in extreme environments, including the capacity to suspend their metabolism for long periods until favourable conditions re-establish. The desiccation tolerance is enhanced by the accumulation of the disaccharide trehalose, which stabilises enzymes and cell membranes, avoiding degradation and breakage during dehydration phases (Sterflinger 2006). On the other hand, glycerol is the most abundant compatible solute produced by halotolerant black yeasts, such as *Hortaea*

werneckii, to compensate the loss of water from the cells in highly concentrated salt solutions (Plemenitaš et al. 2008). The desiccation tolerance is highly correlated with temperature tolerance. Dried fungal colonies are metabolically inactive and can survive temperature up to 120 °C (relatively common on bare rocks exposed to sun) for short time spans. Otherwise, temperatures between 35 and 75 °C are lethal for hydrated colonies (Sterflinger 1998). Rock fungi from cold environments usually produce also a high amount of extracellular polymeric substances (EPS) to increase their resistance against freeze-thaw damage (Selbmann et al. 2015). The best example of psychrophilic black fungi is *Cryomyces antarcticus*, isolated from rocks from Antarctic dry deserts, which shows a growth optimum below 15 °C and still has a detectable growth near 0 °C (Onofri et al. 2007a). Moreover, this fungus and other black fungi isolated from cryptoendolithic Antarctic communities are able to survive repeated freeze-thaw cycles, outstandingly frequent in Antarctic summer season.

7.4 Lifestyle Versatility of Black Fungi

The above-outlined traits of black fungi facilitated their adaptation in a wide range of niches. Many of them seem to be widespread environmental species, whereas certain lineages comprise specific clinical strains (de Hoog et al. 2013). Many strains are also recurrent endophytic components in plants, where they may symbiotically enhance thermal tolerance of their plant hosts (known as dark-septate endophytes; e.g. Rodriguez et al. 2008). Furthermore their thermal tolerance can facilitate their occurrence as opportunists and pathogens in warm-blooded animals (including humans, as well; de Hoog et al. 2000). In the case of many species of human black yeast pathogens, the pathogenicity seems to be mostly coincidental and suggests that the original niche lies outside the human host. These pathogenic black yeasts lack a specific mechanism to enter the host tissue, suggesting a low-level specialisation. Their pathogenic potential in the animal tissues is attributed to thermal tolerance, pleomorphic growth, melanisation of cell walls, and the ability to degrade complex carbohydrates. The ability to tolerate and degrade a range of toxic aromates may also explain why many black fungi are able to associate with ants (Vasse et al. 2018). In fact, Voglmayr et al. (2011) suggested that the basis for the tolerance factors of ant-associated black fungi could be traced back to the adaptation to the lichen habitat, which is discussed later.

However, the highest diversity of black fungi has been detected in rocky environments, and it has been speculated that these fungi represent the ancestors of those lineages of black fungi, which later evolved other lifestyles (Gueidan et al. 2011; de Hoog et al. 2013), including lichens. Black rock-inhabiting fungi are found in every climatic zone on a wide range of surfaces; they also tolerate polar latitudes and extreme altitudes (Onofri et al. 2007a, Gostinčar et al. 2012; Fig. 7.2). Furthermore they also colonise diverse artificial building materials including plastics

Fig. 7.2 Natural environments where black rock-inhabiting fungi co-occur with lichens: (**a**) Alpine habitat at high elevation (Mt. Rosa, Western Alps, 4500 m a.s.l.); (**b**) rock scree richly colonised by lichens; (**c**) outcrops and walls at low elevation (Taya Tal, The Czech Republic)

and concrete. Concrete surfaces, with their enormous extent, are of particular importance. Fungi on concrete have earlier been studied in the context of biodeterioration and pollution (e.g. Krumbein 2012 and references therein). Strains of potentially allergenic *Alternaria* (causing asthma and chronic rhinosinusitis) and *Epicoccum* are frequently found among isolates from concrete (unpublished data). Thus, concrete surfaces might also be considered in public health as a source of fungi contributing to the aerial mycobiome. Spores and hyphal fragments of *Alternaria*, in particular, are among the most abundant allergens spread in airborne samples (Banchi et al. 2018), and the genus is always reported in the pollen bulletins of air monitoring.

7.5 Links to Lichen Symbiosis

Gorbushina and Broughton (2009) considered the rock surface as a kind of 'symbiotic playground', where they found antibiosis (detrimental interactions between species) to be rare and counterproductive. The authors also mentioned that co-cultivation of the cyanobacterium *Nostoc* with a rock-inhabiting fungus (*Sarcinomyces*) resulted in a specific association, without presenting this association in greater detail. Such associations have been observed previously, e.g. by Turian (1977), in his description of *Coniosporium aeroalgicola*. This species, a dematiaceous hyphomycete, seems to be a ubiquitous component of aereo-algal communities and is able to form some sort of symbiotic structures with algae. Rock-inhabiting microcolonial fungi may develop into lichenoid structures within months when co-cultured with lichen algae (Gorbushina et al. 2005). Brunauer et al. (2007) reported an interesting new black fungal strain (ALr-1) isolated from rock-inhabiting lichen *Lecanora rupicola*. During co-culture with the isolated algae of the host lichen, this black fungus started to cover the algal colonies with a layer-like mycelium recalling a primitive form of a lichen thallus. Through a phylogenetic analysis Brunauer et al. (2007) could then also show that this black fungus is basal to typically lichen-forming lineages in the Chaetothyriomycetidae.

The study of lichen-infecting fungi has a long history, and fungal infections have been observed even before lichens were found to represent a fungal-algal symbiosis. Their propagative structures were used to characterise 2000 so far described species of lichenicolous fungi (Diederich et al. 2018). Microscopic analyses show that there are often additional and dark-coloured fungal hyphae in lichens, which cannot clearly be assigned to known species. Culturing and sequencing approaches have shown more recently that many more fungi have a so far unrecognised association with lichens (e.g. Fernández-Mendoza et al. 2017; Muggia and Grube 2018). Their roles in the lichen symbiosis and phylogenetic relationships still need to be explored. Yet, a significant fraction of fungi isolated from lichens belong to black fungi, which are also known from bare rock habitats. Work of Harutyunyan et al. (2008) suggests that rock-inhabiting lichens in arid environments are particularly rich in black fungi otherwise occurring on rocks.

The shared occurrence of black fungi on rocks and on lichens, as well as the transient ability of certain isolates to form associations with algae, indicates a biological link between extremotolerant, lichenised and lichen-inhabiting lifestyles that are reminiscent of a common phylogenetic past. Potential common ancestries of lichenised fungal lineages and black fungi have already been documented by phylogenetic analyses, which place rock inhabitants basal to the mainly lichenised lineages of Arthoniomycetes and Verrucariales (Gueidan et al. 2008; Ruibal et al. 2009). In these groups we also find both complex morphologies with stratified lichen thalli (and occasionally subsequent loss of thallus formation and sporadic evolution towards the lichen-infecting lifestyle). In comparison, the lichen representatives in Dothideomycetes are scattered among different clades within this huge class (Muggia et al. 2008; Nelsen et al. 2009). These lineages generally do not form

complex thallus structures and are more closely related to fungi adapted to other lifestyles, in particular to those growing in oligotrophic rock environments.

Gostinčar et al. (2012) suggested that small protective molecules that are known to accumulate in black fungi as stress-responsive osmolytes could also be linked with potential transition from rock-inhabiting to the lichenised lifestyle. In particular, the polyol metabolism could be involved in both extremotolerance and lichenisation. Ribitol, sorbitol and erythritol (as well as glucose by cyanobacteria) are provided by photoautotrophic symbionts to the fungal partners as 'food molecules', where they are transformed to mannitol (Friedl and Büdel 2008). Efficient osmolyte metabolism, as found in oligotrophic black fungi, could therefore be a preadaptation to facilitate the transition to a lichen symbiotic lifestyle.

Few black fungal species indeed form lichen symbioses with a peculiar morphology. For example, the microfilamentous cushions formed by the genera *Cystocoleus* and *Racodium* consist of algal threads that are enwrapped by fungal hyphae (Muggia et al. 2008). Other (small) lineages in the Dothideales suggest that there is a widespread capacity for evolution of this symbiotic lifestyle (Nelsen et al. 2009), but the lichenised forms never develop a typical thallus morphology as found in the primarily lichenised classes Lecanoromycetes or Arthoniomycetes. To explore the link between rock-colonising and algal-associated lifestyles in more detail, Muggia et al. (2013, 2015) studied the genus *Lichenothelia*. The genus was described by Hawksworth (1981) who already suggested a relationship with Dothideales due to features of the ascomata. Lichenotheliaceae and the order Lichenotheliales (Hyde et al. 2013) are meanwhile confirmed as monophyletic lineage within Dothideomycetes, based on sequences from five species (e.g. *Lichenothelia arida*, *L. calcarea*, *L. convexa*, *L. rugosa* and *L. umbrophila*, and a yet undescribed *Lichenothelia* sp.; Hyde et al. 2013; Muggia et al. 2013, 2015), thus pending the analysis of 23 further accepted species (Henssen 1987; Øvstedal and Smith 2001; Atienza and Hawksworth 2008; Zhurbenko 2008; Etayo 2010; Muggia et al. 2013, 2015; Valadbeigi et al. 2016). *Lichenostigma* was earlier thought to be a closely related genus comprising lichenicolous species, but recent phylogenetic analyses revealed its position at the basis of the primarily lichenised class Arthoniomycetes (Ertz et al. 2014).

Although the mycelium of *Lichenothelia* never builds a typical lichen thallus with an internal algal layer, algae are often found in close contact with the fungal hyphae (Fig. 7.3e, f). So far, in vitro experiments by which both growth rate and structure of mixed culture of *Lichenothelia* with algae were tested (Fig. 7.4b–d, g, h) did not provide clear experimental evidence of symbiosis establishment (Ametrano et al. 2017). This might be attributed to the rich medium conditions, and it thus remains to be tested, whether nutrient-deprived conditions could make the association with algal cells more important for the fungal species. Other black fungi might also suit as experimental models to study lichen-like associations, and particularly, some species of the highly diverse mycobiota associated with lichens may gain benefits from algal products in the host symbiosis (Muggia and Grube 2018). To test potential interactions of lichen-associated and other black fungi with algae, Muggia et al. (2018) introduced a novel method for co-cultivation. They encapsulated fungi in alginate

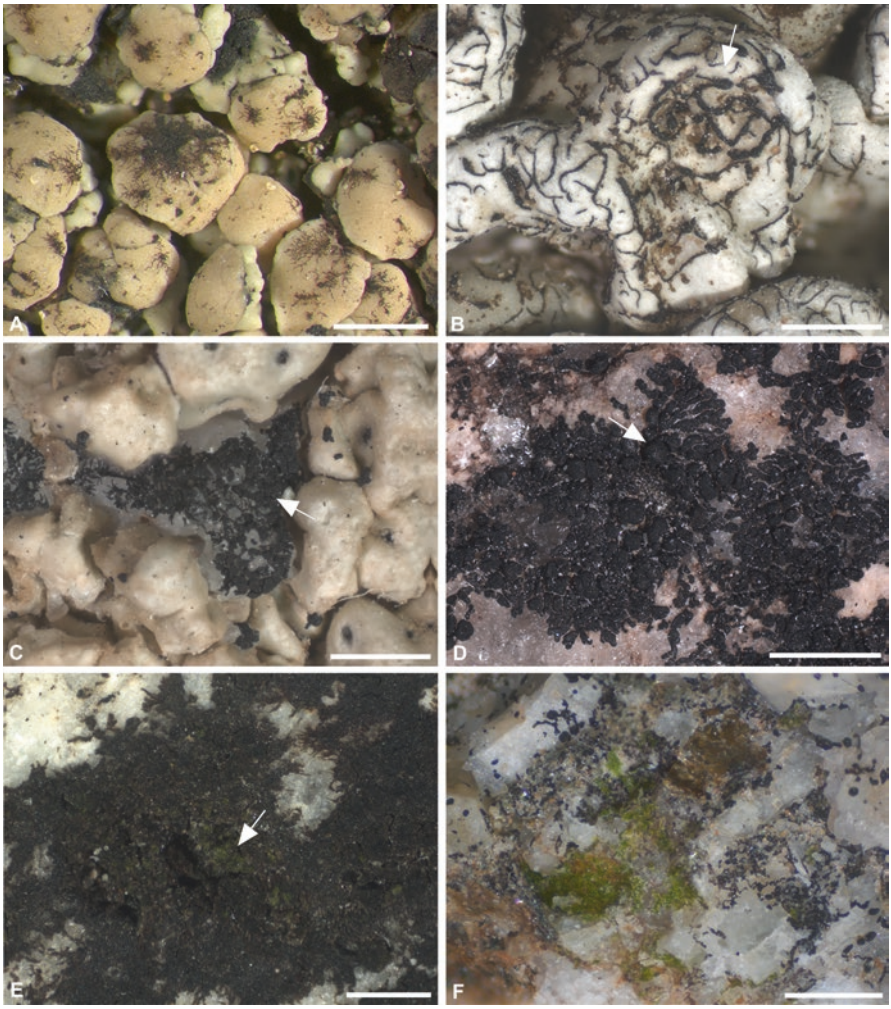

Fig. 7.3 Habit and lifestyles of black fungi in nature (in parenthesis fungal order and/or class are reported): (**a**) lichenicolous black fungus (Dothideomycetes) spreading hyphae on the apothecium of the lichen *Lecanora polytropa*; (**b**) lichen parasitic fungus *Lichenostigma rouxii* (Arthoniomycetes) developing hyphae and ascomata (arrow) on the thallus areolas of *Pertusaria* sp., sample n. together with algal strains isolated from lichens. Symbiotic interactions that are not normally observed in nature can be artificially enforced with this approach. While intertwined growth of slow-growing black fungal mycelia (*Saxomyces* and *Lichenothelia*) and algae was commonly observed, only the specific lichenicolous fungus *Muellerella* developed a layer-like mycelial growth together with algal colonies. Encapsulation in alginate may be a versatile method to experimentally analyse the specificity of interactions among black fungi and algae under a wide range of parameters. Despite the fact that they are little studied, such lichen-like interactions seem to be surprisingly ubiquitous. Removal of dark matter from concrete in urban environments by using adhesive tapes and subsequent microscopic analysis reveals that black fungi cover extensive surfaces in a biofilm-like manner together with microscopic algae (Grube, unpublished). The associations strikingly resemble the lichenoid interaction structures found in co-culture experiments, with algal cells attached to fungal hyphae or partly enwrapped by fungal microcolonies.

Why can black fungi only form very primitive types of associations with algae, but not a typical lichen thallus equipped with a coherent fungal cortex? Lichenised fungi usually shelter their algal partners beneath a protective peripheral fungal layer, which develops by the conglutination of the outer cell walls of the fungi. We argue that one important step towards the evolution of typical lichen thalli from potential black fungal ancestors was the downregulation of fungal melanin production. Highly cross-linked melanins make fungal cell walls rigid and prevent appropriate responses of cell colonies to mechanic stress imposed by fluctuating hydration conditions in the natural environment. Instead, downregulation of melanin and conglutination of cells in a joint extracellular matrix facilitate the functionality of coherent, hydration-responsive symbiotic structures as required in lichen thalli. Moreover, a strongly melanised fungal upper layer would also prevent the transmission of light to the symbiotic algal partner. Most lichens therefore screen against high doses of light found by other means, such as formation of microscopic crystals that are deposited outside of the cell walls (as extrolites). With a crystal-studded layer, light is also better transmitted to the algae in metabolically active humid stage, whereas it is largely reflected in the shrunk dried stage of thalli when metabolism is suspended. The development of highly complex thallus structures of lichenised fungi, and thus structures of their propagation, requires the presence and functionality of compatible algae. In contrast, most black fungi associate live and propagate independently from optional symbiotic stages, which explains the excessive tolerance for environmental variation and the adaptability to a wide range of ecological conditions.

7.6 Omics Approaches for the Study of Black Fungi

'Omics' approaches, genomics, transcriptomics, proteomics, etc. speeded up the view on the organisation of life in twenty-first-century biology. Large amounts of data are generated by these approaches that require substantial statistical and computational analyses (Zhang et al. 2010), as well as easy access to information for

comparative analyses. Fungal comparative genomics have become an affordable and popular endeavour, as exemplified by a project to sequence and analyse 1000 fungal genomes (http://1000.fungalgenomes.org). Yet, we are only beginning to interpret the details of the biology of black fungi within an omics framework.

More than 37 genomes of chaetothyrealean black yeasts are now available in different databases (Moreno et al. 2018b). Black yeast genomes of Chaetothyriomycetidae are similar in size, ranging from 25.8 Mb in *Capronia coronata* CBS 617.96 to 43 Mb in *Cladophialophora immunda* CBS 834.96. These sizes are in the lower average of filamentous ascomycetes, and the length of genomes is not correlated with adaptations to the ecological extremes. However, several protein families in black fungal genomes have undergone extensive gene duplication events (Teixeira et al. 2017). Among the expanded families, cytochromes p450 (CYP), drug efflux pumps, alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) seem to be widely distributed across black yeasts. Retention of duplicated genes suggests that the broadening of corresponding metabolic processes and promiscuity for substrates played a role to adapt to their habitats. Based on these findings, Teixeira et al. (2017) suggested that detoxification by black fungi occurs by catabolism of phenolic compounds via phenylacetic acid and homogentisate.

Since its beginning, genome sequencing of Dothideomycetes has advanced much further and, as of March 2018, the Joint Genome Institute site listed 123 sequenced genomes. The great interest in Dothideomycetes is certainly associated with the large number of plant pathogens in that class (Ohm et al. 2012). The number of sequenced extremotolerant fungi is still fairly low though. Sterflinger et al. (2014) used comparative genomics to study the differences between *Cryomyces antarcticus* and the mesophilic fungi *Neurospora crassa*, *Coniosporium apollinis* (a species highly tolerant to UV radiation, desiccation and high temperature), the halotolerant *Hortaea werneckii* and the human pathogens *Exophiala dermatitidis* and *Cladosporium sphaerospermum*. However, as Sterflinger et al. (2014) concluded, the analysis of draft genomes did not reveal any significant deviations of *Cryomyces* genomes and those of mesophilic hyphomycetes. Subsequent analyses revealed duplications of genes potentially associated with stress tolerance. The genome of *Hortaea werneckii* revealed enrichment of metal cation transporters, beside other duplications (Lenassi et al. 2013). Genome and proteome analyses in four varieties of *Aureobasidium pullulans* detected genes possibly associated with degradation of aromatic compounds, in addition to most of the enzyme families involved in decomposition of carbohydrates and many sugar transporters (Gostinčar et al. 2014). All of the components of the high-osmolarity glycerol pathway were present, and the genomes were enriched in putative stress-tolerant genes, e.g. aquaporins and aquaglyceroporins, alkali-metal cation transporters, genes for the synthesis of compatible solutes and melanin, and bacteriorhodopsin-like proteins. The differences in the genomes among the four *Aureobasidium* varieties prompted Gostinčar et al. (2014) to distinguish them into different species, and this raises the question about the amount of variation that has to be expected when further ecologically different strains would be investigated. Additional genome sequences, with limited effort of comparative analysis, have been provided from Antarctic extremotolerant black fungi of the genus *Rachicladosporium*

(Coleine et al. 2017). Even though the results show that extremotolerance in fungi is not reflected in genome size, genes potentially conferring certain metabolic adaptations to stress tolerance seem to be enriched.

Genome sequencing provides important new insights, but it is still not possible to directly infer the involvement of genes in particular functions by merely using the common annotation classifiers. The genome sequences neither provide information about their regulation. Further work is therefore needed to relate the information of genome sequencing with biological roles, particularly of paralogous genes in larger gene families. For a better understanding of biological roles, information obtained from genome sequencing should therefore be complemented with transcriptomics and proteomics. As gene expression might be modulated by environmental factors, transcriptomics may suit better than genomics in testing specific hypotheses about functional aspects of stress tolerance. Within chaetothyrealean black yeasts, most experiments have been conducted on *Exophiala (Wangiella) dermatitidis*, which may be considered a model among pathogenic black fungi. *E. dermatitidis* has been sampled from diverse environments, ranging from glaciers to saunas and dishwashers (Zalar et al. 2011; Zupančič et al. 2016). Therefore, its transcriptomic responses to a wide range of temperatures (1–45 °C) could be analysed (Blasi et al. 2015). The data showed that *E. dermatitidis* usually responds to low temperatures by upregulating genes which modify lipidome composition towards membrane fluidity, whereas there is almost no stress signal in the transcriptome when the fungus is at 45 °C. However, since variations in membrane fluidity patterns among black fungi have been recognised before, any generalisations should be tempered with caution (Turk et al. 2011). Adaptation to ionising radiations and the role of melanin (claimed by Dadachova et al. 2008) have been investigated from a transcriptomic perspective exposing both wild and melanin-deficient mutants of *E. dermatitidis*. According to these results, a high number of genes (3000) are differentially expressed, and an increased growth rate has been observed in both strains (in comparison to the corresponding non-irradiated samples), when they are exposed to a low dose of ionising radiations. However, the majority of regulated genes overlap between wild strain and melanin-deficient mutant; therefore, transcriptional response to the radiation is mainly determined by cellular components other than melanin. The expression of ribosomal biogenesis genes is significantly upregulated only in the wild-type strain (Robertson et al. 2012), suggesting that transcription regulators contribute to both pigment production and general transcriptional response. Comparative genomic and transcriptomic approaches have complemented in the study of Chen et al. (2014), who investigated the *E. dermatitidis* genome and the transcriptional response to low pH. The genome encodes three independent pathways for the melanin synthesis; these were active during pH stress, likely acting as a defence against oxidative damages occurring under stress conditions. The most recent transcriptomics applied to *E. dermatitidis* was an artificial infection of an ex vivo skin model experiment, which aimed at identifying changes in gene expression during infection and potential virulence factors among coding and non-coding RNAs. Even though the yeastlike growth is prevalent during infection, there are evidences of upregulation of genes related to hyphal growth as well. Melanins (often considered

as virulence factor) and genes associated to its production are only upregulated in the L-tyrosine pathway, which produces pyomelanin (these melanins are hypothesised to be involved in iron uptake as an indirect factor of pathogenicity). The other melanin pathways are instead not modulated during skin infection. Moreover, *E. dermatitidis* switches to gluconeogenesis pathway in order to respond to decreasing levels of glucose when growing on skin instead of growing in a glucose-rich medium. Genes related to metal cation (Fe, Mg) transporters are also upregulated (Poyntner et al. 2016).

Within Dothideomycetes most scientific attention is focused on economically important crop pathogens, while still little is known about transcriptomics of extremotolerant fungi in this group. Nevertheless, due to its halotolerance and its biotechnological potential, *Hortaea werneckii* is among the better-studied dothidealean fungi to date. Its genome assembly has been recently improved via PacBio sequencing and combined with gene expression analyses to complement the genome annotation (Sinha et al. 2017). These analyses confirmed the previous hypothesis of a recent whole genome duplication event (Lenassi et al. 2013) and identified the presence of some novel high-osmolarity glycerol (HOG) pathway components. These are principally similar in other fungi, such as *Saccharomyces cerevisiae* and *Wallemia ichthyophaga*, but relevant differences, which still need further study, may account for the advanced salt tolerance of *Hortaea* (Plemenitaš et al. 2014).

Proteomics has been suggested as a valid approach to investigate peculiar features of extremophilic black fungi (Marzban et al. 2013) but limited proteomic analyses have so far been carried out. The proteome of *Cryomyces antarcticus* was analysed by Zakharova et al. (2014). Conserved protein families involved in the housekeeping metabolism were found, but a fraction of the protein pool differs significantly from other fungal species and might confer adaptation to extreme conditions. *C. antarcticus* differed by the expression of high levels of heat-shock proteins (HSP), even when it is cultured under optimal temperature conditions. This apparent lack of a stringent regulation of these proteins, which are also present during dehydration (Zakharova et al. 2013), makes *C. antarcticus* perfectly adapted to its rather constant, extreme environment, but less competitive than other mesophilic stress-tolerant fungi. The overall number of proteins detected was low, suggesting that only a limited part of the genome, which has an average size among fungi (Sterflinger et al. 2014), is actually transcribed. This was also found for the proteome of *Friedmanniomyces*.

The alteration of protein expression patterns in rock-inhabiting fungi has been analysed also under temperature variation (Tesei et al. 2012) and Mars-like simulated conditions (a combination of temperature extremes, dryness, low O_2 pressure and high radiations; Zakharova et al. 2014). In these almost anaerobic conditions *Cryomyces antarcticus*, *Knufia perforans* and *Exophiala jeanselmei* still proved to be metabolically active yet exhibiting a significant decrease of expressed proteins during the first 24 h of stress exposure. Although both the extremotolerant (e.g. *Knufia*) and extremophilic (e.g. *Cryomyces*) microcolonial fungi are active under stressful abiotic condition, a main difference has been found: extremophiles are

always equipped with a proteome withstanding harsh conditions and just slightly tend to downregulate their activity, and extremotolerants are flexible to change their proteomic profile according to the environmental conditions.

7.7 Conclusion and Future Perspectives

Certain genomic signatures of extremotolerance seem to be widespread in extremotolerant black fungi. Their roles may become clear with more detailed comparisons of genomic data in the future. Also, transcriptomic analyses may find out more details about their differential expression under conditions of stress. It will be particularly interesting to analyse how rapidly the transcriptional responses occur under fluctuating hydration conditions, and how metabolic activities resume after long periods of metabolic suspense. Also, further survival strategies of black fungi should be considered. For example, non-genetic heterogeneity in fungal colonies could indicate a potential self-feeding strategy in the oligotrophic habitats, as dead cells in a colony may be decomposed and used as source of nutrients for surviving cells. We think that a comprehensive understanding of fungal stress tolerance requires an interdisciplinary biophysical and biochemical approach. Hence, we foresee a bright research perspective for black fungi.

Acknowledgments We thank Theodora Gössler for assistance in the lab. Financial support was granted by the Austrian Science Foundation (FWF P24114 to LM).

Chapter 8
Basidiomycetous Yeast of the Genus *Mrakia*

Masaharu Tsuji, Sakae Kudoh, Yukiko Tanabe, and Tamotsu Hoshino

8.1 Introduction

The first fungus recorded from Antarctica was *Scleotium antarcticum* collected at Danco Land, Antarctic Peninsula, on an SY Belgica expedition (Bommer and Rouissean 1900). Over 1000 fungal species from 421 genera have been isolated and recorded from Antarctica (Bridge and Spooner 2012); the list of known species from culturing and collection consists of 68% ascomycetes, 23% basidiomycetes, 5% zygomycetes, and the final 4% made up of various other lineages. Fell et al. (2006) reported that approximately 40% of fungi isolated in Dry Valley, a low-temperature and low-moisture region, are occupied by basidiomycetous yeasts.

Despite several reports indicating that basidiomycetous yeast of the genus *Mrakia* makes up the majority of the mycobiota and is one of the most adaptive fungi in Antarctica (Di Menna 1966b; Tsuji et al. 2013a), there are no reviews about the genus *Mrakia*. In this chapter, we review the history of the genus *Mrakia* and also the biological potential of the genus.

8.2 Taxonomic History of the Genus *Mrakia*

Three new isolates of *Candida* spp. were collected by di Menna (1966a) from Scott Base, Ross Island, Antarctica, and were considered to be new species. These three isolates have several common characteristics, such as the ability to reduce NO_3, and the production of starch-like extracellular polysaccharide compounds. However, they also differ in some characteristics, including sugar sources used for carbon assimilation and fermentation. The three isolates were classified as *C. nivalis*, *C. gelida*, and *C. frigida* on the basis of their characteristics. The history of the genus *Mrakia* perhaps began with this report. Fell et al. (1969) identified a heterobasidiomycetous life cycle in a *Candida* spp. isolated from soil from Antarctica. At this point, *C. stokesii*, *C. nivalis*, *C. gelida*, and *C. frigida* were redesigned as *Leucosporidium stokesii*, *L. nivalis*, *L. gelidum*, and *L. frigidum*, respectively. About two decades after the publication of the article by Fell and colleagues, the genus *Leucosporidium* was reclassified based on the coenzyme Q (CoQ) system. *L. stokesii*, *L. nivalis*, *L. gelidum*, and *L. frigidum* all express CoQ_8, so these species were again reclassified and transferred to the newly established genus *Mrakia* as *Mrakia stokesii*, *M. nivalis*, *M. gelida*, and *M. frigida*. In contrast, other *Leucosporidium* species express CoQ_9 or CoQ_{10} (Yamada and Komagata 1987). The genus *Mrakiella* was established in order to accommodate species in the *Mrakia* clade for which sexual cycles had not been observed (Margesin and Fell 2008). Subsequently, the genus *Mrakiella* was integrated into the genus *Mrakia* (Liu et al. 2015).

Fell and Kurtzman (1990) reported that closely related homothallic species, such as *Rhodotorula*, *Candida*, and *Mrakia*, can be identified by using 230 base pairs of the 18S rRNA large subunit. Suh and Sugiyama (1993) used this approach for the phylogenetic analysis of basidiomycetous yeast using 18S rRNA sequences. Diaz and Fell (2000) analyzed the phylogenetic relationship of *Mrakia* species based on sequences of the intergenic spacer (IGS) and internal transcribed spacer (ITS) regions. In addition, Fell et al. (2000) reported that basidiomycetous yeasts can be classified to the species level using the D1/D2 domain sequence of the 26S rRNA. Recently, the phylogenetic analysis of the genus *Mrakia* was performed using concatenated ITS and D1/D2 region sequences (Tsuji et al. 2016a, 2018).

Currently, the genus *Mrakia* includes a total of 10 species, namely, *M. aquatica, M. arctica*, *M. blollopis*, *M. cryoconiti*, *M. frigida*, *M. gelida*, *M. hoshinonis*, *M. nicombsii*, *M. psychrophila*, and *M. robertii* (Yamada and Komagata 1987; Xin and Zhou 2007; Thomas-Hall et al. 2010; Liu et al. 2015; Tsuji et al. 2018, 2019). A phylogenetic tree of *Mrakia* species generated using the ITS region and D1/D2 domain sequences is shown in Fig. 8.1. According to the phylogenetic analysis, *Mrakia curviuscula* is located in a clade far from the genus *Mrakia* (Fig. 8.1). Fell (2011) reported that this species was isolated from moss from a forest in Central Russia. In comparison, other *Mrakia* species were isolated from snow, soil, and glaciers in cold environments. Moreover, *M. curviuscula* grows at 25 °C, while other *Mrakia* species fail to grow at 25 °C. Fell therefore suggests that *M. curviuscula*

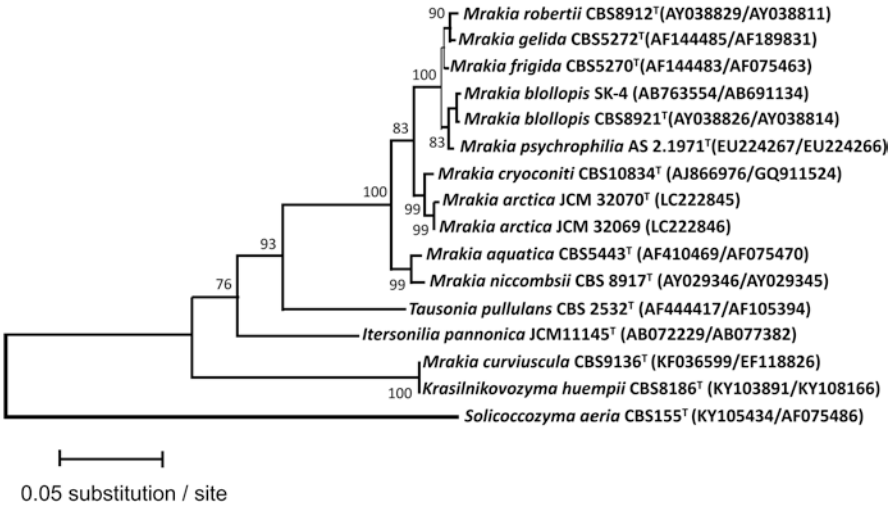

Fig. 8.1 Phylogenetic tree of *Mrakia* spp. and other related species using the ITS region and D1/D2 domain sequences. Maximum likelihood analysis of the ITS region-LSU D1/D2 domain sequences of genus *Mrakia* and closely related species. The tree was constructed by maximum likelihood analysis with MEGA7. Bootstrap percentages of maximum likelihood analysis over 50% from 1000 bootstrap replicates. Bootstrap percentages from 1000 replications are shown on the branches. *Solicoccozyma aerius* CBS155^T was used as an out-group. The scale bar represents 0.05 substitutions per nucleotide position

should be removed from the genus *Mrakia*. Currently, this opinion is widely accepted regarding the classification of the genus *Mrakia*.

8.3 Physiological Characteristics

The most important characteristics for classification of yeast taxonomy are the sugars used as sources for the assimilation of carbon and the ability to ferment different sugars, as well as the sequence information for the ITS region and D1/D2 domain. The primary characteristics of *Mrakia* spp. are shown in Table 8.1. For the assimilation of carbon, *Mrakia* spp. commonly can use glucose and sucrose. *M. frigida* is not able to assimilate maltose. *M. gelida* and *M. robertii* cannot assimilate lactose. *M. arctica* and *M. aquatica* are unable to assimilate inositol. Moreover, *M. blollopis*, *M. frigida*, and *M. robertii* can grow in vitamin-free conditions. *Mrakia* spp. therefore have different characteristics for each species regarding the sources used for carbon or nutrient assimilation.

Little is currently known about ethanol fermentation by basidiomycetous yeasts. Species in the basidiomycetous yeast *Mrakia* are known for their ability to ferment sugars. In fact, seven of the nine *Mrakia* species are able to ferment glucose and sucrose (Table 8.1). *M. blollopis* CBS8921^T and *M. psychrophila* AS2.1971^T are not

Main physiology test results for characteristics of the *Mrakia* species. Physiological data were taken from Fell et al. (1969), Xin and Zhou (2007), Thomas-Hall et al. (2010) and Tsuji et al. (2018)

+ positive, w weak, − negative, *v* variable, *d* delayed positive, *nd* no data

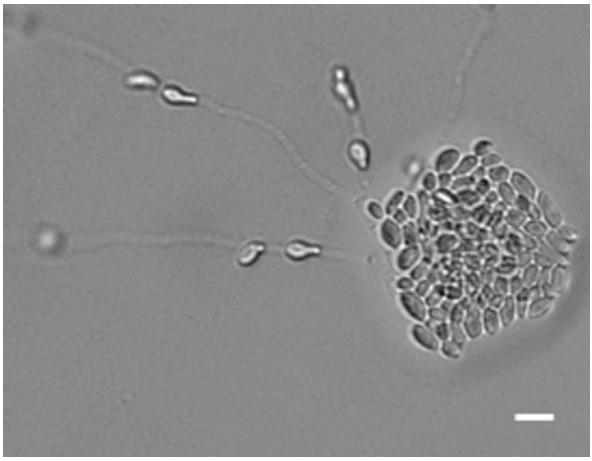

Fig. 8.2 Cell morphology of *Mrakia blollopis* SK-4. Micrograph of *Mrakia blollopis* SK-4. The fungi were inoculated on 1.5% (w/v) water agar and incubated for 4 weeks at 4 °C. Bar: 10 μm

able to ferment raffinose, galactose, lactose, or maltose. *M. frigida* CBS5270^T and *M. gelida* CBS5272^T are unable to utilize lactose for fermentation, and *M. robertii* CBS8912^T is unable to ferment raffinose or galactose.

M. blollopis SK-4 (Fig. 8.2), isolated from an algal matt from Naga-ike in Skarvsnes ice-free area, East Antarctica, shares a high degree of homology of its region and D1/D2 domain sequences with *M. blollopis* CBS8921^T (>99.6%), and strain SK-4 demonstrates similar characteristics of carbon assimilation with *M. blollopis* CBS8921^T. Strain SK-4 is clearly able to ferment maltose; however, CBS8921^T cannot ferment maltose (Table 8.2). Results from phylogenetic analysis indicate that SK-4 should be classified as *M. blollopis*; nevertheless, SK-4 has different characteristics regarding carbon assimilation and fermentative ability for maltose. Therefore, a comparison of the physiological characteristics of strain SK-4 with CBS8921^T is needed. The maximum growth temperature of *M. blollopis* SK-4 is 22 °C, whereas the maximum growth temperature of CBS8921^T is 20 °C. *M. blollopis* SK-4 differs from CBS8921^T in substrate utilization as well. The strain SK-4 thrives on lactose, D-arabinose, and inositol medium, unlike CBS8921^T, which also grows well on vitamin-free medium. A comparison of the fermentation abilities reveals that *M. blollopis* SK-4 can ferment typical sugars such as glucose, sucrose, galactose, maltose, lactose, raffinose, trehalose, and melibiose, while CBS8921^T is a weaker fermenter, and is limited in the variety of sugars it can use for fermentation (Table 8.2).

8.4 Ecological Role

Mrakia spp. have been isolated from various extreme environments, including the Arctic, Siberia, the Alps, Alaska, Patagonia, and Antarctica (Morgesin et al. 2005; Thomas-Hall et al. 2010; Singh & Singh 2012; de Garcia et al. 2012; Panikov &

+ positive, *w* weak, − negative

Sizova 2007). Interestingly, this genus has been detected in frozen fish, frozen yogurt, and soil from Hokkaido, Japan (Komagata and Nakase 1965; Moreira et al. 2001; Nakagawa et al. 2004). According to di Menna (1966b), approximately 24% of culturable yeasts in the soil from Ross Island, Antarctica, are *Mrakia* spp. Moreover, about 35% of the culturable fungi in soil surrounding lakes and in lake sediment from Skarvsnes ice-free area, East Antarctica, belong to the genus *Mrakia* (Tsuji et al. 2013a). These results indicate that *Mrakia* spp. are the dominant and most adaptive fungi in Antarctica.

In a glacier retreating area of the Norway High Arctic, the genus *Mrakia* was isolated from the glacier near the terminus position, and likely served a role as a carbon source supplier by decomposing surrounding cell wall and cell membrane remnants with secreted extracellular enzymes (Tsuji et al. 2016b). Pathan et al. (2010) tested a strain of *Mrakia* spp. isolated from an Arctic glacier for extracellular enzyme activity at various temperatures. In that study, *Mrakia* secreted urease, amylase, protease, and lipase, and these enzymes were highly active when *Mrakia* spp. was cultured at 22 °C, compared to when it was cultured at 8 °C. Yeasts isolated from Patagonia, Argentina, are reported by de Garcia et al. (2007) to show higher lipolytic activity at 4 °C than at 20 °C. Moreover, de Garcia et al. (2012) reported that *Mrakia* spp. isolated from the Patagonian Andes in Argentina produce esterase at 5 °C. Turchetti et al. (2008) showed that approximately 77% of the *Mrakia* spp. isolated from alpine glaciers exhibit lipolytic activity at 4 °C. We have previously reported that lipase activity of the *Mrakia* strain isolated from Skarvsnes ice-free area is higher at 4 °C than at 15 °C (Tsuji et al. 2013b, 2014a, 2015b). *M. arctica* was isolated from Canadian Arctic, and the optimum temperature for lipase secretion from this isolate is −3 °C, and the highest level of protein degradation activity

by *M. arctica* occurs at 10 °C. Singh et al. (2016) report that *M. blollopis*, isolated from the Norwegian Arctic, shows only weak protease activity, and our previous whole genome analysis of an Antarctic strain of *M. blollopis* strain shows that it lacks the protease K gene and ice-binding gene (Tsuji et al. 2015a). Extracellular enzyme tests indicate that the genus *Mrakia* is able to decompose a variety of organic materials over a wide range of temperatures. The *Mrakia* spp. may therefore play an important role in the biogeochemical cycles of polar ecosystems. However, we have only fragmented information regarding the ecological role of *Mrakia* in polar regions. Further experiments are required in order to elucidate the ecological role of the *Mrakia* spp.

8.5 Biotechnological Applications

Cold environments cover a large portion of the planet, with many ecosystems permanently exposed to temperatures below 5 °C (Feller and Gerday 2003). As microbes adapted to cold environments are able to grow at temperatures below 0 °C, it is expected that these organisms employ unique physiological tools in order to survive, such as cold-adapted enzymes and ice-binding proteins (IBPs) (Buzzini et al. 2012; Tiquia-Arashiro and Rodrigues 2016).

M. frigida and *M. gelida* have been evaluated for heat shock response. When these microorganisms are incubated at 20 °C and 25 °C for 3 h, both species induce heat-shock proteins, such as hsp70, hsp90, and 110 kDa proteins. When *M. frigida* is incubated at 25 °C for 3 h, this species induces increased levels of the 90 kDa protein (Deegenaars and Watson 1998).

Margesin et al. (2005) report the presence of a cold-active alkaline pectate lyase in *M. frigida*. This *M. frigida* pectate lyase (*M. frigida* PL) is highly secreted when the fungus is grown at 1–10 °C. The temperature for optimal activity of the enzyme is 25°–30 °C, and the optimal pH is 8.5–9.0. As for the thermal stability of *M. frigida* PL, about 60% of the relative activity is lost when incubated for 15 min at 30 °C. Moreover, when this enzyme is incubated for 48 h at 2 °C, 5–21% of initial activity is lost.

M. frigida strain 2E00797 possesses a cold-active toxin lethal to the pathogenetic crab yeast *Metschnikowia bicuspidata* (Hua et al. 2010). This killer protein toxin was purified and characterized by Liu et al. (2012). After purification, a 55.6 kDa single band is detectable by sodium dodecyl-polyacrylamide gel electrophoresis (SDS-PAGE). This protein has about 35% sequence homology with a protein kinase, but Liu and colleagues did not determine its activity. The optimal temperature for toxicity of the purified protein was 16 °C, and the enzyme is stable at temperatures below 25 °C, even after 60 min of preincubation. The optimal pH for toxin activity was 4.5, and the enzyme was stable, even after 24-h preincubation at pH 4.5. The highest killing activity of this enzyme was recorded in the presence of 3% (w/v) NaCl.

Milk fat curdle in sewage is one of the most refractory materials to active sludge treatment under low-temperature conditions. In an effort to solve this problem using a bioremediation agent, we previously collected about 75 species of *Mrakia* from soil surrounding a lake and from lake sediments in Skarvsnes ice-free area, East Antarctica. We tested the isolates for their ability to decompose milk fat under low-temperature conditions and evaluated their potential for application to an active sludge system in a cold climate. Fifty-six of the 75 *Mrakia* species exhibited a clear zone, consistent with milk fat decomposition (Shimohara et al. 2012). *M. blollopis* SK-4 demonstrated one of the largest clear zones under low temperature. Therefore, we expected that activated sludge containing the yeast strain SK-4 would have the potential to improve the removal of milk fat biological oxygen demand (BOD_5), and tested it in the removal of milk fat in a low-temperature environment. Consequently, SK-4 showed a BOD removal rate that was 1.25-fold higher than that of the control. The SK-4 lipase was then purified, and the enzyme was found to be quite stable under a wide range of temperatures and pH, even in the presence of various metal ions and organic solvents. The effect of nitrogen concentration on cell morphology, and on the formation of the clear zone around the colonies, which is indicative of lipase activity, was also evaluated on fresh cream agar at various culturing temperatures. When grown on high-nitrogen fresh cream agar, the largest clear zone was formed around colonies at 4 °C, and the cell morphology was a yeast form. The cell morphology of SK-4 during lipase secretion, based on fluorescence in situ hybridization (FISH), was that of a yeast form. These results indicate that SK-4 takes a yeast form when growing in aquatic environments, and in this form it may secrete more lipase than when in a mycelial form (Tsuji et al. 2014a). *Mrakia* sp. YSAR-9, isolated from the Arctic, has a high homology of the ITS region and D1/D2 domain sequences compared with those of *M. blollopis* CBS8921^T (> 99%). YSAR-9 is believed to be the same species as *M. blollopis* SK-4. However, when YSAR-9 is inoculated on lipase assay agar at 8 °C and 22 °C, this yeast demonstrates the largest clear zone at 22 °C (Pathan et al. 2010), while SK-4 forms its largest clear zones at 4 °C and fails to form clear zones at 20 °C (Tsuji et al. 2015b). Strong lipase secretion under low temperature was therefore thought to be a unique characteristic of each strain.

The fermentation abilities of *Mrakia* spp. were previously described in the section of physiological characteristics. In general, the fermentation abilities were uncommon characteristics for basidiomycetous yeast (Fell 2011). However, all *Mrakia* species could ferment glucose and sucrose except *M. aquatica and M. cryoconiti* (Fell and Margesin 2011). *M. frigida*, *M. blollopis*, *M. gelida*, and *M. robertii* were evaluated for ethanol fermentation in tests using a home brewing kit. Thomas-Hall et al. (2010) report that all the strains are able to ferment sucrose, but are unable to completely convert sucrose to ethanol, and cell growth is stopped in the presence of ethanol at concentrations greater than 2% (v/v). The ability of strain SK-4 to strongly ferment various sugars, and the findings by Thomas-Hall and colleagues, led us to test SK-4 for its ability to ferment ethanol using various glucose concentrations at 10 °C. Consequently, it was found that SK-4 is able to consume glucose at all the concentrations tested (4%, 6%, and 12%), with 14.4 g/l, 20.4 g/l, and 48.2 g/l

ethanol being produced, respectively. Moreover, SK-4 was evaluated for ethanol fermentation using lignocellulosic biomass hydrolysates, such as eucalyptus and Japanese cedar for substrates. This yeast strongly ferments Japanese cedar hydrolysate, but not eucalyptus hydrolysate (Tsuji et al. 2013d). Since SK-4 has both acetic acid and formic acid tolerances during fermentation, the differences in SK-4 fermentability using Japanese cedar and eucalyptus remain unclear. Direct ethanol fermentation (DEF) from a cellulosic biomass was firstly reported by Takagi et al. (1977). In this technique, enzymatic hydrolysis and ethanol fermentation are carried out at the same time. In the presence of a high concentration of glucose, cellulase activity is considerably depressed. However, when yeast is mixed with an enzymatic hydrolysis reactor, glucose is formed from the cellulase activity on the cellulolytic biomass. The glucose is maintained at a low concentration and is rapidly converted to ethanol by the yeast. Moreover, when a lignocellulosic biomass is saccharified and fermented at the same time, major fermentation inhibitors like furfural and 5-methylfolate (5-MHF) are maintained at very low concentrations compared to the concentrations of major fermentation inhibitors in the enzymatic hydrolysate (Thomsen et al. 2009). Therefore, this technique is expected to improve saccharification and ethanol fermentation rates. Since the inhibition of ethanol fermentation is thought to be prevented by DEF, SK-4 was used for direct ethanol fermentation. SK-4 is able to ferment eucalyptus by DEF, although high concentrations of glucose remain in the DEF solutions. Since a nonionic surfactant is thought to combine with lignin (Eriksson et al. 2002), this unproductive fermentation of eucalyptus was thought to be potentially improved by the addition of the nonionic surfactant. In fact, the ethanol concentration was increased 1.6-fold compared to the ethanol concentration in the DEF solution not containing the nonionic surfactant (Tsuji et al. 2014b).

8.6 Conclusions and Future Perspectives

Mrakia spp., especially *M. blollopis* SK-4, have potential for use as bioremediation organisms for degrading milk fat under low-temperature conditions and demonstrate good potential for use in ethanol fermentation. Does this genus truly lack ice-binding proteins? How many lipase isozymes does this genus have? What is the optimal pH and temperature for *Mrakia* spp.-mediated ethanol fermentation? About 50 years ago, di Menna reported that *Mrakia* spp. is the dominant yeast in Antarctic environments. Since then, it has been demonstrated that this genus has several interesting characteristics, such as its fermentative ability, osmotolerance, and secretion of a stable lipase. For biological and physiological characteristics, information regarding *Mrakia* remains fragmentary and limited. Nevertheless, *Mrakia* spp. are thought to have good potential as agents for bioremediation and bioethanol production under conditions of low temperature. Studies must continue on the physiological, morphological, and genomic characteristics of *Mrakia* spp. We believe that the results obtained in previous studies will contribute to the progress of the related

research fields and hope that further investigation will offer many opportunities to obtain more valuable knowledge on the Antarctic microbes and their potential uses for human activities. In the near future, this genus will become an important agent in the field of low-temperature microbiology.

Chapter 9
Adaptation Mechanisms and Applications of Psychrophilic Fungi

Muhammad Rafiq, Noor Hassan, Maliha Rehman, and Fariha Hasan

9.1 Introduction

Frozen environments (cryosphere) represent world's largest share of psychrophilic habitats including snow, ice sheets, ice lake, ice caps, permafrost, glaciers, frozen parts of the ocean, frozen rivers and lakes (Musilova et al. 2015; Kudryashova et al. 2013), in both polar regions (NOAA 2018), glaciers and lakes of nonpolar mountain ranges (Walsh et al. 2016; Salazar and Sunagawa 2017), and man-made freezers (Ahmad et al. 2010) and refrigerators (Flores et al. 2012). Psychrophilic environment is harsh due to low temperature along with at least one of these, i.e., UV rays, low nutrients and water availability, freeze-thaw cycles, and osmotic pressures, and yet these are of ecological and environmental importance. Cold conditions, and other limiting factors, strongly influence survival of organisms in a cold habitat (Margesin and Miteva 2011). Freezing temperature damages cells by disrupting them via ice crystals, stops the activity of enzymes and other proteins, and decreases fluidity of cytoplasm and membranes, thus hindering their normal function in low-temperature environment without proper adaptation tools (Raymond et al. 2007). Cold temperature freezes cell wall and cell membrane that leads to inability to carry out transportation in or out of the cells. Similarly, a frozen cytoplasm is unable to offer favorable environment for enzymes to perform the biochemical processes of a cell. Low temperature affects structure of enzymes which could not achieve their activation energy required to metabolize a reaction (Chandler 2018).

https://doi.org/10.1007/978-3-030-19030-9_9

For survival in extreme environments soil fungi compete with microbes of the soil, acquire the intermittent nutrients, and also utilize secondary metabolites for survival (Yogabaanu et al. 2017). Ice veins inside the glaciers and ice sheets represent micro-environment that serves as habitat for existence of microbes (Thomas and Dieckmann 2002). Microorganisms in the ice veins face many physicochemical stresses, i.e., low water activity and pH, lowered solute diffusion rates, and damage to the membranes owing to ice crystal formation. Psychrophiles demonstrate various structural and functional approaches for their survival under reduced liquid water, extremely cold temperature, high solar radiation, and nutrient scarcity (Garcia-Lopez and Cid 2017).

Psychrophiles and psychrotrophs include all three domains of life such as archaea, prokaryotes (e.g., bacteria), and eukaryotes (e.g., fungi) (Margesin and Miteva 2011; Boetius et al. 2015; Hassan et al. 2016); inhabit stressful low-temperature environments; and are dependent on each other for active ecological processes. Fungi are widely distributed in the cryosphere (Hoshino and Matsumoto 2012), and play an important role in nutrient recycling; thus they are termed as "the survivor community." They also decompose organic compounds under subzero temperatures (Tsuji 2016).

Cold environment constitutes extremely diverse cold-adapted fungi including representatives of all phyla (Wang et al. 2017). Cold-tolerant fungi, belonging to phyla Ascomycota, Deuteromycota, Zygomycota and Basidiomycota, including *Mucor*, *Cladosporium*, *Alternaria*, *Aspergillus*, *Penicillium*, *Lecanicillium*, *Botrytis*, *Geomyces*, *Monodictys*, and *Rhizopus*, have been reported from Antarctica (Kostadinova et al. 2009). Cold-adapted fungi are varied; dwell as saprobes, symbionts, parasites, and pathogens of plant and animal; and also carry out critical functions in diverse ecosystems. Few fungal species cause diseases in plants and animals in cold regions (Wang et al. 2017) and can have both ecologic as well as economic impact on vegetation or animal life.

Adaptation to low temperature makes fungi an appealing resource for obtaining new enzymes and secondary metabolites for use in biotechnology and pharmaceuticals (Wang et al. 2017). Fungi secrete cellulose, hemicellulose and lignin-degrading enzymes, secondary metabolites, and bioactive compounds, and have great potential in biotechnological applications. In nature, soil fungi decompose dead plants, carry out mineral cycling to maintain soil fertility, and thus have an important role in biogeochemistry (Watkinson 2016), the same role of fungi in low-temperature habitats. Scientists have reviewed cold-adapted fungi, properties of enzymes, biotechnological applications and use of metagenomics to screen for enzymes, cold gene expression systems and enzymes used for washing purpose (Cavicchioli et al. 2011), synthesis of biotechnologically important cold-active enzymes, genome sequences, proteomics and transcriptomics of adaptation mechanisms under cold conditions (Feller 2013; Alcaíno et al. 2015), and influence of climate change on microbes of permafrost and their function (Jansson and Taş 2014). Boetius et al. (2015) explained microbial ecology, composition of frozen waters and biogeochemical activities of the microbial communities, and living strategies and ecological functions of cold-adapted fungi reviewed by Wang et al. (2017). This chapter elaborates strategies used by cold-adapted fungi to survive in cold and avenues to exploit their strategies as potential applications in various industries and biotechnology.

9.2 Adaptation Mechanisms

In cold temperature, fatty acid tails of phospholipids become rigid due to less movement, and fluidity of membrane is decreased, thus decreasing permeability to molecules (oxygen and glucose) into the cell. Long exposure to temperatures below-freezing points freezes the liquid inside the cell and forms crystals that damages the membrane, resulting in death of cell (Chandler 2018).

Low temperature affects the cells by impeding chemical reaction rate, denaturing proteins, enhancing water viscosity, limiting activities of microbial enzymes and fluidity of cell membrane (Hassan et al. 2016), and restraining water availability as a solvent for biochemical reactions (Wynn-Williams and Edwards 2000) and frequent freeze-thaw cycles (Montiel 2000).

Eukaryotic microorganisms survive in hypersaline environments by accumulation of "compatible solutes" in their cytoplasm (Oren 1999) and maintain intracellular concentrations of sodium ions below the toxic level (Plemenitaš et al. 2008).

In fungi, melanin provides protection against the undesirable effects of UV radiation (Gessler et al. 2014), drying, high amount of salts, heavy metals, and radionuclides. Melanin helps fungi to live under high electromagnetic radiation in higher altitudes and deserts and on plant surfaces (Zhdanova et al. 2005; Dighton et al. 2008; Grishkan 2011).

Radiations from sunlight comprise UV-A and -B radiations with shorter wavelengths that cause damage to biological systems in glaciers (Cockell and Knowland 1999). To counteract this, organisms have developed repair processes like photoreactivation, base excision repair, nucleotide excision repair, and mismatch repair (Rastogi et al. 2010a, b). UV-absorbing pigments are produced by some organisms (Rastogi et al. 2010a, b). Solar UV-A interacts with cellular photosensitizers that generate reactive oxygen species and induce oxidative stress with proteins as the main target for damage. UV-B negatively affects ecology and evolution of biological systems (Cockell and Blaustein 2001).

Various strategies of cold tolerance in fungi include production of antifreeze proteins (AFPs), plasma membrane fluidity, trehalose, compatible solutes, and many other cold-shock proteins and mechanisms (Robinson 2001). Scientists are looking for molecular or genetic basis of adaptations. High expression of unknown or novel genes in *Glaciozyma antarctica* PI12 could have an important role in cold adaptation (Firdaus-Raih et al. 2018).

9.2.1 Plasma Membrane Fluidity Maintenance

Microorganisms living in cold habitats deal with low temperature by changing composition of lipid membrane (Russell 1990) and increasing level of unsaturated fatty acids. Increased unsaturation of lipids is observed at low temperature in *Geomyces pannorum*, with decrease in production of ergosterol in *Mortierella elongate* (Weinstein et al. 2000). *M. elongate* showed increase in production of stearidonic acid, a fatty acid previously reported in psychrotrophic zygomycetes. *Rhodosporidium diobovatum* (psychrotolerant Arctic yeast) demonstrates increased membrane fluidity through unsaturation of fatty acids (Turk et al. 2011).

9.2.2 Compatible Solutes

Compatible solutes are low-molecular-weight osmoregulators that stabilize the cells and provide favorable environment for function of enzymes and other molecules inside cell in cold, heat, drought, and other stress conditions. These solutes have cryoprotective ability and maintain membrane and cytoplasm's structure and function. Different classes of compatible solutes produced by psychrophilic fungi to cope with low temperature include polyols, melanin, mycosporines, trehalose, and betaine (Ruisi et al. 2007). Cold-adapted fungi also adapt to repeated freeze-thaw cycles, low water availability, osmotic stress, desiccation, low nutrient availability, and high UV radiation (Ruisi et al. 2007).

9.2.2.1 Polyols

Polyols are organic compounds which contain more than two hydroxyl functional groups, for example sugar alcohol, including mannitol and glycerol. Synthesis of compatible solutes by enzymatic activities is elicited by induced dehydration and osmotic stress in fungi at low temperature, and glycerol is one of them (Pascual et al. 2003). Fungi use mannitol to store carbon, balance redox, and serve as an antioxidant and stress tolerant (Son et al. 2012). Turgor pressure can be controlled against decline in external water potential by raising mannitol and glycerol concentrations (Grant 2004). It is known that mannitol has protective role in water stress condition and can be used as a protective agent in cryoenvironment (Weinstein et al. 1997). Han and Prade (2002) reported glycerol and erythritol synthesis in *Aspergillus nidulans*, triggered by exposure to high salinity.

9.2.2.2 Trehalose

Increase in trehalose concentration is observed on exposure of fungi (e.g., *Hebeloma* sp., *Humicola marvinii,* and *Mortierella elongate*) to cold environment (Tibbett et al. 1998a; Weinstein et al. 2000).

Lack in ergosterol and increase in trehalose concentration in *Mortierella elongate* at low temperature have been documented by Weinstein et al. (2000). Trehalose accumulates in fungal hyphae and reproductive bodies to protect from adverse effects of low temperature (Robinson 2001).

9.2.2.3 Betaine

Betaine is glycerolipid with a non-phosphorous, polar moiety attached to diacylglycerol through ether linkage. It is found in many lower eukaryotes like bryophytes, algae, protozoa and fungi, and some prokaryotic bacteria. There are three types of betaine: diacylglyceryl-trimethyl-homoserine, diacylglyceryl-hydroxymethyl-trimethyl-β-alanine, and diacylglyceryl-carboxyhydroxymethylcholine (Murakami et al. 2018). Betaine is soluble in water and protects the cells by two mechanisms:

i) by osmoregulation to adjust osmotic pressure in and outside the cell, and ii) also acting as scavenger of reactive oxygen species. Studies indicated the presence of gene responsible for production of betaine on genome of *Aspergillus fumigatus*. Betaine is produced in a two-step process of oxidation followed by dehydration. Substrate choline is converted to betaine aldehyde (BA) by monooxygenase and BA is transformed to betaine by BA dehydrogenase (Chen and Murata 2011). Hoffmann and Bremer (2011) and Bashir et al. (2014) reported that bacteria can use betaine both as antistress molecule in extreme environment and a source of energy, whereas Lambou et al. (2013) reported fungi to use betaine as a source of carbon and energy.

9.2.2.4 Mycosporines

Mycosporine having oxo-carbonyl chromophores has been found in terrestrial fungi (Shick and Dunlap 2002). Basidiomycetous yeasts, *Rhodotorula minutia* and *R. slooffiae*, produced mycosporine-glutaminol-glucoside (Sommaruga et al. 2004). An Antarctic fungus *Arthrobotrys ferox* produced carotenoid pigments and mycosporines, having a strong role in UV protection (Arcangeli and Cannistraro 2000). Cold-adapted *Dioszegia patagonica* sp. nov, a yeast from Patagonia, accumulated carotenoid and mycosporines (Trochine et al. 2017). Mycosporines are not extensively studied in fungi inhabiting polar and nonpolar regions, but their occurrence in other fungi enables them to shield from UV.

9.2.2.5 Melanin

In mesophilic fungi, melanin plays a role as virulence factor in pathogenesis of fungi, stress protection (e.g., oxidative, UV), attachment, and penetration of appressorium (Yu et al. 2013). All biological kingdoms synthesize melanin (Eisenman and Casadevall 2012) which protects them from UV and ionizing radiation and desiccation.

9.2.3 Cold-Active Enzymes

These are known for sustaining microbial proliferation including fungi, at a very low temperature (Kuddus et al. 2011; Hassan et al. 2017). In cold environment, psychrophiles face low enzyme activity, modified transport systems, reduced membrane fluidity, and protein cold-denaturation among others (D'Amico et al. 2006). Elevated amounts of unsaturated and methyl-branched fatty acids and shorter acyl-chain fatty acids are produced by psychrophiles that increase fluidity of membrane (Chintalapati et al. 2004). Cold-shock proteins are also produced to assist in membrane fluidity or protein folding (Phadtare 2004), and antifreeze proteins hinder growth of ice crystal (Sarmiento et al. 2015). As temperature drops, proteins are denatured due to decrease in water molecule availability (Karan et al. 2012). A number of structural adaptations are known in cold-adapted enzymes that makes

these enzymes flexible as compared to mesophilic or thermophilic enzymes. It makes them catalytically active at low temperatures (Siddiqui and Cavicchioli 2006), as well as thermolabile. Psychrophilic enzymes have more flexibility and activity at reduced temperatures: high surface hydrophobicity, reduced core hydrophobicity, decreased ratio of arginine/lysine, increased glycine residues, less proline in loops, with more α-helices, more nonpolar residues on surface of protein, weaker protein interactions, hydrogen bonds and other electrostatic interactions, and less/weaker metal-binding sites, less disulfide bridges, reduced secondary structures, with increased number and size of loops, and increased conformational entropy of the unfolded protein state (Feller 2010; Cavicchioli et al. 2011). Therefore, rate of reaction in psychrophilic enzymes decreases when temperature decreases (Feller 2013). Interestingly, cold-adapted xylanases are reported more active at low temperatures, and more thermolabile at higher temperatures (Collins et al. 2002). Psychrophilic *Humicola fuscoatra* and *H. marvinii* recovered from Antarctica and solubilized produced phosphatase and extracellular protease at 15 °C (Weinstein et al. 1997). Hassan et al. (2017) reported production of lipases, amylases, phosphatases, proteases, and DNAase from different fungal species isolated from Siachen glacier, Pakistan. He et al. (2017) gave new insights into *Aspergillus oryzae* cold-adapted amylase and application of gene AmyA1 in the food and starch industries. Cold-adapted *Cladosporium herbarum* ER-25 produced extracellular invertase and assisted in removal of toxical dark-brown pigments (melanoidins) along with laccase and manganese peroxidase (Taskin et al. 2016).

9.2.4 Antifreeze Proteins (AFP)

Antifreeze protein is an effective strategy used by psychrophilic organisms, for survival at subzero temperature (Duman 2001). AFP DUF3494-type proteins are present in all domains of life specifically restricted to cold-adapted taxa (Bowman 2017). Ice growth and nucleation are hindered by AFPs and organism stays supercooled until atmospheric temperature is lowered below freezing point.

New fungal AFP has been identified and purified from psychrophilic *Antarctomyces psychrotrophicus* (Ascomycetes) (Xiao et al. 2010). AFP-producing fungi are pathogenic for different plant species (Snider et al. 2000; Hoshino et al. 2003; Hoshino 2005).

9.2.5 Exopolysaccharides (EPS)

Exopolysaccharide production is an adaptive strategy used by fungi to survive in extreme condition by preventing damages in subzero temperature. *Phoma herbarum* CCFEE 5080 from Antarctica was observed for EPS production (Selbmann et al. 2002).

9.3 Applications

Psychrophilic fungi (metabolite or whole cell) can be used as biotechnological product (Fig. 9.1) for production of compounds, and bioremediation in cold regions and their proteins can be used in medical research, molecular biology, biotechnology, detergents or cosmetics, and food or feed technologies (Margesin and Feller 2010; Tiquia-Arashiro and Rodrigues 2016).

9.3.1 Novel Source of Cold-Active Enzymes

Low-temperature-active enzymes represent a striking reserve for biotechnological applications (Santiago et al. 2016; Hamid et al. 2014; Cavicchioli et al. 2011; Tiquia and Mormile 2010), with uses in food processing, textile, detergents, feed stocks, bioremediation, cosmetics, paper, and pharmaceutical industries (Javed and Qazi 2016). Psychrophilic yeasts produce cold-active enzymes, used in fine chemical synthesis, and various domestic and environmental applications (Hamid et al. 2014). They do not require processes requiring heating that hampers the quality, sustainability, and cost-effectiveness of production at industrial level (Santiago et al. 2016), and elimination of heating results in saving substantial energy, efficient function at low temperatures, increased yield, and high stereo-specificity, and avoids the unwanted chemical reactions that occur at high temperatures. Psychrophilic fungi produce various intra- and extracellular enzymes, which enable them to confront

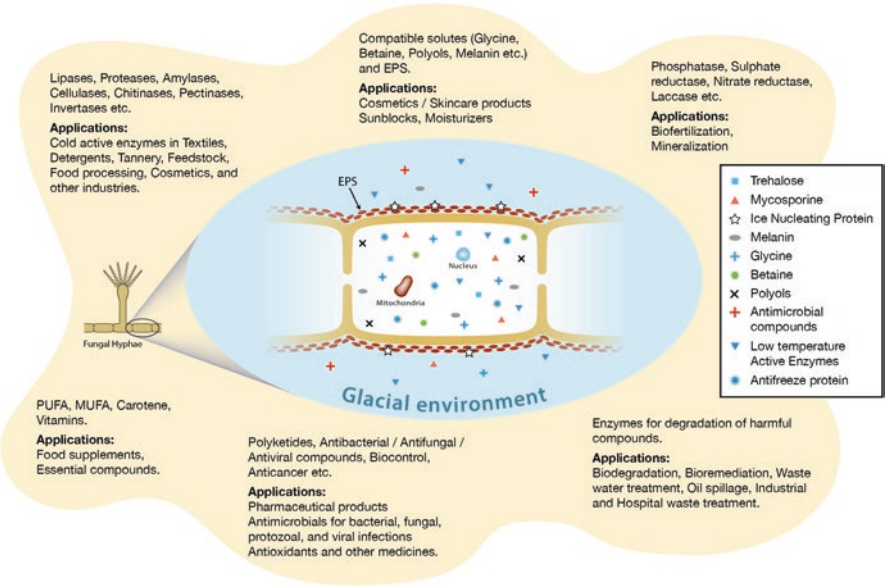

Fig. 9.1 Schematic representation of adaptation mechanisms of psychrophilic fungi that can be used for potential biotechnological purposes

and aid in harsh conditions and in degradation of large molecules and uptake of nutrients (Gerday et al. 2000; Feller and Gerday 2003; Gomes and Steiner 2004; Margesin et al. 2005).

Yeast and fungi from cold habitats deliver usefulness of fermentation procedures feasible at room temperature, that reduce production cost and influence on environment (Perfumo et al. 2018), and are economically important based on their activity at moderate and low temperatures (Allen et al. 2002; Margesin et al. 2002).

Poveda et al. (2018) isolated pectinase producing *Geomyces* sp. strain F09-T3-2 from marine sponges in Antarctica, with probable uses in food and beverage industry. Psychrophilic fungi from Baramulla (Jammu and Kashmir) produced cold-active pectinases (pectin esterase, exo-galacturanase, and endo-galacaturanase) for potential in the wine making and juice industries (Singh et al. 2012). Polygalacturonase from psychrophilic *Sclerotinia borealis* (Takasawa et al. 1997) has applicability in fruit ripening, pollen, and abscission.

Yusof et al. (2017) characterized the sequence of a chitinase produced by psychrophilic yeast, *Glaciozyma antarctica* PI12. Fungi belonging to Ascomycota and Basidiomycota from Antarctic soil and sea samples produced cold-adapted hydrolytic enzymes (e.g., phytase, glucosidase, chitinase, invertase, tannase, pectinase, lipase, protease, α-amylase, cellulase, subtilase, and xylanase) and oxidoreductases (laccase and superoxide dismutase) (Duarte et al. 2018). Cold and pH-tolerant *Penicillium* spp. produced cold-active lipases (Pandey et al. 2016).

Ascomycetes, Deuteromycetes, Basidiomycetes, and white-rot fungi produce laccases that degrade lignin and have been used in petrochemical, pulp, paper, and textile industries; food processing; medical and health care; and designing of biosensors and nanotechnology (Upadhyay et al. 2016).

Cold-active cellulases by psychrophilic microorganisms can hydrolyze biomass at low temperature and convert cellulosic biomass into monomeric sugars for bioethanol production (Tiwari et al. 2015). *Aspergillus niger* SH3 from Himalayan region (India) produced endoglucanase, *β*-glucosidase, FPase, and xylanase and can be a potential candidate for biofuel production (Tiwari et al. 2015). Cellulose decomposing *Cladosporium* (WR-C1) was isolated from a hypothermal litter layer (Da-qing et al. 2016). Cellulases and lipases produced by *M. arctica* reported to be highly active at 3 °C and have significant role in biogeochemical cycle of glacial ecosystems (Tsuji et al. 2018). *Verticillium* sp. *AnsX*1 having enhanced cellulytic activity in cold was recovered from Antarctic and has potential for bioconversion of lignocellulosic biomass into biofuels (Wang et al. 2013).

Efficient activity of endo-1, 4-β-glucanase (endoglucanase) is reported at low temperature from *Cladosporium, Penicillium, Cadophora,* and *Geomyces* by Duncan et al. (2006), and Gawas-Sakhalkar et al. (2012) reported phosphatase activity of *Penicillium citrinum, Aspergillus niger*, whereas *Aspergillus aculeatus* exhibited amylase and pectinase activity.

Psychrophilic enzymes have a great prospective as detergents for cleaning/washing at low temperature (Cavicchioli et al. 2011). Novozymes have developed Celluzyme® and Celluclean® using cellulases from cold-adapted *Humicola insolens* (Adapa et al. 2014). Mukherjee and Singh (2011) reported α-amylase with possible use in the food and textile industries and as additive in detergent for cold washing. They have a great

potential of applications in "peeling" of leather at industrial scale, baking and wine industry, food and feed industry, molecular biology, cheese ripening, resizing denim jeans, and paper industry (Petrescu et al. 2000; Mayordomo et al. 2000).

Phytase was produced by *Morchella importuna*, a psychrophilic mushroom which can be used as fish feed additive enzyme (Taskin et al. 2016).

9.3.2 Pharmaceutical Products

Fungi are reported to produce pharmaceutical products (Schulz et al. 2002) but the recovery of such bioactive metabolites from fungi of cold regions is quite rare. *Penicillium lanosum* and *Penicillium soppii* synthesized bioactive secondary metabolites such as cycloaspeptide A and griseofulvin (Frisvad et al. 2006). Psychrophilic *Penicillium jamesonlandense* produced cyclic peptides cycloaspeptide A and D (Frisvad et al. 2006). *Penicillium ribium* was found to synthesize compound, cyclic nitropeptide psychrophilin A (Dalsgaard et al. 2004a; Frisvad et al. 2006), whereas *Penicillium rivulorum* produced communesin G and H and psychrophilin B and C (Dalsgaard et al. 2004b, 2005). *Penicillium algidum* synthesized cycloaspeptide A and D and psychrophilin D (Dalsgaard et al. 2005). These cyclic peptides reported only in fungal isolates from cold habitats showed antimalarial and insecticidal properties (Dalsgaard et al. 2005; Lewer et al. 2006), along with other biological activities.

Polyketides (PKs) have antimicrobial activity and other clinically important applications. PKs promote struggle for nutrients, to demote the potentials of its competitors and to establish chemical interaction with organisms in its vicinity (Mukherjee et al. 2012). Penilactones A and B, the oxygenated polyketides, were produced from *Penicillium crustosum* PRB-2 from deep sea of Antarctic (Wu et al. 2012), and 5 fungal hybrid polyketides, including cladosins, were obtained from deep-sea *Cladosporium sphaerospermum* 2005-01-E3. Cladosin C demonstrated slight activity against influenza A H1N1 virus (Wu et al. 2014). Chloro-trinoreremophilane sesquiterpene, eremophilane sesquiterpenes, and eremofortine recovered from an Antarctic *Penicillium* sp. PR19N-1 showed cytotoxic activity against cancer cell lines (Wu et al. 2013). *Dichotomomyces cejpii* F31-1, a marine fungus, produced polyketide Scequinadoline A showing inhibitory activity against dengue virus serotype 2 production (Wu et al. 2018). Polyketide, anthraquinone-xanthone**,** from *Engyodontium album* LF069 exhibited inhibition against methicillin-resistant *Staphylococcus aureus* (Wu et al. 2016).

Psychrophilic halophilic *Penicillium chrysogenum* from Vestfold Hills' saline lake produced bis-anthraquinone (rugulosin and skyrin) with possible application as insecticide and medicine (Parker et al. 2000; Sumarah et al. 2005). Some important and potential bioactive secondary metabolites by fungi of Antarctic were documented by Marinelli et al. (2004) and Rojas et al. (2009). Fungi from King George Island, Antarctic, and Svalbard, showed antimicrobial potential against *Bacillus subtilis*, *Bacillus cereus*, *Pseudomonas aeruginosa*, *Enterococcus faecalis,* and *Escherichia coli* (Yogabaanu et al. 2017).

Moghaddam and Soltani (2014) isolated psychrophilic endophytic fungi *Phoma* sp., *P. herbarum,* and *Dothideomycetes* spp., with an ability to synthesize

metabolites active against phytopathogenic fungi and antibacterial activity against ice-nucleating *Pseudomonas syringae*. Depsipeptide, chaetomiamide, and diketopiperazines showing anticancer and cytotoxic activity were recovered from endophytic *Chaetomium* sp. (Wang et al. 2017).

9.3.3 Bioremediation Potentials

Psychrophilic microbes are useful for bioremediation of waste water and soil in temperate regions in winter. Bioremediation potential of psychrophilic fungi is not studied well yet; however, it would be quite effective in cold regions.

Mortierella sp. from Antarctica used dodecane as carbon and energy source and can be a good candidate for bioremediation of hydrocarbon spill (Hughes et al. 2007). Antarctic *Aspergillus fumigatus* degraded phenol via production of phenol hydroxylase, hydroquinone hydroxylase, and catechol 1,2-dioxygenase (Gerginova et al. 2013).

D'Annibale et al. (2006) reported *Allescheriella* sp. DABAC 1, *Stachybotrys* sp. DABAC 3, and *Phlebia* sp. DABAC 9 to produce laccase and peroxidases, and removed naphthalene, dichloroaniline isomers, o-hydroxybiphenyl, and 1,1-binaphthalene. *Stachybotrys* sp. DABAC 3 remediated 9,10-anthracenedione and 7H-benz[DE]anthracen-7-one. Dechlorination of polychlorinated biphenyls (PCBs) has been demonstrated by *Phanerochaete chrysosporium* (Bedard et al. 2006). *Candida antarctica* could degrade petroleum compounds (Hua et al. 2004).

9.3.4 Pigment/Lipid Production

Pigments and lipids synthesized by psychrophilic fungi confront low temperatures. Increased amount of lipids like fatty acids and polyunsaturated triglycerides has been found in psychrotolerant and psychrophilic fungi (Weinstein et al. 2000).

Singh et al. (2014) reported pigments (carotenoid) and fatty acids (linoleic, stearic, linolenic, myristic, heptadecanoic, and palmitic acid) from cold-tolerant fungus, *Thelebolus microspores*. Linolenic acid is used as a food supplement for patients of diabetic neuropathy, eczema, and cardiovascular disease. Carotenoid biosynthesis was also reported in *Neurospora crassa* at low temperature (Castrillo et al. 2018).

9.3.5 Exopolysaccharide (EPS) Production

The production of EPS is the response to stress or harsh conditions. Mycelium of fungi surrounded by EPS has high growth rate as compared to unembedded mycelium in response to repeated exposure to freeze-thaw cycles (Selbmann et al. 2002). *Phoma herbarum* CCFEE 5080, an Antarctic fungal isolate, showed production of exopolysaccharide identified as β 1-3, 1-6 glucan of 7.4 × 10 6 Dalton (Selbmann et al. 2002). Meristematic black fungi isolated from Antarctica were reported by Onofri (1999) and Selbmann et al. (2005) for production of extracellular polymeric

substances around their hyphae that surround their multicellular conidia and same is the case found in *Friedmanniomyces endolithicus*.

Endolithic fungus *Cryomyces antarcticus* CCFEE 515 isolated from the most comparable referent for Mars environment present on Earth, McMurdo Dry Valleys of Antarctica. It is used as eukaryotic model for astrobiological studies and in space experiments under UV and ionizing radiation (Selbmann et al. 2018).

Melanized microorganisms are dominant in harsh environments, like soils contaminated with radionuclides (Dadachova et al. 2007). Upregulation of many genes is caused by exposure to radiation, and an inducible microhomology-mediated recombination pathway is expected as a possible mechanism for eukaryotic evolution.

Exopolysaccharide is often used in cryopreservation, e.g., alginate beads containing EPS preserve the sample from freezing damage (Martinez et al. 1999). Psychrophilic Antarctic *Thelebolus* sp. IITKGP-BT12 produced EPS characterized as glucan and showed antiproliferative activity in cancer cells (Mukhopadhyay et al. 2014).

9.3.6 Biofertilization Capabilities

In nature, phosphorus is found in both inorganic and organic states, and it is one of the principal nutrients required for the crop development and increased yield. Soil comprises inorganic phosphates in insoluble form and plants cannot uptake insoluble form, it is useless for plants until solubilized. Solubilization changes the inorganic phosphates into organic soluble state, which the plants can take up.

Microorganisms play a key role in solubilization of phosphates to its organic soluble counterpart via chelation, exchange reaction, and acidification (Narsian and Patel 2000; Reyes et al. 2002). Bacteria, actinomycetes, and fungi involved in phosphate solubilization have been reported (Trivedi and Pandey 2007; Stibal et al. 2009; Nenwani et al. 2010; Singh et al. 2011). Ectomycorrhizal macromycetes (Sharma and Baghel 2010) and ectomycorrhizal *Hebeloma* (Tibbett et al. 1998b) produce phosphatase, whereas *Penicillium* and *Aspergillus niger* from nonpolar cold habitats produced inorganic phosphatase (Goenadi and Sugiarto 2000; Pandey et al. 2008). *Aspergillus niger*-1 and 2, from tundra in Arctic Archipelago of Svalbard, showed an ability for phosphate solubilization. Cold-tolerant *Penicillium citrinum* PG162 produced intracellular acid phosphatase (Gawas-Sakhalkar et al. 2012). Cold-tolerant fungi with an ability to produce phosphatase (Singh et al. 2011; Tibbett et al. 1998a, b; Gawas-Sakhalkar et al. 2012) suggest a good potential of biofertilizers in place of chemical fertilizers with efficient activity and ecofriendly characters.

9.4 Conclusions

Present review gives a detailed account of adaptability processes of cold-adapted fungi and how their strategies could be exploited for applications in biotechnology and industry. Psychrophilic fungi are a splendid resource of new and unique products and can have numerous opportunities in food industry, pharmaceuticals,

enzymes, and so on. Unfortunately, these are not studied extensively yet, and therefore hold a promising future. The fungi in low-temperature environments including icy habitats and deep-sea environments are of diverse nature and are in abundance. Their strategies to thrive under extreme conditions make them versatile and their metabolites can be of potential use in many dimensions.

9.5 Future Perspectives

This review provides a baseline or food for thought regarding the exploitation of cold-adapted fungi and their metabolites for biotechnology and industrial uses. Adaptive mechanisms of low-temperature fungi need to be investigated further on molecular and genetic basis. Two of the most important avenues are pharmaceuticals and replacing synthetic compounds with biobased or biologically synthesized metabolites of use in industry and biotechnology. Psychrophilic fungi need to be investigated in practical application for the bioremediation of domestic, industrial, and hospital wastes because they are active at low temperature and can effectively work in winter season all over the globe. Therefore, we strongly recommend bioprospecting for fungal diversity in cold habitats and investigate their processes in detail.

Acknowledgement We would like to thank and acknowledge Simon Powell, University Graphics Officer, School of Earth Sciences, University of Bristol, UK, for illustration.

Chapter 10
Melanin as an Energy Transducer and a Radioprotector in Black Fungi

Mackenzie E. Malo and Ekaterina Dadachova

10.1 Introduction

Melanins represent a unique and ancient class of pigments that exist through all kingdoms of life with well-studied biological functions, yet despite their ubiquitous nature they have been challenging to define (Solano 2014). Due to their complex composition, function, and distribution melanins can be difficult to classify, and as of yet have eluded all currently available structural analysis. The inability to define melanin structurally impedes the ability to follow the "structure defines function" paradigm, and forces innovation in the field of functional study of the pigment.

Our understanding of the role of melanin in the fungal world has been well characterized yet continues to evolve. Melanized fungi have been observed across all phyla in the kingdom, with some species existing as constitutively melanized (i.e., *Wangiella dermatitidis*), while others only produce melanin under the appropriate conditions (i.e., *Cryptococcus neoformans*) (Cordero and Casadevall 2017). Table 10.1 shows some of the melanized fungi which are considered human pathogens as well as nonpathogenic ones. The presence of melanin corresponds with enhanced survival and improved fitness, imparting an advantage in harsh environments. This is apparent when observing the high incidence of melanized fungi in such extreme locations as the damaged nuclear reactor at Chernobyl (Dighton et al. 2008), the Antarctic rocky deserts (Selbmann et al. 2015), and under simulated Mars-like conditions (Onofri et al. 2008). These three locations deliver varied forms of stress including salinity, aridity, rapid and extreme temperature fluctuations, and little to no nutritional sources, but they also share a unique form of stress: high exposure to ionizing radiation. For the purposes of this chapter we will review the

Aspergillus niger	*Cladosporium spherospermum*

properties of melanin that provides resistance to ionizing radiation within the fungal community.

The general term "melanin" refers to a family of chemically different pigments with similar properties including their dark color, insolubility, resistance to acid hydrolysis, and susceptibility to oxidizing agents (Eisenman et al. 2007). There are two common forms of melanin found in fungi including 3,4-dehydroxyphenyalanine (L-DOPA)-melanin, which is synthesized from L-tyrosine or L-DOPA, and dihydroxynaphthalene (DHN)-melanin, which is formed via the polyketide pathway (Butler and Day 1998). During melanin synthesis toxic free radical intermediates are generated, necessitating a system to protect the cell, consequently structures akin to mammalian melanosomes compartmentalize this process and transport the polymer to the extracellular space (Casadevall et al. 2017). Alternatively, some fungi are able to synthesize melanin directly at the cell surface when an extracellular precursor is available, negating the need for self-protection. Location and form of the synthesized melanin then vary depending on the species investigated. In the case of the pathogenic yeast *C. neoformans*, melanin forms concentric layers adjacent to the cell membrane, and internal to the cell wall (Wang et al. 1995). Whereas in other species the polymer is more commonly deposited within the cell wall. Despite variation in deposition locale, melanin interacts with other cellular components within the space, forming a heterogeneous arrangement with lipids, proteins, and carbohydrates. This interaction leads to the formation of a granular microstructure that can arrange to form a more ordered macrostructure that mediates the deposition of newly synthesized melanin, or the movement of other cellular or extracellular components through the cell wall, and ultimately contributing to the unique role that melanin plays (Nosanchuk et al. 2015).

Synthesis of melanin by the cell is a costly endeavor as it can account for a significant portion of the biomass of the cell. In the case of *Agaricus bisporus* it can account for as much as 30% of the dry weight of the spores (Rast and Hollenstein 1977), while for *C. neoformans* the melanized strain has a cell wall approximately double the size of its non-melanized counterpart (Mandal et al. 2007). Considering the presence under the harshest of conditions, and knowing the especially taxing nature of synthesis, melanin must contribute a significant advantage. We will now consider the biological advantage that melanin affords fungi.

Here we will review the recent literature with the goal of not simply providing the examples of the resistance of melanized fungi to ionizing radiation, but with the emphasis on the functional response of melanin to ionizing radiation and the ways

this functional response translates into the biological response of melanized fungi to ionizing radiation.

10.2 Biological Response of Melanized Fungi to Ionizing Radiation

The bacterial extremophile *Deinococcus radiodurans*, with an LD_{10} range of 2–15 kGy, is considered the most radiation-resistant microorganism (Sghaier et al. 2008), yet several melanized fungi such as *C. neoformans* and *Histoplasma capsulatum* have been shown to exhibit LD_{10} falling within that same dose range, with many more approaching the 1 kGy range, which is the standard dose for food irradiation in the US (Dadachova and Casadevall 2008). The ability of melanized fungi to survive such high acute doses of ionizing radiation, in addition to the ability to survive the harsh selective pressures of extreme environments with high ionizing radiation, is an example of *radioresistance*. Evidence for the role of melanin in enhanced survival can be found not just in its resistant to ionizing radiation, but also in its response to it.

The phenomenon of *radiotropism*, which refers to the ability to grow towards a radiation source, was observed in a number of strains of melanized fungi such as *Aspergillus versicolor* and *Cladosporium cladosporioides* that were isolated from the damaged Chernobyl reactor (Zhdanova et al. 1991). These fungal strains were able to grow towards radioactive particles, overgrow, and absorb them, and the capacity of accumulation was observed to correlate to the degree of pigmentation. This phenomenon was further characterized when it was observed that the germinating hyphae of these previously exposed spores exhibited directional hyphae growth towards a collimated source of ionizing radiation, independent of a nutritional carbon source, and was promoted by both beta and gamma radiation (Zhdanova et al. 2004). Furthermore, it was found that control fungal strains not previously exposed to radiation did not exhibit radiotrophic qualities, and it was suggested that differences could be due to the increased quantity of melanin in the responsive strains, in addition to some *radioadaptive* response due to previous exposure. Transcriptomic studies exploring the molecular and cellular response to ionizing radiation in *W. dermatitidis* have in fact shown that many transporter genes, as well as a number of genes involved in ribosomal biogenesis are upregulated specifically when melanin is present (Robertson et al. 2012), suggesting a mechanistic means by which the presence of melanin may impart advantage.

The upregulation in response to radiation positions melanized fungi for growth by improving means of nutrient transport and increasing capacity for protein synthesis. It has been shown by several groups that melanized fungal cells do in fact exhibit *radiostimulation*, or improved growth in the presence to radiation. Melanized *C. neoformans* and *W. dermatitidis* both show enhanced growth over non-melanized mutants when exposed to a 0.5 mGy/h radiation with significant increases in

colony-forming units (CFU) and ^{14}C-acetate incorporation (Dadachova et al. 2007). Improved spore germination and hyphal growth were also demonstrated in previously exposed fungal cultures relative to radiation-naïve controls, and were found to show selectivity to types of radiation, as well as correlation between response and exposure dose history (Tugay et al. 2006), further suggesting a *radioadaptive* response to ionizing radiation. DNA damage caused by ionizing radiation could promote an adaptive response, and surprisingly, one study showed that cell cycle progression genes were downregulated while a few genes involved in translesion synthesis were upregulated in response to a low dose of ionizing radiation (Robertson et al. 2012), which could provide conditions in which DNA damage could be disregarded enabling the possibility of adaptive mutations. Additionally ionizing radiation has been shown to cause global changes to DNA methylation from bacteria to murine models, presenting an epigenetic mechanism of adaptive response (Miousse et al. 2017).

Metabolic changes in response to exposure to radiation have also shown a correlation when comparing melanized to non-melanized fungal strains. Performing side-by-side metabolic assays with the cell-impermeable tetrazolium salt XTT [2,3-bis-(2-methoxy 4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide] versus the cell-permeable salt MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] allows to find out where exactly the electron-transfer events are taking place—on the surface of the cell or in the cytoplasm. It was observed in *C. neoformans* that there was an increased reduction of XTT in response to ionizing radiation only in the melanized strain, at doses similar to those at the damaged Chernobyl reactor (Dadachova et al. 2007). This result was not due to the reducing action of melanin alone, as the increase in XTT reduction was only observed in live melanized cells. Conversely, there were no marked changes in MTT reduction following irradiation in the melanized fungi, an additional support that the electron-transfer event is taking place at the cell well where melanin is located. Another experiment looked at the response of melanized *C. neoformans* to three different forms of radiation: light, UV, and gamma radiation. ATP levels were measured as an indicator of cellular energy (Bryan et al. 2011). It was noted that under all conditions, there was a reduction in ATP levels in response to ionizing radiation in the melanized *C. neoformans* relative to the non-melanized control, suggesting a universal melanin-related mechanism resulting in energy expense following irradiation. A more recent study has addressed the differences in metabolic response, as measured using an XTT assay of melanized fungi to protracted low-dose exposure in fast-growing (*C. neoformans*) versus slow-growing (*Cryomyces antarcticus*) species, and found that like the acute doses that are more represented in the literature, the melanized strains displayed increased metabolic activity relative to their non-melanized controls despite the two species having significantly varied metabolism (Pacelli et al. 2018).

Compiling what has been presented thus far it can be suggested that the melanin-related response to irradiation occurs over a broad range of dose rates, under a variety of metabolic models as demonstrated by the various species studied, and in response to different forms of radiation. To assess the mechanism by which melanin

contributes to *radioresistance*, *radiotropism*, *radiostimulation*, and altered cellular metabolism we will address the functional role of melanin.

10.3 Functional Response of Melanin to Ionizing Radiation

The macrostructure that melanin forms in fungi whereby granules are deposited in the extracellular space as a heterogeneous and rigid structure surrounding the cell or spore suggests a role in *physical shielding*. To assess the role of melanin in *radioresistance* melanized and non-melanized forms of two fungal species were subjected to lethal and sublethal doses of radiation and it was determined that the spherical spatial arrangement of the melanin acted as a shield using the Compton effect to protect the cells from high-energy photons and improving overall survival (Fig. 10.1) (Dadachova et al. 2008). Furthermore, when melanized and non-melanized *C. neoformans* cells were exposed to either sparsely ionizing gamma radiation or densely ionizing alpha particle or deuteron irradiation, the melanized cells showed increased structural stability, as demonstrated by using transmission electron microscopy (TEM) to assess cellular morphology following irradiation (Fig. 10.2) (Malo et al. 2018). It was observed that the presence of a 20–30 nm thick layer of melanin provided an efficient barrier to the ionizing radiation lowering the relative biological effectiveness (RBE) of the densely ionizing radiation. It was also noted that in

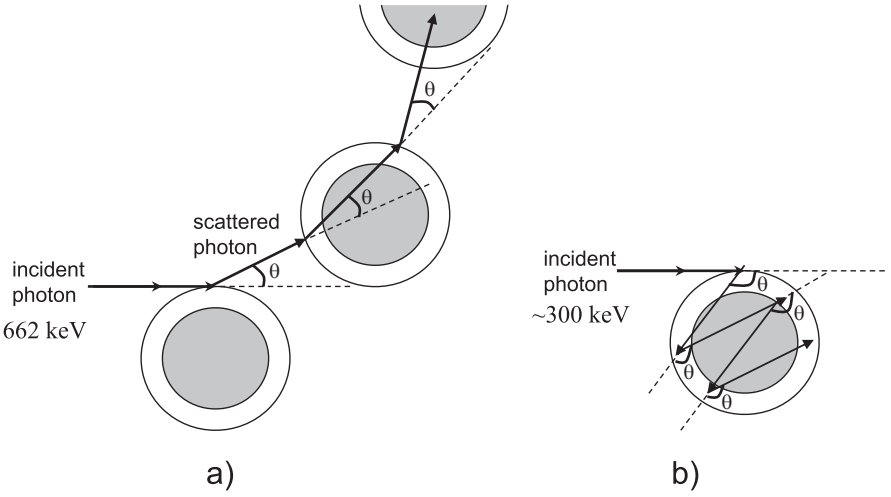

Fig. 10.1 Proposed model of scatter of ionizing radiation by melanin spheres: (**a**) forward scatter of initial high-energy photons incoming at arbitrary angle θ when forward scatter predominates; (**b**) oscillation within melanin spheres of secondary scattered photons which energies fall below 300 keV and both forward and backward scatters take place with backward scatter starting to predominate. *Source* Dadachova et al. Fig. 10.2 Micrographs of melanized and non-melanized *C. neoformans* cells obtained with TEM following alpha particle irradiation. *C. neoformans* cultures were subjected to a sham exposure and to low and high alpha particle irradiation at 0, 150, or 500 Gy (dose rate 72 Gy/min, energy 8.5 MeV). (**a**) H99 strain grown in the presence of L-DOPA; (**b**) H99 strain grown without L-DOPA. Scale bar, 200 nm. *Source* Malo et al. (2018). Copyright @ Fungal Biology (Elsevier). Reproduced with permission

several metabolic studies where MTT activity and ATP levels were measured, the non-melanized controls had higher MTT levels and ATP levels were further depleted following irradiation (Dadachova et al. 2007; Pacelli et al. 2018). It was suggested by the authors that in response to ionizing radiation the cell was upregulating metabolism in order to respond to the radiation assault, while the melanized strains were physically shielded.

Physico-chemical studies have also confirmed the high degree of stability and resistance to ionizing gamma irradiation of melanin occurs first by reducing the energy of the radiation by the Compton effect followed by the capture of the resulting recoil electron by the stable free radicals in the pigment (Schweitzer et al. 2009). This protective effect has also been demonstrated in a study where mice were fed a melanin-containing black edible mushroom prior to total body irradiation with 9 Gy (Revskaya et al. 2012). Among the mice that were fed with the melanin-containing mushrooms, or white mushrooms supplemented with melanin, 80% survived the dose, while all mice not fed melanin died from gastrointestinal syndrome. The barrier-like *physical shield* that melanin provides clearly protects varied organisms from damage caused by ionizing radiation, but it also appears to provide *chemical shielding* in response to increases in reactive oxygen species (ROS) from resulting free electrons and the radiolysis of water.

The unpaired electrons in melanin readily interact with free radicals and other reactive species providing a melanin-dependent antioxidant system in melanin-containing organisms (Shcherba et al. 2000). In fungi previously reported to present *radioadaptive* properties, it was demonstrated that ionizing radiation induced an upregulation in the expression of melanin almost twofold in addition to increasing activities of several other melanin-regulating enzymes, significantly increasing the antioxidant capacity of the organism (Tugay et al. 2011). More recently, using novel electrochemical reverse engineering methods, two forms of melanin, including a fungal-derived melanin, were shown to have rapid and repeatable scavenging activities (Kim et al. 2017) which would be essential to a radioprotective role in response to ionizing radiation, which generates ROS. In addition to further characterizing melanin's scavenging capabilities this study demonstrated that it was linked to melanin's redox activity. The observation of melanins' redox capability within a physiological range indicates that the pigment could be sensitive to redox content in vivo which suggests a possible role in energy harvesting or redox signaling (Liu et al. 2017).

The concept of *radiosynthesis* is analogous to photosynthesis, in that it proposes a mechanism by which the energy from radiation is converted to chemical energy, and is a phenomenon suggested to explain radiation-induced growth observed in melanized fungi (Dadachova et al. 2007). Melanin is capable of electron transfer, and following irradiation, the velocity of electron transfer increases, and using electron spin resonance spectroscopy (ESR) a stable free radical can be detected in melanin that is altered in response to irradiation. Other studies have also demonstrated the ability for melanin to alter its redox potential resulting in the generation of an electric current following gamma irradiation (Turick et al. 2011).

10.4 Conclusions

The advantage melanin imparts on fungi starts first with its ability to act as a physical shield, reducing the RBE of ionizing radiation and reducing its potential for destruction. It then protects the organism further by scavenging for ROS generated by ionizing radiation. The physical and chemical protective qualities of melanin can explain the increases in cell survival, and the selective growth of melanized species observed in in vitro studies. This is further demonstrated in nature where it was observed that 80% of the fungal species recovered from the damaged nuclear reactor at Chernobyl were melanized (Zhdanova et al. 2000), black rock fungi are some of the only organisms capable of surviving with exposure to high solar radiation in the Antarctic deserts (Selbmann et al. 2015), and various melanized fungal species have survived cosmic radiation while exposed on the Mir Spacecraft (Novikova 2004).

Following shielding, melanin next provides advantage with its electrochemical capacity. In response to exposure to radiation melanin undergoes various electrophysical changes, demonstrates increased capacity for electron transfer, and alters

its redox potential. The melanized organism also experiences a melanin-dependent increase in growth and metabolic activity, and in some cases this increased growth carries the organism closer to source the of radiation. The correlation indicates that the changes in melanin are linked to the changes in growth. This suggests that the role that melanin is playing in resistance to ionizing radiation is as a protective agent, and as a player mediating the fungal biological response to ionizing radiation.

10.5 Future Research Directions

The key question yet to be solved is how melanin translates the electrochemical changes that occur in response to ionizing radiation into the biological changes in growth and survival in the organism. Is this due to the ability of melanin to mediate *radiosynthesis*, and if so what is the mechanism, and what pathways are involved? Alternately could it be melanin's role as a redox mediator? Due to its ability to rapidly accept and donate electrons, and its position at the interface of the extracellular and intracellular space, melanin could be positioned for an important role in cellular communication (Liu et al. 2017). If this is the case, what types of signaling events is melanin initiating in response to ionizing radiation?

Improving our understanding of how melanin mediates its effects on biological systems is important for various reasons. By exploiting the shielding properties of melanin we could develop novel methods to protect individuals undergoing radiation treatments, or individuals exposed to radiation following nuclear accidents. Uncovering the capacity for melanin-related energy transduction in fungi will allow us to consider the role that the fungi could contribute as energy generators, which could be of great importance as our global environment changes in response to global warming.

Chapter 11
Fungi in Biofilms of Highly Acidic Soils

Martina Hujslová and Milan Gryndler

11.1 Introduction

This chapter summarizes current knowledge about the diversity of acidophilic fungi and proposes new insight into their ecology. In this regard, the list of highly acidic localities (pH <3) along with the list of methodological approaches applied for studying fungal diversity and inventories of the main fungal groups and/or species connected with the studied habitats is useful in many aspects of studies of extremophilic fungi. The text of our contribution further tracts the concept of acidophilic behavior in fungi in connection with basic knowledge about the evolution of acidophilic fungi, possible strategy used for colonization of highly acidic sites, and main fungal roles within acidophilic communities. Some aspects of the above information suggest the linkage between acidophilic behavior and biofilm life strategy as an ecological phenomenon of adaptation to life in highly acidic environments including soils.

There are several review articles dealing with the diversity and functioning of acidophilic microorganisms and the whole communities. However, most of them aim mainly on prokaryotic organisms and where eukaryotic assemblage is under review acidophilic fungi are mentioned only marginally (e.g., Johnson 1998, 2012; Aguilera 2013; Aguilera et al. 2016; Quatrini and Johnson 2018). Some of the review articles focused exclusively on microbial communities inhabiting highly acidic habitats like acid mine drainage systems (Baker and Banfield 2003; Das et al. 2009; Méndez-García et al. 2015) or corroding concrete sewer environment (Li et al. 2017). The first paper summarizing particularly fungal data has been published

by Gross and Robbins (2000). The authors reviewed all fungi and yeasts isolated from habitats having pH up to 4 along with their morphological and habitat characteristics and provided a guide for identification of 81 fungal species. This chapter focuses exclusively on fungi forming the core of the fungal assemblage inhabiting highly acidic habitats (pH < 3). This is the first comprehensive view on acidophilic fungi, their diversity, functioning, and ecology.

11.2 The Concept of Acidophilic/Acidotolerant Fungi

Fungi are common inhabitants of the soil and are, as a group of organisms, highly taxonomically and functionally diversified. Fungal species can be divided into three ecological groups according to their abilities to inhabit extreme environments: mesophiles, generalists, and specialists (Gostinčar et al. 2010). Mesophiles do not tolerate extreme conditions and only their resting structures may survive under harsh conditions for a considerable time. Generalists tolerate various stressful environments but not the most extreme ones. Although they successfully populate stressful habitats in the nature, in the laboratory they grow best under moderate conditions. Specialists can tolerate or even prefer extreme environmental conditions. The specialists with some preference for extreme conditions are called extremophilic species (extremophiles). Gostinčar et al. (2010) distinguish two groups of extremophiles: adaptive and obligate. Adaptive extremophiles have much broader ecological amplitude compared to obligate ones. Though the obligate behavior is typical for prokaryotes, it is occasionally encountered also in fungi. For instance an obligate halophilic fungus *Wallemia ichthyophaga* has been isolated and described exclusively from hypersaline environments (Gostinčar et al. 2010).

Acidophiles are organisms (mainly microorganisms) capable of growing in the environments with low pH (Johnson 2012). Cavicchioli and Thomas (2000) define acidophiles as organisms that have a pH optimum for growth close or below 3. Magan (1997) delimits acidophiles as organisms showing active growth at pH values below 4. According to generally accepted consensus, the organisms inhabiting low pH habitats can be divided into three categories based on their growth optima. Extreme acidophiles have pH optima for growth lower than 3, moderate acidophiles grow best at pHs 3–5, and acid-tolerant organisms have pH growth optima at values higher than 5 but are also metabolically active in acidic environments (Johnson 2012).

Almost all fungal species known to date from highly acidic environments are able to grow at pH 1 or even lower (*Acidomyces acidophilus*) (Starkey and Waksman 1943; Gould et al. 1974; Hölker et al. 2004; Yamazaki et al. 2010; Hujslová et al. 2010, 2013, 2014; Vázquez-Campos et al. 2014). At the same time, they do not require low pH values to survive, since they can grow in a broad range of pH. With respect to the concepts mentioned above, currently known fungal species inhabiting highly acidic sites can be regarded as extreme or moderate acidophiles with broad ecological amplitude. No obligate acidophilic fungus has been described to date (Hujslová et al. 2017).

11.3 The Origin of Acidophilic Life Strategy

Extreme acidophiles are widely distributed throughout the three domains of life (Johnson 2009) and, besides prokaryotic microorganisms, they include eukaryotes like fungi, algae, protozoa, and rotifera. It appears that the ability to grow at low pH has arisen independently several times and recent acidophilic organisms thus do not have a single acidophilic common ancestor (Johnson 2012).

The evolutionary distances between acidophilic species that have been detected in Tinto River and their neutrophilic relatives showed that adaptations associated with the transition from a neutral to an acidic environment must develop relatively rapidly (Amaral-Zettler et al. 2002). This ability to adapt to environments with the broad pH range has been observed in very different evolutionary lineages (Amaral-Zettler 2013). Close phylogenetic relations between acidophilic and neutrophilic fungi (Amaral-Zettler et al. 2002, 2003; Baker et al. 2004, 2009; Hujslová et al. 2017) support the notion of rapid development of the adaptation to acidic environments.

Baker et al. (2004) suggest that acidophilic fungi have a selective advantage in surviving in acid environments that other closely related fungi do not have. It seems that highly acidic sites represent a vacant niche with limited competition. Acidophilic fungi, as weak competitors, then take their opportunity and colonize these sites (Hujslová et al. 2017). This strategy is typical for generalist species that successfully populate stressful habitats where competition with mesophiles is limited. Consequently, the generalists can be taken as a reservoir of potential candidates for the evolution of taxa specialized for living under extreme conditions because they are able to persist across a range of environments due to their "robust" genotypes (Gostinčar et al. 2010). This mechanism of colonization is probably commonly used across various extreme environments (Gostinčar et al. 2010) and extremophilic fungal communities consisting of both generalists and specialists represent the typical pattern encountered in a variety of extreme habitats, e.g., acidic, alkaline, and hypersaline (Hujslová et al. 2017).

11.4 The Main Reasons for Studying Soil Acidophilic Fungi

Fungi from extreme environments, including acidophilic ones, belong to biotechnologically most attractive organisms. They are studied as a source of enzymes and metabolites with uncommon properties and may actively participate within bioremediation processes (Johnson 1998; Baker and Banfield 2003). The review focusing on biotechnological potential of acidophilic fungi is in preparation.

The second reason is more essential. There is a notion that environments with extreme conditions were probably far more widespread during the early life of our planet. Therefore, some extremophilic organisms are representatives of archaic forms of life (Johnson 1998). However, eukaryotic extremophiles including fungi,

as noted above, are able to develop their secondary ability to grow under extreme conditions relatively quickly. These events thus probably occurred many times throughout different geological periods. As a result, the group of recent extremophilic fungi probably represents a complex mix of organisms with very different phylogenesis, ecological traits, and taxonomic position. The research on acidophilic fungal communities thus may bring radically new information about various mechanisms of adaptation and is highly desirable. Acidic soils represent complex environments with diversified mycoflora which can serve as particularly rich source of interesting fungi.

11.5 Chemical and Biological Characteristics of Extremely Acidic Environments

Highly acidic environments (pH <3) are of both natural and anthropogenic origin and their genesis is closely connected with microbial processes such as dissimilatory oxidation of elemental sulfur, reduced sulfur compounds, and ferrous iron. The first one is typically encountered in geothermal and volcanic areas where elemental sulfur is oxidized by autotrophic and heterotrophic microorganisms to sulfuric acid, which can result in the lowering of the pH (Johnson 1998).

The second and the third processes are involved in oxidation of sulfide minerals. In locations where metal sulfide-rich rocks occur, microbial oxidation together with exposure to air and water contributes to the generation of highly acidic solutions referred to as acid rock drainage (ARD) or acid mine drainage (AMD). Since sulfide minerals largely encompass metals such as Au, Ag, Cu, Zn, and Pb, the waters acidified by products of oxidation of these minerals are often rich in these elements (Baker and Banfield 2003; Tiquia-Arashiro and Rodrigues 2016) and the types and concentrations of heavy metals present in the environment are determined by local geochemistry. Extremely acidic environments may be enriched also in soluble metalloid elements, of which the most important one is arsenic (Johnson 1998). Besides high concentrations of hydrogen ions and heavy metals, high concentrations of dissolved sulfates are also typical in extremely acidic habitats (Baker and Banfield 2003; Zak and Wildman 2004). At the same time, high temperature represents the feature often encountered in these places (Brock 1978).

Highly acidic environments may be classified as oligotrophic since they contain relatively low concentrations of dissolved organic carbon that can be exploited by saprotrophic organisms as a source of nutrition. Dissolved organic carbon is derived from biomass of primary producers. In sites where sunlight is missing, like abandoned deep mines, the dissolved organic carbon is produced exclusively by chemolitho-autotrophic organisms and, as such, is of strictly prokaryotic origin (Johnson 1998). Illuminated sites mainly depend on photoautotrophic acidophiles including eukaryotic microalgae (Johnson 1998; Amaral-Zettler et al. 2002). Heterotrophic microorganisms including fungi depend on carbon nutrition derived from biomass of primary producers (Johnson 1998, 2012). Potential extraneous

sources of organic matter like bat guano or wooden components of mine roof supports in subterranean environments as well as terrestrial organic carbon sources such as leaf litter accumulated on the surface of acidic soils can be encountered as sources of organic matter potentially available for saprotrophic acidophiles (Das et al. 2009; Johnson 2012).

11.6 Acidophilic Fungi in Biofilms

Since acid mine drainage systems represent the global environmental problem, these sites have been extensively studied. The most abundant biological structures encountered in these places were the microbial communities forming biofilms. This is not surprising if the ability of the organisms to live in biofilms represents an adaptation to extreme environmental conditions, including acidity. In abandoned pyrite mine Cae Coch in North Wales, streamer and slime growths have been estimated to exceed 100 m^3 in volume. It is the largest accumulation of macroscopic acidophilic biomass yet described (Johnson 1998). Macroscopic structures like streamers, slimes, mats, snottites (stalactite-like structures), and drapes were found to cover 30% of the surfaces occurring in the acidic mine drainage environments (Méndez-García et al. 2015). These microhabitats differ in physicochemical factors like temperature, pH, and ionic strength, and thus harbor communities formed by different microorganisms (Baker and Banfield 2003).

Fungi have been described as an abundant element of the acidophilic biofilm and the biomass of fungal hyphae represents a significant portion of the total biomass in biofilm communities (Baker and Banfield 2003). This finding has been confirmed by microscopic observation (Baker et al. 2004; López-Archilla et al. 2004a; Zirnstein et al. 2012) as well as culture-independent approaches like fluorescent in situ hybridization (FISH) and cloning and sequencing of SSU rDNA gene (Bond et al. 2000; Amaral-Zettler et al. 2002; Baker et al. 2004, 2009; Zirnstein et al. 2012). High amounts of the fungal biomass have also been confirmed by analysis of intact polar lipids and total fatty acids (Bühring et al. 2012). In addition, Zirnstein et al. (2012) have found out that fungal hyphae made up between 10 and 20% of the total cell biomass in stalactite biofilms compared to approximately 5% portion in acid streamer biofilms. Higher amounts of fungal filaments were observed in flowing acid mine drainage solutions than in pools where the water was stagnant (Baker et al. 2004). Fungi belong to the most abundant groups in mature biofilms (Wilmes et al. 2009; Zirnstein et al. 2012).

It is thus obvious that fungi provide the backbone for three-dimensional structure of biofilms, anchor them to physical surfaces, and serve as secondary surfaces for other organisms during the biofilm development (Baker and Banfield 2003). Filamentous character of hyphae of mycelial fungi may contribute to mechanical stability of biofilm structures and may speed up the transport of metabolites within the volume of macroscopic biofilms. This “mechanical” function of biofilm fungi may be of great ecological importance. Wilmes et al. (2009) described that fungal

filaments in mature biofilms provide structural support for pellicles subjected to shear stress in flowing streams. Robbins et al. (2000) have mentioned that fungi significantly help to form drip (stalactite) structures. Another example of significant contribution of fungi to formation of biofilms has been provided by Amaral-Zettler et al. (2003) in highly acidic Tinto River.

Because the majority of soil microorganisms are living as members of the biofilm, it is probable that significant analogies in the ecology of acidophilic organisms inhabiting the soil and organisms inhabiting biofilms in other acidic environments (slimes, mats, and snottites mentioned above) do exist. Unfortunately, the function of filamentous fungi in biofilms inhabiting acidic soils was hitherto almost neglected in spite of the fact that the contribution of fungi to the formation of three-dimensional cohesive biofilms may stabilize soil structure.

11.7 Diversity of Acidophilic Fungi

Since prokaryotic members of acidophilic microbial communities actively participate on the genesis of extremely acidic places, the majority of investigations have been focused on bacterial communities. Nevertheless, the evidence of eukaryotic life, including the fungal one, in extremely acidic habitats has been gathered as well. One of the first observations of fungi in a highly acidic substrate has been presented by Starkey and Waksman (1943) who obtained two fungal isolates from acid solutions containing copper sulfate having pH values between 0.2 and 0.7. Later Sletten and Skinner (1948) isolated two fungi from a sulfuric acid-rich solution, and these two isolates were identical to the one of the fungi mentioned by Starkey and Waksman. In 1953, a report of microbiological assemblage inhabiting acid mine waters in West Virginia and Pennsylvania was presented by Joseph (Joseph 1953). Seven fungal genera have been detected during this study. Later on, altogether 186 fungal species have been described from acid streamers and surrounding soils from areas in Ohio and West Virginia by Cooke (1976). In 2000, Gross and Robbins summarized the data on fungi isolated from habitats characterized by pH values below 4, primarily soils, and published the list of 81 species with their morphological features along with literature sources.

During the last decades, the interest in studying acidophilic microbial communities has increased and fungi have been detected in various extremely acidic substrates including acid mine waters and sediments (López-Archilla and Amils 1999; López-Archilla et al. 2001, 2004b; Gadanho and Sampaio 2006; Oggerin et al. 2016), mine process water (Vázquez-Campos et al. 2014), acid mine biofilms (Bond et al. 2000; Amaral-Zettler et al. 2002; López-Archilla et al. 2004a; Baker et al. 2004, 2009; Macalady et al. 2007; Zirnstein et al. 2012), corroding concrete sewer environments (summarized in Li et al. 2017), oil shale by-products (de Goes et al. 2017), and soils (Hujslová et al. 2010, 2017). Some of these studies have proposed just the evidence of the fungi and their potential role within the studied substrate. Some of them have also provided the data on fungal diversity

(see Table 11.1). It is apparent that the core fungal assemblage mostly consists of species inhabiting exclusively highly acidic habitats as well as of taxa known from less acidic but otherwise extreme environments (Hujslová et al. 2017).

The first acidophilic fungi have been described in the beginning of this century. New fungal species *Hortaea acidophila* (current name *Neohortaea acidophila*) has been described from an extract of brown coal containing humic and fulvic acids at pH 0.6 (Hölker et al. 2004). Selbmann et al. (2008) have completed the data on fungal isolates published by Starkey and Waksman (1943), Sletten and Skinner (1948), and later Gould et al. (1974), Sigler and Carmichael (1974), and Gimmler et al. (2001) and concluded that the dark pigmented isolates studied in these papers are identical. The authors described them as a new acidophilic fungus *Acidomyces acidophilus*. The first record of acidophilic fungus detected in sexual state has been reported by Yamazaki et al. (2010) as *Teratosphaeria acidotherma*. Later on, this fungus has been ascribed to the genus *Acidomyces* (Hujslová et al. 2013). New acidophilic genus *Acidiella* with two new species *Acidiella bohemica* (Hujslová et al. 2013) and *Acidiella uranophila* (Vázquez-Campos et al. 2014; Kolařík et al. 2015) has been described. There is however a possibility that *Acidiella bohemica* and *A. uranophila* are conspecific (Hujslová et al. 2017). Recently, four new acidophilic fungal species *Acidea extrema*, *Acidothrix acidophila*, *Soosiella minima* (Hujslová et al. 2014) and *Coniochaeta fodinicola* (Vázquez-Campos et al. 2014) have been described.

The inventories of mycoflora of acid sites indicate wide geographic distribution of different species of acidophilic fungi. With exception of *Neohortaea acidophila* and *Soosiella minima*, all currently known acidophilic species have been reported from more than one highly acidic site (see Table 11.1). *Acidomyces acidophilus* is a typical member of the acidophilic fungal assemblage known from distinct highly acidic places (Selbmann et al. 2008; Hujslová et al. 2013). *Acidomyces acidothermus*, another extremophilic species, must be taken as a ubiquitous inhabitant of acidic environments as well, being detected in the USA, the Czech Republic, Iceland, Japan, China, and Australia (see Table 11.1).

Further, at least some species of acidophilic fungi are not strictly specialized to a particular substrate/environment. For example, *Acidiella bohemica*, originally described from highly acidic soil (Fig. 11.1), has also been detected as the most abundant species in acidic oil shale by-products (de Goes et al. 2017). In addition, Amaral-Zettler et al. (2002) probably detected this species in Tinto River by molecular tools (Hujslová et al. 2017, see Table 11.1). The capnodialean fungal isolate obtained by Oggerin et al. (2016) from Tinto River seems to be very similar to *Acidiella uranophila* described from mine waters (see Table 11.1). An acidophilic soil fungus *Acidothrix acidophila* has been detected as one of the four members of a consortium attained during laboratory cultivation of archaeal Richmond mine acidophilic nanoorganisms (Krause et al. 2017) as well as from acidic soil (see Table 11.1 and Fig. 11.2). *Coniochaeta fodinicola* belongs to one of the most abundant species at highly acidic soil of Cihelna v Bažantnici site studied by Hujslová et al. (2017) as well as in uranium mine water (Vázquez-Campos et al. 2014). The genus *Coniochaeta* has also been noticed among the most abundant fungal groups

Table 11.1 The list of highly acidic localities (pH <3) from which fungal diversity data are available

Locality	The main physicochemical characteristics	Studied samples	Methods for studying diversity	The main fungal groups/species connected with highly acidic habitats	References
Richmond mine, Iron Mountains, California, USA (subterranean)	pH 0.8–1.38 Temperature 30–50 °C metal-rich (Fe, Zn, As, Cu) High levels of sulfates	Biofilm	**Combination of culture dependent and culture independent** (18S rRNA and β-tubulin cloning and sequencing, fluorescent in situ hybridization)	Dothideomycetes ***Acidomyces acidothermus*** Eurotiomycetes	Baker et al. The main physicochemical characteristics of the studied sites, types of collected samples, methodological approaches applied for studying, and main fungal groups and/or species connected with highly acidic habitats are included. Current names are used for all taxa. Acidophilic fungal species are in bold

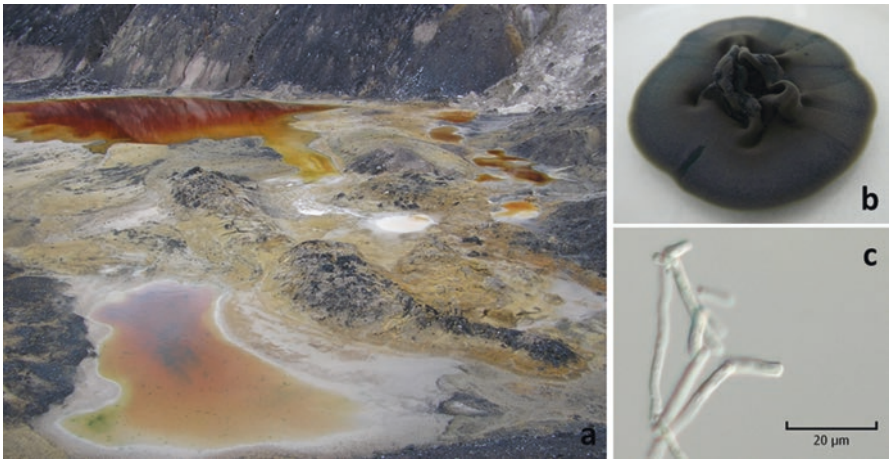

Fig. 11.1 (**a**) General view of Mírová kaolin quarry; (**b**) *Acidiella bohemica*. Colony on MEA at 24 °C, 28 days; (**c**) Thin-walled mycelium fragmented to arthroconidia. Microscopic photo was made by Miroslav Kolařík

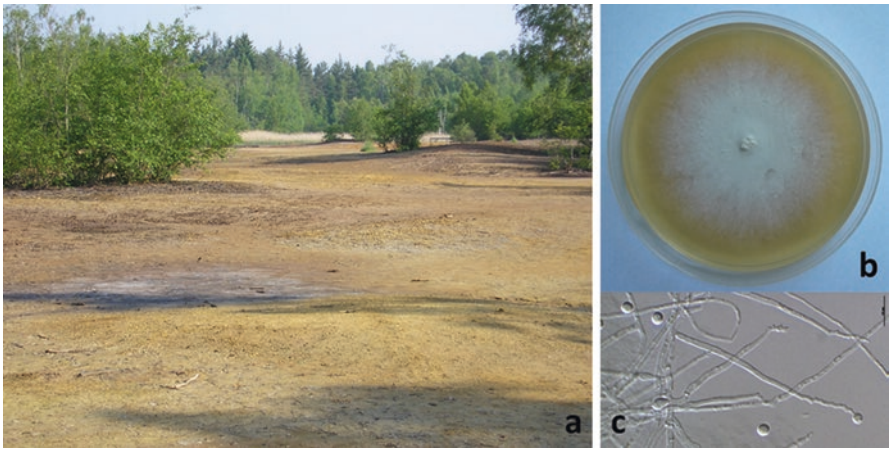

Fig. 11.2 (**a**) General view of Soos National Nature Reserve; (**b**) *Acidothrix acidophila*. Colony on MEA (pH 2) at 24 °C, 21 days; (**c**) conidiophores and conidia. Microscopic photo was made by Miroslav Kolařík

detected in Tinto River by López-Archilla et al. (2004b) (see Table 11.1). Another fungus dominating in highly acidic soil, *Acidea extrema*, probably occurs in Tinto River locality since two eukaryotic rDNA clones RT3n5 and RT5in6 found here by Amaral-Zettler et al. (2002) and a clone C573 detected at the same locality by Gadanho and Sampaio (2006) seem to be similar to this species (see Table 11.1).

Nevertheless, compared to other acidophilic fungi, *Acidea extrema* is not exclusively associated with highly acidic sites as it has been reported from slightly alkaline Antarctic soil with pH 8 as well (Hujslová et al. 2014).

Several other fungi, such as *Penicillium* species, *Aspergillus fumigatus*, *Hypholoma fasciculare, Talaromyces helicus* var. *major*, and *Trichoderma harzianum*, are present in highly acidic soils (Hujslová et al. 2017). Indeed, the list of hitherto known acidophilic fungi is not complete because many highly acidic environments, especially soils, were still not studied in this regard and the overview of the taxa presented in Table 11.1 must be taken as provisional.

Insufficient identification of the fungal taxa to the species level in many cases hampers the precise comparison of the fungal communities in different acidic environments. It is, however, apparent that acidophilic fungal assemblage is worldwide similar and it is much more diversified than it has been supposed so far (Hujslová et al. 2017). Considerable portion of the above-cited observations of extremophilic fungal taxa in acidic soils and other acidic substrates strongly suggests that it is the acidity of the environment and not its type (i.e., soil vs. acidic waters) what determines the community of the inhabiting fungi. Thus, some similarities in composition and behavior of acidophilic mycoflora can be supposed across different acidic substrates/environments.

11.8 The Main Functions of Fungi in Acidophilic Communities

Just as in other habitats acidophilic fungi actively participate in carbon cycling as decomposers (e.g., Méndez-García et al. 2015; Mesa et al. 2017). They keep organic carbon levels low and produce dissolved carbonate ions, which are likely important for the growth of chemolitho-autotrophic acidophilic prokaryotes (Baker and Banfield 2003). Baker et al. (2004) proposed that fungi may impact the community structure and function by the consumption of organic waste products and the production of organic polymers and other compounds, possibly including antibiotics.

Recently, the application of omics-based technologies helps to reveal genetic background of fungal role in metabolism of acidophilic biofilm community (Mosier et al. 2013, 2016). For example, the fundamental role of the melanized fungus *Acidomyces acidothermus* in metabolism of taurine, the compound that protects the organisms against osmotic stress, was noted. In addition, this fungus actively participates in biosynthesis of phosphatidylethanolamine lipids that may prevent the excessive uptake of Fe cations (Mosier et al. 2013).

The upregulated transcripts produced by *Acidomyces acidothermus*, involved in denitrification and in degradation of complex carbon sources, were detected in floating biofilms. On the contrary in streamer biofilms transcripts linked to central carbon metabolism and stress alleviation are upregulated (Mosier et al. 2016).

Another natural process in which acidophilic fungi also actively participate is biomineralization, biologically assisted formation of minerals (Oggerin et al. 2016). An example of biomineralization is the formation of jarosite, a basic hydrous sulfate of potassium and iron, associated with acid mine drainage and acid sulfate soil

environments. Formation of this mineral is assisted by acidophilic filamentous fungus *Purpureocillium lilacinum* which has been isolated from the banks of Rio Tinto (Oggerin et al. 2013).

11.9 Methodology Used in Studies of Acidophilic Fungi

Already the first studies using traditional cultivation approaches provided the evidence of fungi inhabiting highly acidic habitats and the basic knowledge dealing with their diversity and ecology. The identification of the obtained isolates was based exclusively on morphological features. Later on, the application of molecular markers such as 18S, 28S, ITS rDNA, or β-tubulin gene contributed to the more accurate identification of the isolated strains and first acidophilic fungi have been reliably distinguished as taxonomical units (e.g., Selbmann et al. 2008; Hujslová et al. 2013, 2014; Vázquez-Campos et al. 2014). The use of culture-independent approaches helped to reveal the portion of fungal diversity that escaped attention using classical cultivation methods. All methods used for studying fungal diversity in highly acidic sites are summarized in Table 11.1.

Advanced molecular technologies have been used to elucidate genetic background of the functioning of acid mine drainage biofilm community of Richmond Mine. Within the frame of this study, the reconstruction of partial genome of *Acidomyces acidothermus* has been performed, providing the insight into the main metabolic pathways in which this fungus actively participates (Mosier et al. 2013, 2016). It is probable that similar molecular approaches will be used more extensively in future to further increase our understanding of life in highly acidic habitats.

The investigations focusing on isolation of fungi inhabiting extremely acidic soils applied traditional cultivation techniques that are commonly used for isolation of soil fungi. These methods were based on direct inoculation and suspension plating method. Classical cultivation media like malt extract agar or soil extract agar (pH 5.5) as well as special media with low pH value (pH 2) were used to cover the demands of various fungi from those preferring soil with moderate pH to acidotolerant/acidophilic ones (Hujslová et al. 2010, 2017).

If the extreme values of pH are to be simulated in isolation media for acidophilic fungi, high concentrations of agar have to be used to reach satisfactory solidity because the solidification of agar is difficult under acidic conditions (Hujslová et al. 2013). High concentration of agar is an unnatural attribute of the cultivation medium which probably leads to stimulation of growth of some organisms and suppression of the growth of others (Harris 1985).

Still other methodological aspect of the isolation of fungi from acidic biofilms may be important: the purification of isolates. As the fungi are typically present in acidic environments (soils) as members of complex communities and, at the same time, are typically slow growing, they have to be mechanically separated from other community members before cultivation attempts. The failure in this step may con-

stitute a serious obstacle for the obtaining of pure isolates. The separation of microbial cells is not always an easy task, mainly if the soil biofilm is used as a source of isolates (M. Hujslová and M. Gryndler, unpublished observation). In these cases, the isolation efficiency might be potentially increased by using selective antibiotics added to the cultivation medium.

The above text suggests that contemporary isolation techniques may be insufficient to cover a representative portion of the acidophilic mycoflora diversity. The obtaining of cultures of many important acidophilic organisms including fungi is probably not possible which, in turn, makes taxonomic and ecological studies very difficult. Any future progress in isolation technique development thus may bring new perspectives for the research of acidophilic mycoflora of biofilms in general and soil biofilms in particular.

11.10 Conclusions

A considerable portion of acidophilic fungi that inhabit acidic waters and biofilm accumulations can also be found in soils. At the same time, the formation of biofilms in acidic environments, including soils, may represent the adaptation to extreme acidity. This strongly suggests that acidity is the most important factor that determines microbial community behavior and composition at the site, probably regardless of the type of the environment. Further, hitherto performed inventories of mycoflora of acid sites show wide geographic distribution of different species of acidophilic fungi.

The above facts suggest that acidophily in fungi, connected with their life strategy as biofilm inhabitants, represents a general ecological phenomenon that merits serious scientific study. More detailed knowledge in taxonomy, physiology, and diversity is needed for deeper understanding processes and adaptations used by acidophilic fungi in soils. Specific research techniques directed to fungi inhabiting acidophilic biofilms should be developed.

Chapter 12
Global Proteomics of Extremophilic Fungi: Mission Accomplished?

Donatella Tesei, Katja Sterflinger, and Gorji Marzban

12.1 Introduction

12.1.1 Extremophilic and Extremotolerant Fungi as Model Organisms for Stress Resistance

Extremophiles are organisms living under conditions that extend far beyond those considered optimal for human life and therefore grow under extremes of temperature, pH, salinity, pressure, radiation, or other limiting constraints (Burg et al. 2011). Organisms, which tolerate and thrive at the edges of the extreme conditions and can only grow optimally under more human environmental conditions, are instead known as extremotolerants (Cavicchioli 2002).

That of extreme is a rather relative concept, as it has been shaped based on the ambient parameters supporting mammalian life (Selbmann et al. 2013). Nevertheless, it has become clear that life under extreme environmental conditions is mostly a prerogative of microorganisms (Gunde-Cimerman et al. 2003). An increasing number of investigations carried out during the last decades showed the ability of fungi to sustain and even to thrive at different environmental extremes such as permafrost, snow and glacier ice (Abyzov et al. 1998; Nienow and Friedmann 1993), cold and hot deserts (Selbmann et al. 2005), ocean depths (López-García et al. 2002), hypersaline waters (Gunde-Cimerman et al. 2000), acidic environments (Selbmann et al. 2008), and areas contaminated by pollution and radioactivity (Blasi et al. 2017; Dadachova and Casadevall 2008).

The organism life expectancy seems to be connected to either existing or extraordinary fast adaptive cellular or metabolic characteristics (Magan 2007). Eukaryotic

cells have evolved over millions of years tailored cellular response to both biotic and abiotic stresses in the natural ambiance, which manage several aspects of cell machinery like gene expression, metabolism/catabolism, cell cycle, cytoskeletal arrangement and homeostasis, as well as modification of enzymatic activity (Mafart et al. 2001). Such stress tolerance reactions can produce both immediate and long-term adaptations—the latter called S-selected strategies—which are especially crucial for the survival of an organism under continuous exposure to extreme environmental parameters (Magan 2007).

Due to their fascinating lifestyle, extremotolerant and extremophilic organisms may serve as model organisms for studies of the stress resistance aiming at the elucidation of the molecular basis of survival. Moreover, proteins and metabolites from extremotolerant and extremophilic producers offer some advantages over novel proteins and bioactive components from less tolerant microorganisms. Enzymes produced by both thermophiles and psychrophiles have for instance received particular attention for their commercial value (Tiquia-Arashiro 2014; Tiquia-Arashiro and Rodrigues 2016). The search for new products and compounds has additionally promoted a renaissance for unusual and interesting organisms as emerging model systems, which also include black fungi, a morphological group of ascomycetes, whose physiological features include a high stress resilience (Onofri et al. 2012; Pacelli et al. 2016; Selbmann et al. 2014; Sterflinger et al. 2012). Previous studies suggested that this group of fungi, which is specified by melanin generation and absence of sporulation, has adapted survival strategies quite different from those of the majority of fungal species (Blasi et al. 2017; Tesei et al. 2017). Hence, an extended knowledge about the systems biology of extremophiles is of crucial impact.

12.1.2 Black Fungi

Microcolonial fungi (MCF) and black yeasts are among the most stress-resistant eukaryotes known up to now (de Hoog and Grube 2008). Grouped under the general name black fungi, they represent a heterogeneous taxonomic group having polyphyletic origins within the orders of *Ascomycota Chaetothyriales*, *Dothideales*, *Capnodiales*, *Pleosporales*, *Xylariales*, *Myriangiales*, *Mycocaliciales*, and *Hysteriales*, among others (Selbmann et al. 2008). While MCF prevalently live on rock substrates, several black yeast species have a life cycle in association with plant, animal, and human hosts (Fig. 12.1). Black fungi's high stress tolerance is demonstrated by the wide geographical distribution, which includes the most extreme habitats on the planet—ranging from mountain peaks (Branda et al. 2010) to nuclear power plants (Selbmann et al. 2014)—where the life of the majority of organisms is at risk. The role of black fungi as human opportunists and pathogens (Woo et al. 2013), as degraders of volatile compounds (Prenafeta-Boldú et al. 2012), and as a dominant member of the epi- and endolithic microbial populations (Sterflinger and Krumbein 1997) has additionally emerged (Sert et al. 2007).

Survival tests demonstrated how these organisms can cope with extreme physicochemical stress factors far beyond those in their natural habitats. Additionally some species showed resistance against high doses of ionizing radiation, by conversion of β and γ radiation into chemical energy used for growth (Dadachova et al. 2007; Pacelli et al. 2016; Robertson et al. 2012). On these premises, pathogenicity has been reconsidered as the result of the combination of extremotolerance and assimilative abilities of aromatic compounds, together enhancing the nature of black fungi, which is primarily opportunistic (Teixeira et al. 2017). Further investigations demonstrated the ability of black fungi, especially MCF, to endure outer space as well as simulated Martian conditions (Onofri et al. 2012; Zakharova et al. 2014a), thereby giving support to the hypothesis of lithopanspermia and interplanetary transfer of life (Onofri et al. 2008).

Microcolonial growth morphology; strong melanization of the multilayered cell wall; synthesis of carotenoids, exopolysaccharides (EPS), trehalose, and polyols; and lack of sexual reproductive structures are adaptations to the extreme environments spread across the black fungi group, despite its polyphyletic origins (Mafart et al. 2001; Magan 2007). While melanin plays a role in UV protection, pathogenicity, and improving the desiccation and radiation tolerance, polyols and trehalose act as osmoprotectants and as stabilizer of enzymes and membranes, respectively. The absence of spores or conidia results in the use of each single vegetative cell as both a survival and a dispersal state and represents a crucial energy-saving mechanism under unfavorable life conditions (Pacelli et al. 2016).

Multi-OMICS analyses recently performed on black fungi species indicate that these organisms have a rather different strategy to cope with nonoptimal conditions than other fungal species. The presence of "stress-resistant" proteins and the thermostability of the basic set of proteins have been suggested to be crucial aspects of the ecological plasticity that characterizes black fungi (Tesei et al. 2015b). The potential of these organisms however does not solely lie in the protein pool. Transcriptomics studies recently carried out showed how black fungi recur to further mechanisms of tolerance involving diverse *RNA* species. *CircRNAs*, *ncRNAs*,

and fusion transcripts seem to enable the synthesis of proteins under temperature stress, thus being at the base of both survival and pathogenicity (Blasi et al. 2015; Poyntner et al. 2016).

The scientific results obtained over the last few years of research demonstrated how black fungi offer potential as natural resource of novel proteins and compounds, the latter acting as stabilizer of proteins and cellular structures (Armengaud et al. 2014; Gostinčar et al. 2012; Moreno et al. 2018; Seyedmousavi et al. 2014; Sterflinger et al. 2012; Tesei et al. 2017; Zakharova et al. 2014a). This combination of properties supports the adaptation not only to temperature changes but also to a multitude of other biotic and abiotic factors like osmotic, UV and oxidative stress, desiccation, water supply, and nutrient availability (Vember and Zhdanova 2001) and might prove to be of great biotechnological significance. The study of black fungi ecophysiology and adaptations could additionally provide tools to shed light on the actual limits for life and the existence of life beyond planet Earth.

The investigation of the proteome—as a pool of all synthesized proteins, their abundance, variations, and modifications as well as their interactions and networks (Aebersold and Mann 2003; Geisow 1998)—in part already had and will aid to improve the understanding of the ecology, physiology, and system biology of these organisms. Analyzing protein expression profiles and their modulation under a given set of conditions that are out of the organisms' growth range or beyond those considered optimal for human life could thereby provide invaluable information about the cellular mechanisms of stress resistance.

12.1.3 Discovery of the Stress Adaptation in Extremophilic and Extremotolerant Fungi by Proteomics

Investigations of the proteome—as a global collection of all expressed proteins in response to one single physiological state (Wasinger et al. 1995)—can play an important role in the elucidation of the ecophysiology of the adaptive behavior toward different kinds of stresses. As the product of transcription and translation, protein processing, and turnover (Burg et al. 2011), a proteome contains the whole information about the proteins that are synthesized, their abundance, variations, modifications, interactions, and networks (Aebersold and Mann 2003; Geisow 1998; Pandey and Mann 2000). Proteomic measurements are achieved through a combination of highly sensitive instrumentation and the application of powerful computational methods to produce high-throughput qualitative (i.e., protein identity) and quantitative (i.e., protein abundance) data and therefore simplify the clarification of cellular pathways and processes in a given cell as well as a community. On this premise, proteomics of extremophilic and extremotolerant fungi allow to understand the modifications at the base of structure and stability of proteins, biologically active under extreme conditions (Evilia 2018). Discovery of adaptive

mechanisms helps, therefore, to develop strategies at gene and protein level toward novel therapeutics and biotechnological innovations.

Despite the extremophilic character of fungi is known, there is still very little information regarding the molecular mechanisms, which lie behind their stress resistance. The majority of studies about microbial adaptation mechanisms have been indeed so far focused on the stress response of a low number of widely investigated mesophilic model organism such as *Candida*, *Penicillium*, and *Saccharomyces*, among others. During the last decade the number of "omics" studies concentrated on stress-resistant fungi has increased significantly and reached over less known species, thereby raising our understanding of the system biology of those microorganisms to a higher level (Moreno et al. 2018). However, the knowledge at the functional proteomic level is unfortunately still poor, mainly due to the challenging application of protein techniques to extremophiles, whose major bottleneck is the sample preparation. The lack of proteomics data for most of extremophiles indeed indicates major analytical and methodological challenges (Marzban et al. 2013). As a consequence of the adaptation to extreme conditions, proteins have evolved a range of specific properties (Siddiqui and Thomas 2008), which actually hamper the extraction and separation procedures. Generally, thermostable and chemical denaturant-resistant proteins hardly undergo denaturation, while proteins with altered surface charges—e.g., from acidophiles or alkaliphiles—usually cause migration troubles in the isoelectric focusing (IEF) (Burg et al. 2011). Similarly, less water-soluble proteins—from organisms inhabiting dry environments—are susceptible to irreversible precipitation.

In the case of black fungi, the rigid cell wall and the high content of melanin, pigments, polysaccharides, and lipids represent major obstacles to cell disruption and to protein determination and separation, respectively. Moreover, the fungal protein solubility is quite low and tends toward spontaneous precipitation (Marzban et al. 2013). Therefore, the low protein yield and the high content of impurities represent the major issues toward the proteomics of extremophilic fungi. The analysis of their protein profiles thereby requires optimization and a case-by-case assessment of the protein preparation and separation procedures. Although the molecular basis of both extremotolerance and extremophilia is far from being clarified, crucial indications have been obtained. Comparative proteomic profiling methodologies such as classical 2D-E and 2D-DIGE and the more recent shotgun proteomics techniques have been applied to the investigation of the response mechanisms toward a number of stress like supra- and sub-optimal temperature values, salinity, pH, desiccation, Mars-like conditions, and host-pathogen interaction (Magan 2007; Onofri et al. 2012; Seyedmousavi et al. 2013; Wasinger et al. 2013). The analysis of the repertoire and abundance of proteins for both the rock inhabitant and pathogenic species under temperature stress reported striking changes in the proteome. Interestingly, rock-associated species with different ecology and distribution all react to temperatures far above their growth optimum by decreasing the number of expressed proteins. The opposite trend is instead observed as a result of the exposure to temperatures far below the optimum (Tesei et al. 2012). A similar reaction was detected in the thermophilic and pathogenic species *E. dermatitidis*; however

high temperature (45 °C) seemed not to induce any stress response, likely reflecting the high level of adaptation of the fungus to elevated temperature. Long-term exposure to the cold (1 °C) reduced metabolic activities of carbon and pyruvate metabolism, along with triggering rearrangements of the cell wall and cell membrane (Tesei et al. 2015a). Downregulation of genes involved in metabolic processes, including metabolism of amino acids, carbohydrates, and glycolysis, is consistent with and complementary to earlier reports in *E. dermatitidis* transcriptomics (Blasi et al. 2015). A downregulation of the metabolism seems to represent the typical response of black fungi also upon desiccation and the exposure to Mars-like conditions (Co_2 and pressure) (Zakharova et al. 2014a). While this phenomenon is mostly observed in extremophilic species, extremotolerant mesophilic black fungi react to water loss by expressing additional proteins (Zakharova et al. 2013). These results mostly indicate that black fungi, independently on their ecotype, habitat, and degree of specialization, play similar strategies while coping with nonoptimal environmental conditions. Such strategies additionally appear to be quite different from the stress response mechanisms exhibited by other fungal species like mesophilic hyphomycetes (Jami et al. 2010a) and human fungal pathogens (Enjalbert and Whiteway 2003; Jami et al. 2010a), where a HSR is generally observed. A direct connection between the extremophilic nature of the organisms and the minimization of changes at the protein pattern level has been further detected and can be explained with the recourse of black fungi to energy-saving mechanisms. On this basis, a fine-tuning regulation of the protein expression upon unfavorable growth conditions—mostly involving housekeeping proteins—was suggested. Temperature and desiccation-resistant proteins might constitute a basic set of proteins commonly present in black fungi and supporting the tolerance of temperature and desiccation stress. If morpho- and physiological characters—spread across the black fungi group—were initially considered as the main factors responsible for the stress resistance, these studies demonstrated that a fine modulation of the proteome indeed plays a major role in the survival of these model organisms.

The combination of different proteomics workflows and bioinformatics analyses will allow in the near future to gain information about protein identities and functionalities as well as cellular pathways and processes, involved in the survival of these organisms. The availability of whole-genome sequences and annotation in particular has already had a key role in accelerating the study on mechanisms of adaptation. Comparative genomics has proved that extremophiles in general possess the unique set of genes and proteins that empower them with biochemical machinery necessary to thrive in extreme environments (Kumar et al. 2018). One such example of adaption is the initiation of the unfolded protein response (UPR) in psychrophiles. It is known that the rate of protein folding is adversely affected by low temperature (Piette et al. 2010). The activation of UPR and the simultaneous upregulation of the proteasome and induced expression of genes involved in protein folding aid in maintaining protein-folding homeostasis of the ER under temperature stress (Su et al. 2016). In organisms thriving in hypersaline environments, both genome alterations and protein structural modifications were reported (Plemenitaš et al. 2014). The genome of the obligate halophile and basidiomycetous fungus

Wallemia ichthyophaga displays a significant expansion of several protein families, including the hydrophobins, small proteins (≤20 kDa) also present in the cell wall of filamentous fungi and involved in an array of processes of cellular growth and development (Wösten 2001). A number of genes encoding for hydrophobins undergo differential expression in the presence of varying salt concentration (Zajc et al. 2013). Similarly to what is observed in halophilic archaea, these proteins also display a higher proportion of acidic amino acids compared to homologs from other fungi, which might play a role in water and salt binding to prevent conformational change and loss of activity (Siglioccolo et al. 2011). Molecular biology data have shown how the same regulatory pathways and proteins can be of importance for survival under a variety of stress conditions. Proton/Na + symport switch as well as the Rim101 transcription factor and calcineurin-dependent regulatory are for instance both involved in high salt and alkaline conditions (Lambert et al. 1997). Studies of *Yarrowia lipolytica*, the only known ascomycete to grow on alkaline media and salt at near-saturating point, elucidated a key role for proteins such as Hsp12 (Champer et al. 2012). The stress protein Hsp12, that under normal conditions provides a launch of emergency responses to stress allowing only a short-term survival in all studied yeasts, promotes rearranging and repairing of the membrane compartments under prolonged stress conditions (Epova et al. 2012).

Proteomics has also provided the tools to improve the understanding of the mechanisms at the base of pathogenicity. Until now proteomic methods have particularly been used to screen for specific biomarkers of infections and virulence factors (Champer et al. 2012; Rodrigues et al. 2014), to characterize the response to antifungal agents (Kniemeyer 2011), and to identify fungal opportunists and clinical species (e.g., *Aspergillus* sp.) (Lau et al. 2013). Vesicle proteomics in the opportunistic yeasts *Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Paracoccidioides brasiliensis* has supported an important role for the extracellular vesicles (EV) as transport vehicles of microorganism modulators to distant sites inside the host, through the detection of proteins (e.g., laccase, urease, phosphatase) with both immunological and pathogenic activities (Rodrigues et al. 2014; Vallejo et al. 2012). As pathogens undergo stress exposure themselves during infection, pathogenicity and stress resilience are strictly connected matters. Increased temperature is likely the first stressor that opportunistic and pathogenic fungi encounter after gaining entry to the host and proteins such as the mitochondrial manganese superoxide dismutase (SOD) have been suggested to augment adaptation to human host body temperature through the rapid degradation of superoxide into hydrogen peroxide and O_2 (Brown et al. 2007). Proteomics reports documented the role of several other proteins involved in pathogenicity: Cu, Zn superoxide dismutase, peroxidases, and the glutathione system, all being involved in the resistance to oxygen radicals and laccases, important for the production of the pigment melanin, which is a free radical scavenger and thus plays a protective role in stress resistance (Garcia-Rivera et al. 2005).

Based on these premises, proteomics appears to be a very powerful tool in understanding how extremophiles persist at extreme ecological conditions. Through the elucidation of what proteins are present under given conditions, their levels, and

posttranslational modifications, proteomics also plays a significant role in the field of biotechnology and can directly contribute to the screening for biotechnologically relevant enzymes.

The first aim of the work presented in this chapter is thus to perform a systematic review of the state of the art of proteomics workflows applied to the investigation of extremotolerant and extremophilic fungal species, with a special focus on black fungi. To this end, we have collected and described methods for protein identification and quantitative analysis as well as for the preparation of different types of samples aiming at a critical evaluation of their advantages and pitfalls. While doing this, we wish to introduce the reader to diverse approaches for managing proteomics of black fungi, including strains' cultivation, protein extraction, and bioinformatics tools for meaningful data interpretation. By presenting examples of strategies to successfully overcome sample-related challenges and by providing a first comprehensive overview of the current status of proteome research in the black fungi field, we wish to ultimately promote the application of protein science to the study of emerging model organisms and to thereby contribute to make proteomics of black fungi an established field from an emerging one. If proteomics has been for long time considered as not yet entered at full right in black fungi research, the progresses and achievement in method optimization have finally created the conditions for more studies to come in the future.

12.2 Methodologies and Approaches

12.2.1 Fungal Cultivation In Vitro and Sample Collection

The cultivation of black fungi under laboratory conditions usually aims at the simulation of their natural habitat or of stress conditions. According to the research targets, fungal cultivation can be performed on solid or in liquid media. Cultivation in medium broth within flask, vials, or in microtiter plates is particularly suited to experiments, where the effects of fungal exposure to pollutants in liquid or aerosol form (e.g., toluene, phenol) are to be tested (Blasi et al. 2016, 2017). Chemicals in solid or powdered form can also be added to liquid media, in order to maximize the chances of contact with the fungus. Incubation in liquid media generally results in enhanced growth rates and in a consequent production of more biomass in shorter time ranges, as compared with the growth in petri dishes. However, biomass collection from liquid media is inevitably laborious and time consuming, as it requires filtration or centrifugation to separate the mycelium from the culture supernatant.

On the other hand, fungal biomass can be easily harvested from the surface of solid media by means of a scalpel or a spatula. Growth on solid media is also compatible with the use of neutral matrix of cellulose sheet, which eases biomass collection as well as transfer and is especially useful in workflows, where separation of the biomass from the media is required before treatment (Zakharova et al. 2013).

Due to a particularly slow growth rate, which has evolved hand in hand with extremotolerance, obtaining an amount of biomass sufficient for protein analyses might require weeks. Among black fungi, black yeasts usually display shorter generation times while rock-associated species grow at a slow pace. An accurate estimation of the growth rate is therefore paramount in view of a wise planning of the experimental work.

The inoculation of solid media can be carried out by direct transfer of small amounts of fungal biomass on top of the agar by means of inoculation needles or loops (the latter, to be used in the case of yeasts). Alternatively, drops of a cell suspension can be transferred to the solidified medium to be thereafter distributed using a spreader. Slightly different methods are used for the preparation of liquid cultures. As for yeasts, a cell suspension is generally used as inoculum. Alternative procedures need to instead be applied for those species of black fungi exhibiting microcolonial growth and lacking both sporulation and budding. Biomass gentle disruption with a homogenizer can be performed in order to break down hyphae or cell agglomerates into single cells, whose concentration can thereafter be assessed by cell count or OD measurement (Nai 2014). Accidental cell breakage is unfortunately a drawback of this method; therefore, cell survivability and viability must be evaluated each time. Otherwise, pellet or biomass can be directly added to the liquid media. If cell concentration cannot be determined, it is recommended to resort to biomass dry weight.

Experimental conditions are set based on the research aim. Extreme or more moderate values of temperature, humidity, salinity, UV, radiation, CO_2 and ozone concentration, etc. can be applied alone or in combination, to simulate abiotic stress. Similarly, biotic stress can be mimicked. As widely reported in literature, adaptation and survival to both abiotic and biotic stressors is often associated with melanization (Blasi et al. 2016, 2017; Cordero et al. 2018; Poyntner et al. 2018; Selbmann et al. 2018; Sterflinger and Krumbein 1995). The exposure of melanotic fungi to stress conditions thereby most often results in an enhanced production of melanin, one of the major contaminants interfering with proteomic analyses. In order to counteract or to reduce melanin synthesis to a minimum, the growth and incubation of cultures of black fungi and black yeasts in the dark are suggested.

12.2.2 Sample Preparation

Due to the protein-specific properties evolved in conditions of abiotic extremes, the preparation of protein samples is the most crucial and laborious of all aspects of a proteomics workflow and is the very step that requires sample-designed optimization when working with extremotolerant and extremophilic fungi (Siddiqui and Thomas 2008). Thermostable proteins and proteins particularly resistant to denaturation, hardy cell walls, polyphenolic compounds, polyols, and exopolysaccharides are some of the aspects potentially hindering the progress of proteomic analyses. Additionally, a slow growth rate often observed in species from the extremes results

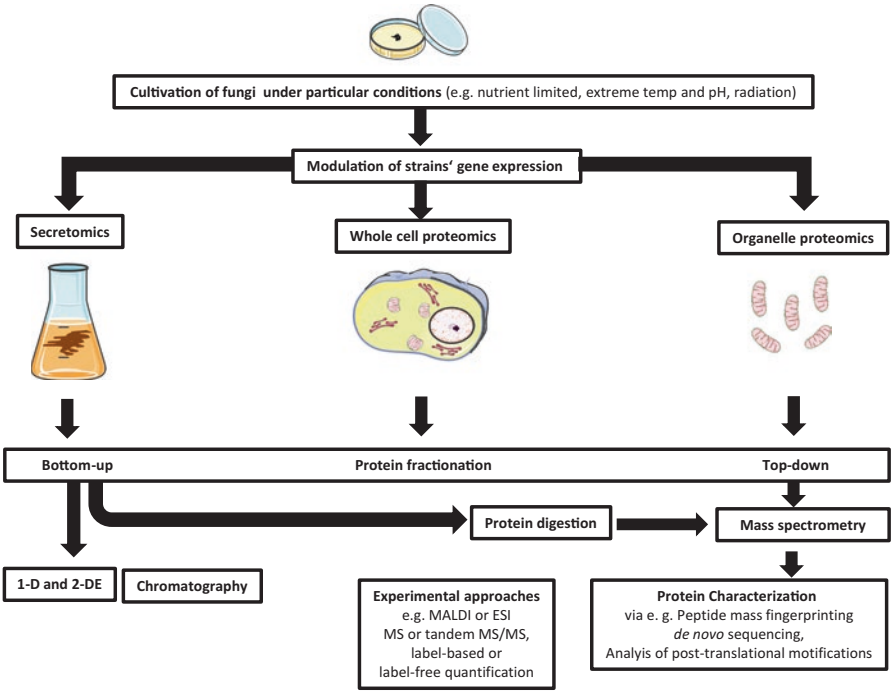

Fig. 12.2 General workflow for fungal proteomics. Both bottom-up and top-down approaches are indicated. As compared to top-down, a bottom-up approach allows, however, a wider methodological analysis of the samples by independent tools and repeats

in very poor amounts of mycelium as starting material for protein extraction. Besides the obstacles posed by the sample, the choice of reagents and techniques is also a crucial aspect in proteomics workflows which needs to be assessed case by case (Fig. 12.2). According to the downstream analyses, the preparation of protein samples can thereby be performed using a number of different methodologies.

Different approaches are additionally chosen to achieve extraction of whole-cell proteome or of protein subfractions. While the first amounts to the whole-sample extract, the subcellular proteome comprises three main fractions: the secretome, consisting of the culture supernatant and containing extracellular proteins; the insoluble fraction, consisting of membranes, membrane proteins, and large complexes; and the soluble fraction, which primarily contains cytoplasmic proteins (Burg et al. 2011). An integrated analysis of the different fractions potentially provides the most complete overview about protein function and compartmentalization within the cell. In the following sections, proteomics approaches in use, as well as the adaptation and optimization of these approaches to the use with extremophiles, are described.

12.2.2.1 Whole-Cell Proteome

The definition of "whole-cell proteome" includes the sum of all cytoplasmic, subcellular, and membrane proteins. Prerequisite to the isolation of the whole-cell protein content for all proteomic analyses is the protein extraction, whose aim is to lead to the purest obtainable protein mixture, free from interfering compounds such as polysaccharides, lipids, nucleic acids, phenols, and lower molecular weight components of cell matrix. Fungal proteins are especially effortful to extract, due to the chitin content of the fungal cell wall, and, moreover in the case of black fungi, strong pigmentation by melanin that additionally disturbs all consequent steps from isolation to quantification procedures (Isola et al. 2011; Özhak-Baysan et al. 2015; Uranga et al. 2017). We are for instance often confronted with very complex samples having a cell matrix, which is specialized in the protection of the cell content (e.g., proteins and biomolecules) from physicochemical environmental harms. All the strategies to disintegrate the cells and reach out for the molecules of interest can thereby potentially be outsmarted by millions of years of evolution. However, a combination of different approaches using mechanical as well as biochemical interventions showed success and paved the way for extensive investigation of fungal proteome (Marzban et al. 2013).

The disruption of the mycelium can be performed using mechanical and enzymatic methodologies or a combination of both (Barreiro et al. 1991). The rigid cell wall of black fungi makes the effective cell disruption a crucial step for consequent separation methodologies (gel-based or gel-free approaches). Glass and metal beads in beating mills are often used to achieve the disruption of fungal biomass. As an extensive milling is generally required to successfully break the cells, performing this step at 4 °C is crucial, in order to minimize heat generation as well as protein lysis by intracellular proteases or protein fragmentation and oligomerization (Coumans et al. 2010; Fernández-Acero et al. 2006; Jami et al. 2010b; Yildirim et al. 2011). The milling can be also performed in a mortar with pestle under liquid nitrogen (Kniemeyer 2011); however the reachable particle size is incomparable with that obtained with milling procedures. Moreover, this technique requires a bigger effort not to damage the material. Freeze-drying or lyophilization of the biomass can additionally be used before the milling procedure to aid cell breakage (Uranga et al. 2017).

Mechanical cell disruption can also be combined with homogenization buffers with different concentrations of detergents and chaotropes, to enhance the disintegration of cell walls and inhibit the activity of proteases (Barreiro et al. 1991). Urea at different molarities (7–9 M) and 2 M thiourea are often used to solubilize and re-solubilize proteins in filamentous fungi (Vödisch et al. 2011). However, care must be taken when overcoming the saturation limit of chaotropes in order to prevent crystallization at temperatures other than room temperature and higher. High concentrations of urea and thiourea can also interfere with different protein determination procedures later on. The addition of NaOH at 0.1–1 M can further enhance the protein solubility and destabilize the cell wall tremendously (Suh et al. 2012). Protein solubilization is also achieved by adding nonionic detergents as CHAPS to

the cell homogenization buffers. CHAPS is generally used at concentrations in the range of 1–4%, depending on the sample type and the protein yield (Barreiro et al. 1991). DTT and ß-mercaptoethanol are added to both increase protein solubility and achieve protein reduction (Longo et al. 2014; Lu et al. 2010; Oh et al. 2010). Ampholytes at a concentration of 0.5–2% can also be used to aid protein solubility; nevertheless their interference with downstream sample labeling procedures as well as the heat formation and high currents during the isoelectric focusing step must be taken into consideration (Sørensen et al. 2009). Tris–HCl or phosphate buffers at 10–30 mM are additionally added to the sample to keep the pH constant and/or to be compatible with protein labeling (Kubitschek-Barreira et al. 2013). Protease inhibitor cocktails with or without (for MS applications) EDTA can be added to the mycelium upon sample collection or to the homogenization buffer to reduce lysis of the proteins to a minimum (Onofri et al. 2012). As protease inhibitors can potentially disturb the isoelectric focusing, urea and thiourea can be used instead in the homogenization buffer. Protease inhibitors can otherwise be removed from the protein sample through buffer exchange procedures.

Enzymatic and chemical cell wall lysis was also used in fungi, however with less success (Barreiro et al. 1991). Multilayered formations and the deposition of melanin at the cell wall level in black fungi make the extraction and solubilization of proteins more challenging than in filamentous fungi types. Therefore, the selection of an appropriate method resulting in a good protein yield must be optimized for each species. Quite recently, a protoplast-based system was established for genetic transformation of black fungi (Noack-Schönmann et al. 2014). Such workflow, which applies a combination of fungal enzymes to produce protoplasts, could possibly serve as a starting point in proteomics application to enhance extraction of intracellular proteins.

The removal of interfering compounds is another critical step on the way to obtaining a high-quality protein extract. Pigments, exopolysaccharides, nucleic acids, and lipids are examples of the compounds mostly hampering protein extraction in fungi. Melanins and carotenoids are long chain polymers with several functions in cell protection (Cordero et al. 2017; Flieger et al. 2018). In melanotic fungi, multiple layers of melanin granules from phenolic or indolic precursors (Nosanchuk and Casadevall 2003) accumulate at the cell wall level contributing to a thick and rough cell surface (Eisenman and Casadevall 2012). Carotenoids are usually masked by melanin, however are also located in the cell walls, and are displayed in melanin mutant strains (Nai 2014). Despite efforts, the elimination of pigments remains still challenging [87]. Bleaching using chlorine or hydrogen peroxide prior or after biomass disruption can be attempted however not without risking to affect the proteins disulfide bonds. The benefit is that both components are labile and do not remain in the sample as additional residues (*personal communication*). However, their influence on the mass spec analysis must be studied. The use of charcoal powder by direct addition to the homogenization buffer has also proved to be quite useful to reduce the abundance of melanin in the final extract, however not without drawbacks (personal communication). The removal of melanin goes hand in hand with a low protein yield, probably due to the loss of cell wall proteins as well as melanin-

bound cellular proteins (Jacobson 2000). Attention needs to be paid also when using phenol-based methods for protein extraction, followed by precipitation steps. As polyphenolic compounds, melanins are soluble in organic solvents such as phenol (Amin et al. 2018), thus resulting in the co-extraction of melanin and proteins. Furthermore, melanin and proteins coprecipitate in the presence of organic solvents, thus resulting in darkly pigmented protein pellets. Methods for the successful isolation of melanin are available and include multiple precipitation steps induced by shifts in the pH conditions of the medium as well as boiling at high temperature (Amin et al. 2018; Pinto et al. 2018). Parameters—temperature and pH—however influence protein stability during extraction and are therefore not compatible with protein downstream analysis.

Precipitation steps are used to selectively purify proteins from several types of contaminants ranging from salts to polysaccharides and fatty acids, which can interfere with both gel-based (Crichton et al. 2013) and gel-free analyses. Precipitation with trichloroacetic acid (TCA) and acetone or a combination of the two is often used for fungal protein extracts (Bhadauria et al. 2009). Nevertheless the precipitation in ammonium acetate in methanol has also been described for black fungi (Isola et al. 2011; Tesei et al. 2015b; Vödisch et al. 2011; Zakharova et al. 2014b) as a way to bypass protein re-solubilization problems often occurring when using TCA. Precipitation steps are sometimes not enough to achieve the efficient elimination of interfering compounds, and washes of the protein pellet with organic solvents as methanol and acetone at different concentrations are therefore additionally performed. Nevertheless, these steps are in the case of black fungi often only contributing to a reduction in the amounts of contaminants, whose complete removal is extremely arduous. Polysaccharides, for instance, which make up the core of the cell wall, represent a substantial part of the cell lysate. A wide array of different proteins are anchored in various ways to cell wall polysaccharides like glucans and chitin, which makes both the isolation of the proteins and the removal of polysaccharides difficult (Pitarch et al. 2008). Most species of black fungi are also well known to produce massive amounts of extracellular polysaccharides (EPS) forming matrices or capsules around the cell surface and having roles in stress protection and infection (Breitenbach et al. 2018; Rodrigues et al. 2014). As these polymers are associated with the mycelia, they are hardly removed during the extraction procedures, thereby hindering proteomic protocols and interfering with spectrophotometric methods (Bianco and Perrotta 2015; Marzban et al. 2013). A number of strategies to enhance the removal of polysaccharides, fatty acids, and gelatinous material in general have been reported in literature for fungal species and could be applied to black fungi. These strategies most often involve high-speed centrifugation and/or filtration as well as sample dialysis before or after precipitation (Adav et al. 2010; Fragner et al. 2009).

The abovementioned procedures for the preparation of whole-cell protein extract can be applied to both gel-based and gel-free approaches, however not without the need for adjustments and optimization, which have to be assessed case by case. The requirements can indeed be different among gel-based and gel-free methods for protein separation. For instance, if maintaining the protein integrity is crucial in

gel-based techniques—especially native gel proteomics—protein fragmentation is less of an issue in gel-free proteomics, where proteins necessarily undergo tryptic digestion prior to chromatographic separation (Fernández et al. 2014). Keeping the amount of detergents, salts, and organic solvents in the sample at a minimum is paramount when using all kinds of separation procedures. Despite aiding the extraction and improving the solubility of hydrophobic proteins, detergents interfere with mass spectrometry (MS) analysis and must therefore be removed from protein samples (Yeung et al. 2008). Salt interference significantly affects the quality of the first-dimensional electrophoresis, isoelectric focusing (IEF) (Wu et al. 2010). Similarly, organic solvents, used in the extraction procedures for removal of distinct interfering compounds such as phenolic compounds and pigments, often contribute to the hardening of the protein pellet, thereby hindering protein solubilization (Parkhey et al. 2015). In all cases where the use of chemicals and reagents potentially interfering with MS cannot be avoided as this would result in a very poor protein yield, methods such as dialysis or buffer exchange are applied. Along with commercially available kits for sample cleanup, which often result in considerable protein loss (Marzban et al. 2013), the use of filter units has become in recent years more popular (Wiśniewski et al. 2009). Filter-aided sample preparation (FASP) or generally methods carrying out detergent removal, buffer exchange, chemical modification, and protein digestion into centrifugal filters have proved to be effective also for the processing of recalcitrant fungal samples (Adav et al. 2010; Wiśniewski et al. 2009; Zhong et al. 2018; Zoglowek et al. 2018).

A very low number of studies report protein extraction workflows, which only make use of MS-compatible reagents and were successfully applied to the analysis of proteins from extremophilic and extremotolerant fungal species. Romsdahl and colleagues adapted 100 mM triethylammonium bicarbonate (TEAB) extraction buffer containing protease inhibitors in combination with mechanical homogenization of mycelia at 4 °C to extract total proteins from melanotic fungal strains isolated from or exposed to the International Space Station (ISS) (Romsdahl et al. 2018). The same protocol was also used for both mycelial protein and secretome extraction in black rock-inhabiting fungi (Tesei et al. in preparation). After debris elimination through high-speed centrifugation, despite no effort was put in trying to remove contaminants, coloration was not observed in the supernatant. The persistence of a slight pigmentation due to melanin and carotenoids was instead observed in secretome samples, as expected.

12.2.2.2 Secretomics of Extremophiles and Extremotolerant Fungi

As the first fungal genome was sequenced, researchers employed comparative proteome analyses to discover how fungi could adapt to the occupation of a wide variety of ecological niches. The secretome or extracellular proteome explains a repertory of protein entities released by fungal cells with crucial importance for the organism to acquire nutrients and communicate with the environment (Krijger et al. 2014).

Secreted proteins are necessary for the exchange of information with the environment, especially in sessile organisms, which are precluded from actively seeking out nutrients, such as several species of extremophilic fungi. Fungi exhibit a wide diversity of nutritional lifestyles, ranging from strict saprobe—feeding on dead or decaying organic matter—to pathogenic or parasitic, whose life cycle is in strict association with a living host organism. Obviously fungal secretome plays important roles in the degradation of organic material, and in managing directly or indirectly symbiotic and pathogenic lifestyle with their hosts (Krijger et al. 2014). The secretome of extremophiles additionally holds particular interest for identifying enzymes of potential biotechnological value, such as proteases and cellulases (Blumer-Schuette et al. 2008; Miyazaki et al. 2005; Sanchez-Pulido and Andrade-Navarro 2007).

Secretomics of extremophiles use different strategies and employ various techniques like IPG-shotgun, SDS-PAGE-MS/MS (or GeLC-MS/MS), and 2-DE-MS/MS (Ellen et al. 2009; Muddiman et al. 2010; Vincent et al. 2012). Taking into consideration that there are no methodological boundaries existing for application of large-scale and high-throughput tools, like LC/LC-MS/MS (Vincent et al. 2012; Williams et al. 2010), the gel-based secretomics have been ever a favorite approach (Vincent et al. 2012). The sample preparation by means of fractionation is hitherto to be considered as the most critical step in the analysis of the secretome. Therefore, additional strategies are necessary to guarantee that the fractionation is robust enough (e.g., including test systems for cytoplasmic markers), so that the obtained data can be annotated with high confidence (Williams et al. 2010). The main challenge is to differentiate secretome from proteins, which are not originating from the extracellular repertory (Barreiro et al. 2012). The secretory proteins are generally collected from the nutrient media after filtration or centrifugation to separate the mycelia tissue from the culture supernatant. Proteins are thereafter isolated through precipitation. Secretome fractions may also contain membrane or outer membrane proteins that are released by endopeptidases during cultivation or by cell death (Ellen et al. 2009); this can be avoided by culture collection at early stages of growth, although early harvesting downturns the protein yield. Other types of contaminants such as pigments and polysaccharides often populate the secretome of melanotic and extremophilic fungi, and protein separation by means of precipitation is sometimes not sufficient to guarantee their removal. However, downstream procedures for the cleanup of secretomics samples prior to MS such as FASP demonstrated their efficacy in the elimination of contaminants from the extracts. Despite the fact that robustness against impurities is not among the strengths of in-solution digestion (Wiśniewski et al. 2009), this method proved a particular effectivity in separation of melanin from fungal protein extracts (Tesei et al. in preparation). While peptides elute in a colorless buffer, melanin is retained on top of the membrane filter.

Hydrophilic proteins can be separated from the insoluble hydrophobic fraction by phase extraction and centrifugation (e.g., chloroform extraction); however this method has its limitations concerning MS (e.g., detergents). Obstacles with gel electrophoresis caused by hydrophobic proteins including post-solubilization

precipitation can occur during the IEF and lead to vertical streaking lines in the gels (Rabilloud et al. 2008). Methanol as proven solvent has been often used for non-soluble proteins accompanied with thermal denaturation and insolvent digestion with higher success than detergents and more compatibility for MS (Mitra et al. 2007; Zhang et al. 2007). Dimethyl sulfoxide (DMSO), an additive to animal cell culture media, can also be used to increase the protein solubility of membrane-based proteins (*personal communication*).

Studying the insoluble proteome of extremophiles helps to explore the membrane and surface proteins, which are associated with environmental interactions. For example, the halophilic alkalithermophile *Natranaerobius thermophilus* is assumed to accommodate to multifactorial environmental extremes by huge depot of Na + (K+)/H+ antiporters (Mesbah et al. 2009). Proteomic studies of non-soluble fractions discovered proteins, which are associated with signal transduction/transport of different substances in the psychrophilic methanogens *Methanococcoides burtonii* (Burg et al. 2010; Williams et al. 2010).

In order to identify those proteins different strategies are suggested, which envisage the development of specific protocols in direction of sample collection and post-identification protein analysis (Barreiro et al. 2012; Jami et al. 2010b). The multifunctional proteins and proteins, which are rarely ever identified from secretomics samples, represent the main challenge. Whereas the post-identification protein analyses are focused on the cultivation and harvesting time ranges (detection of proteins at different time points of cultivation) to justify if a protein is secreted or released by cell lysis, the rare proteins can only apply the available proteomics data (Barreiro et al. 2012; Bendtsen et al. 2004). Fractionation of proteins and/or tryptic peptides prior to MS represents a good strategy for the enrichment and the detection of less abundant peptides and protein species (Ly and Wasinger 2011). An intensive research in the literature for possible routes of secretion or lysis is therefore strongly recommendable. Signal peptides can help discriminate intracellular proteins from proteins that are ultimately destined to the secretory pathway or to the cell membrane (Kapp et al. 2009). Although the signal sequence is usually removed in the mature protein, a number of bioinformatics tools are available to aid the prediction of the presence and location of signal peptide cleavage sites in amino acid sequences from different organisms. In the near future, we expect that the developments in the area of data storage and annotations deliver cutting-edge progresses toward secretome knowledge levels, which are deciding for the understanding of fungi survival evolution, pathogenicity, and extracellular communication.

12.2.2.3 Subcellular, Membrane, and Vesicle Proteomics of Extremophilic Fungi

Most of the proteomics research work hitherto carried out in fungi has been focused on the whole-cell proteome and on the secretome. Several crucial biological processes however occur specifically within cell compartments (Kim et al. 2007), therefore shedding light on the proteome profile of organelles, and vesicles would

give additional insight not only into the cell basic metabolism but also into stress survival and pathogenesis. The complexity of protein extraction from extremophilic and extremotolerant fungi however reflects the low number of subproteomics studies.

The nature of the fungal cell wall, especially in melanotic species, requires resorting to harsh treatments for cell disruption, which can on the other hand compromise the organelle integrity (De Oliveira and de Graaff 2011). Bead milling-mediated breakage of the biomass is preferentially performed at low temperatures and is coupled with the use of lysis buffers added with protease inhibitors (Grinyer et al. 2004). More gentle methods for the mechanical breakage of the mycelium have been suggested, such as the French pressure and mortar instead of the bead beating. Sonication can be additionally applied for the lysis of organelles. Similarly, biomass boiling as well as the use of detergents should be avoided (Nandakumar and Marten 2002). Enzymatic methods like cell wall digestion and protoplast formation could represent a valuable alternative, however not without possible drawbacks. Protoplast formation protocols extend for hours and have effects on the physiology of the fungus. Decreased reproducibility of the method is instead experienced when using different batches of enzyme cocktails (De Oliveira and de Graaff 2011). Organelle isolation is made also difficult by the presence of microtubules supporting the hyphal development, which increases the clustering of different organelles, thus making their separation more difficult (Bianco and Perrotta 2015). An additional obstacle to extraction of proteins from organelles is represented by proteases, which are abundantly secreted by fungi, thereby enhancing the common problem of protein degradation common to other eukaryotes.

Subfractionation procedures are applied following cell disruption and usually involve low-speed centrifugation to allow a first separation of the organelles based on size and weight. Ultracentrifugation steps are additionally performed to obtain the distribution of organelles in different fractions. Along with centrifugation, antibody-based methods are also used for organelle separation. Immunomagnetic separation (IMS), among others, proved to be quite efficient; however its application is strictly dependent on the availability of antibodies as well as on the antibody specificity. One method increasingly used to enrich organelles is free-flow electrophoresis (FFE). In FFE, the organelle mixture moves along carrier medium between two slanted plates (Karkowska-Kuleta and Kozik 2015).

If the characterization of organelle proteins in extremophilic and extremotolerant species of fungi is yet to be accomplished and optimization work needs to be done in order to adapt preexisting methods to the study of these organisms, cell wall proteomics recently witnessed the fast development of a wide variety of techniques. The fungal cell wall acts as a protective layer sheltering the cell from the outer environment and represents the place of cell-to-cell first contact and communication. The cell surface is actively involved also in phenomena such as pathogenicity and infection; thus cell wall-accessible molecules are targets for host immunity as well as for new drugs (Karkowska-Kuleta and Kozik 2015). With the cell wall playing a critical role in the biology and the ecophysiology of fungal organisms, investigating the structure and function of cell wall proteins is of great importance, also

in view of a full understanding of yet-unresolved issues such as cell wall morphogenesis and host-pathogen interaction.

Many proteins are located at the cell wall level, most of them displaying modification with N- and O-linked glycans. A number of these proteins originate as cell membrane glycosylphosphatidylinositol (GPI)-linked polypeptides and end up in the cell wall, where they are covalently linked to ß-1,6-glycans (Gow et al. 2017). Others are instead associated to the wall via non-covalent interactions, or disulfide bonds to polypeptides that are themselves covalently bound to structural glycans (Agustinho et al. 2018).

The analysis of proteinaceous components of the fungal cell wall generally involves the separation of the wall from the protoplast and can be carried out either with or without cell disruption, however avoiding cell breakage and the consequent release of cell content. To this purpose, usually vortex or gentle agitation of the fungal cells with vertical turntable is chosen over more invasive methods (Klis et al. 2007). Protocols involving mechanical disruption of the cells include washing steps with buffers with ionic strength for the removal of cytoplasmic and membranous contaminants (Pitarch et al. 2008). The use of a DTT-based homogenization buffer for cell incubation has been shown to help protein extraction in black yeasts without affecting membrane integrity (Longo et al. 2014). Short enzymatic treatments can otherwise be performed (Vialás et al. 2012). As in the procedures described earlier for the extraction of whole-cell proteome, detergents and denaturing and reducing agents are used, however here mostly for the isolation of proteins non-covalently incorporated into the wall. Additional steps are needed to extract proteins associated with cell wall polysaccharides, and they usually involve hydrolytic enzymes and chemicals (Karkowska-Kuleta and Kozik 2015). Several classes of commercially available enzymes—e.g., β-glucanases and chitinases—have been applied to the cleavage of specific proteins based on the nature of their linkage to the wall (i.e., alkali-sensitive linkage (ASL), GPI linkage, chitin-bound proteins). Alkali and acids serve a similar purpose. Trifluoromethanesulfonic acid (TFMS), among others, is often used to isolate and simultaneously deglycosilate proteins, in order to ease protein gel-based separation (Maddi et al. 2009). The biomass incubation in cell wall digestion cocktails can also be performed in the presence of protease inhibitor cocktails to diminish protein degradation (Champer et al. 2016). Similarly, live intact cells can be incubated with proteolytic enzymes—e.g., trypsin, chymotrypsin, and proteinase K (Olaya-Abril et al. 2014)—to promote protein cleavage and the release of peptides, which can thereafter be identified by mass spectrometry. Such procedure is better known as “cell shaving” (Yin et al. 2008). All these strategies firstly set up and developed in bacteria and classical yeasts are increasingly being applied to the study of species of black fungi, especially the opportunistic and pathogenic ones, to investigate the role of surface-exposed proteins during infection.

Because of its impact on fungal pathogenesis, the proteome of extracellular vesicles (EVs) has additionally gained increasing interest in recent years. The production and secretion of EVs—whose size ranges from 50 nm to 400 nm in diameter (Oliveira et al. 2013)—have been observed in a number of species of melanotic fungi and yeasts (Joffe et al. 2016; Rodrigues et al. 2014, 2015; Vallejo et al. 2012); neverthe-

less many aspects related to EVs remain unknown. EV biogenesis and release are yet to be fully elucidated; however a number of studies confirmed the diversity in EV composition (Rodrigues et al. 2015). EVs are characterized by a conserved set of molecules across species—e.g., lipid raft molecules, membrane trafficking molecules, MHC class I molecules, and heat-shock proteins (Furi et al. 2017)—suggesting life-preserving functions (De Toro et al. 2015). The comparison of EV protein profiles from opportunistic species further revealed overlapping in protein composition, thus suggesting the presence of signature proteins with clear roles during infection (Vallejo et al. 2012). Remarkably, most of the proteins found in fungal vesicular fractions lack the characteristic signal peptides required for conventional secretion (Oliveira et al. 2010; Rodrigues et al. 2008); thereby the origin of EV from unconventional or still unknown pathways of secretion can be hypothesized.

The analysis of EVs by proteomic-based approaches requires the purification of the vesicles from cell-free culture supernatants. In order to aid the recovery of EVs, the culture supernatant is initially concentrated by membrane ultrafiltration using membrane with high molecular weight cutoff (MWCO, 100 kDa). A number of separation techniques can be used individually or combined, to remove aggregates and obtain a vesicles fraction. These methods include sequential centrifugation and ultracentrifugation, density gradient centrifugation, filtration (0.22 μm or 0.1 μm) polymer-based precipitation, and immuno-affinity (Simpson et al. 2008; Taylor and Shah 2015). Density gradient separation combines sucrose gradients with ultracentrifugation; polymer-based precipitation uses polyethylene glycol; immunoselection employs antibodies binding to vesicle surface markers. Ultracentrifugation (100,000 × g) appears to be the method most frequently used for the isolation of EVs from black fungi, however not without limitations. Low recovery of EVs and of the rations of exosomal proteins and non-vesicular macromolecule contamination have been observed independently on the cell type and on the organism (Furi et al. 2017; Taylor et al. 2011). Further purification steps in HPLC can additionally be performed to aid in the removal of contaminating non-exosomal material (Rodrigues et al. 2008). Along with vesicle enrichment, melanin contamination represents the major obstacle to proteomic analyses of EVs from melanotic fungi, as it affects both protein determination and separation. Melanin is often found in liquid media during incubation of black fungi; thus concentrating the culture supernatant prior to vesicle isolation also results in the concentration of this pigment. Notably, melanin is additionally found in and exported extracellularly by EVs (Eisenman et al. 2011; Joffe et al. 2016; Rodrigues et al. 2014). Filter-aided procedures for protein sample cleanup such as buffer exchange could support the removal of pigments. Due to melanins' large size (Langfelder et al. 2003), multiple ultrafiltration steps on membranes with different cutoffs could be necessary to separate melanins from the protein fraction.

The thorough isolation of pure fractions and the integrity of the sample (e.g., membrane integrity) are both crucial aspects having an impact on downstream analyses. Protein extraction from purified vesicles is generally achieved without mechanical disruption. Proteins can be isolated using the TRIzol extraction procedures for RNA and protein analyses or recovered by centrifugation after precipitation (e.g., TCA) on ice and afterward be lyophilized or resuspended in a buffer

(Taylor et al. 2011; Vallejo et al. 2012). Alternatively, they can be solubilized by incubation in chaotrope-based homogenization buffers and thereafter be processed for reduction, alkylation, and finally digestion (Rodrigues et al. 2008). In the majority of studies the characterization of protein fractions from EVs has been carried out resorting to gel-free techniques as liquid chromatography-tandem mass spectrometry (LC-MS/MS) (Rodrigues et al. 2014).

12.2.3 Protein Separation and Identification

Two major proteomic technologies have been applied to resolve the fungal proteome: gel-based separation techniques coupled to mass spectrometry (MS) or tandem mass spectrometry (MS/MS) and shotgun (gel-free) methods based on LC-MS/MS.

The different methodologies for protein separation via SDS-PAGE acrylamide gels have been very popular for decades through their simplicity and robustness. SDS-PAGE in one- and two-dimensional feature has also been for long time the most often used approach applied to separate fungal proteins. In particular, SDS-PAGE has been proven to be the most favorite tool to study hydrophobic proteins with lowered solubility, such as membrane- and cell wall-embedded proteins. The separation and visualization of proteins from MCF and black yeasts were indeed mostly performed by using one- and two-dimensional electrophoresis (1-D and 2-DE). These methodologies showed to be capable of visualization of a high number of proteins and to also visualize the alteration of protein patterns (Bhadauria et al. 2009; Isola et al. 2011; Tesei et al. 2012).

One-dimensional electrophoresis is a useful technique for the rapid fingerprinting of protein samples as well as to assess the quality of protein extract (e.g., protein degradation); it is often used for protein separation prior to MS/MS and additionally represents an essential step of immunoblotting techniques (González-Fernández et al. 2014; Guimarães et al. 2011; Loginov and Šebela 2016). Despite the simplicity of this technique and its low resolution, 1-DE led to the identification of proteins as malate dehydrogenase and peptidyl-prolyl cis-trans isomerase, contributing to important steps forward in fungal proteomics (Dodds et al. 2009; Jorrín-Novo et al. 2009; Marzban et al. 2013). Two-dimensional gel electrophoresis (2-DE) aids in the characterization of protein profiles and their alterations in response to different experimental conditions, and eases the detection of protein isoforms as well as of posttranslational modifications (Bhadauria et al. 2007; De Oliveira and de Graaff 2011; Tesei et al. 2015b).

Despite the major contribution given by gel-based techniques to the investigation of the fungal proteome in species from extreme habitats, the number of applications has decreased over the last years in favor of gel-free techniques, which allow more in-depth proteomic analyses (Loginov and Šebela 2016). Complete and annotated sequences of a growing number of fungal genomes in combination with the development of more sophisticated and sensitive high-throughput LC-MS instrumenta-

tion have indeed resulted in the identification of increased number of proteins. The gel-free LC-MS-based methodology like isobaric tag for relative and absolute quantitation (iTRAQ) was for instance reported to be the most effective technique for the identification of membrane-associated proteins in filamentous fungi (Barreiro et al. 2012; Ouyang et al. 2010).

Nevertheless, the success of gel-based and gel-free approaches is limited both within the boundaries of the sample preparation and protein yields. Therefore, the choice between classic gel-based techniques—or more exactly their updated version—and gel-free ones strictly depends on the research goal and on the nature of the sample.

In the next section, the functionality and the applications of gel-based and gel-free techniques to the analysis of proteins from extremophilic and extremotolerant fungi will be described, not without reviewing the need for workflow optimization as required by difficult samples.

12.2.3.1 Gel-Based Protein Separation: One-Dimensional and Two-Dimensional SDS-PAGE

In fungal proteomics, 1-D SDS-PAGE has been extensively employed to investigate hydrophobic proteins, such as membrane- and cell wall-anchored proteins. Indeed, one of the first intracellular proteomic studies in filamentous fungi biology was carried out on white/red *P. chrysosporium* and *Lentinula edodes* (De Oliveira and de Graaff 2011). Iron-binding plasma membrane proteins were analyzed by using only 1-D SDS-PAGE, since the authors failed to detect them by 2-DE. Another example is a similar approach to explore mitochondrial proteins of *Neurospora crassa*, a filamentous fungus secreting enzyme capable of complete digest of plant cellulose (Schmitt et al. 2006).

One-dimensional SDS-PAGE is to be seen as the first routine step in the analysis of fungi proteomics and occupies a fix position in every established workflow despite its disadvantages, e.g., low resolution and absolute protein amounts that can be applied to the gel (Fig. 12.3a). It can be used in native feature as the only and sole tool for the separation of membrane and insoluble proteins in combination with mass spectrometry (Nguyen et al. 2005). This variation of SDS-PAGE, termed Blue Native PAGE (BN-PAGE), showed extensive progress in the investigation of insoluble or native large protein complexes, which are embedded in fungal membranes or mycelium and secretome (Crichton et al. 2013).

1-D SDS-PAGE remains a qualitative methodology and the protein separation is not optimal and results in more proteins of identical molecular weight falling into a single and thereby heterogeneous band. However, it remains versatile and flexible in the case of comparative analysis with large number of samples. Through the rapid fingerprinting of fungal extracts, 1-D SDS-PAGE allows differentiating among various genotypes as well as between wild-type strains and mutants, different cultivation modes, or environmental stresses.

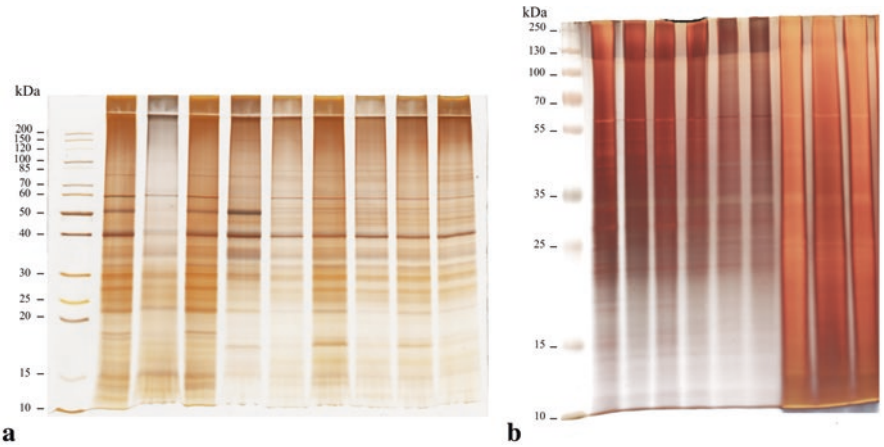

Fig. 12.3 SDS-PAGE 1-D electrophoresis gel. (**a**) Total protein extracts of the rock-associated fungus *Knufia chersonesos* wild-type MA5789 and mutant MA5790 using different extraction methods. Protein amount: 4 μg. (**b**) Secretomes of *K. chersonesos* MA5789. Interference of melanin, present in the samples, is observed in the gel. As silver nitrate binds to both melanin and proteins, a dark background is generated on the gel after silver staining, thereby masking the protein bands. Protein amount: 2 μg

It is quite often applied particularly for the separation of membrane proteins and for the detection of immunogenic proteins and fungal allergens through antibody-based immunoblotting techniques (Supek et al. 2011; Westwood et al. 2005). Despite the borders of denaturing and native SDS-PAGE effectivity, it can provide a first but, in some cases, the only technique to have a prompt glimpse inside the proteome of fungal species.

Two-dimensional quantitative electrophoresis (2-DE) in combination with silver staining or DIGE technology and a wide spectrum of mass spectrometry techniques have a proven history in the investigation of extremotolerant and extremophilic black fungi (Tesei et al. 2012, 2015b; Zakharova et al. 2013, 2014a, b) (Fig. 12.4). Since the first and most prominent systematic mapping of lignocellulolytic *Trichoderma harzianum* has been performed by MS-MALDI-TOF and 2-DE as reported by Bianco and Perrotta (2015), a series of different researchers started to explore the extremophile fungi by various criteria. The response to zinc in pathogenic *Paracoccidioides* sp. yeast cells could be clarified by comparative 2-DE during zinc starvation. The results showed the physiological rearrangement of *Paracoccidioides* sp. to the probable oxidative stress induced during zinc withdrawal (de Arruda Grossklaus et al. 2013; Parente et al. 2013). Earlier mycelial proteins were separated by 2-DE, analyzed by peptide mass fingerprinting (PMF) and tandem MS and successfully identified (Jami et al. 2010a). Accordingly, protein maps for different filamentous fungi could be established using 2-DE and MS (Lu et al. 2010; Ravalason et al. 2008; Yildirim et al. 2011). Similarly to 1-DE, the 2-DE technique has also provided the unique tool for immunomics in fungi (Barreiro et al. 2012). By the use of high-resolution 2-DE in combination with IgE immunoblot-

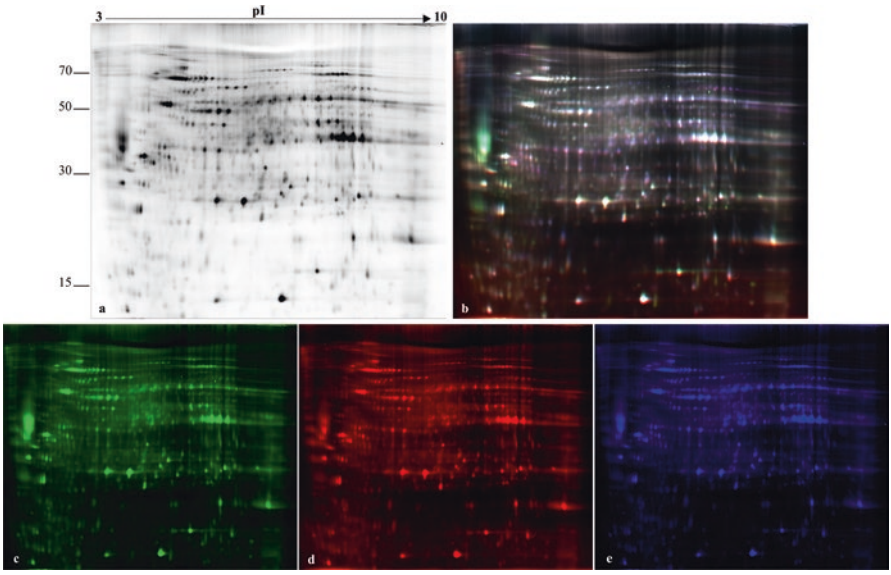

Fig. 12.4 SDS-PAGE 2-D electrophoresis gel of total protein extracts of the opportunistic black yeast *E. dermatitidis* CBS 525.76. (**a**) Classical 2-D, protein spots are visualized by silver staining; (**b**) 2-D DIGE, overlay of the three images obtained by separating on the same gel three samples differentially labeled with fluorescent dyes; (**c–e**) three separate images obtained using three different lysine-binding fluorescent dyes

ting, the allergenic proteins of fungal spores of *Aspergillus versicolor* could be identified and a component-resolved allergen testing could be obtained using patients' serum IgEs (Benndorf et al. 2008).

The invention of quantitative differential electrophoresis (difference gel electrophoresis, DIGE) revolutionized the comparative analysis and provided a reliable approach by 2-DE technique. Before the development of DIGE, the major obstacle using 2-DE was the irreproducibility of the gels running with the identical repeats. The fluorescent dye-based labeling and the labeling chemistry allow the multiplexing of the samples applied into one single IEF strip (Marouga et al. 2005). A maximum of three different samples can be run in the same gel, along with a reference sample, created by pooling all samples involved in the experiment. This achievement catapulted 2-DE into a new era and comparative mapping could thereby be extended to quantitative proteomics and be directly coupled with MS pipelines for protein identification and characterization, a milestone which allowed the establishment of universal protocols and the standardization of the running conditions. In the meanwhile, two or three different applications for DIGE protein labeling have been developed. Together with the minimal dyes (lysine-based) and saturation (cysteine-based) dyes for the quantitative comparison of protein expression even in samples with as little as 3–5 μg protein, dyes for the visualization of complex oxidative responses of the proteome are nowadays also available (Kondo and Hirohashi 2007; Kratochwill et al. 2015; Strohkamp et al. 2016).

Although the general proteomics workflow remains identical for any analyzed sample, the first attempt to establish a workflow for black fungi is not older than one decade (Isola et al. 2011). High melanin and low soluble protein content slowed down the process of isolation of cell components not only at the proteome but also at the transcriptomic and genomic level. The developments at the protein analytical level were promising and the investigation of the proteome modulation in extremophilic and extremotolerant fungi became soon a reality. The first step was the mapping of the proteins in the black yeast *Exophiala jeanselmei* and the meristematic fungus *Coniosporium perforans* (Isola et al. 2011). The first 2-D protein maps opened the doors for extensive studies and analyses of protein alterations under different environmental conditions (Tesei et al. 2012; Zakharova et al. 2013, 2014a, b). However, the full optimization of a working protocol needed more time and experimental genius. First deep investigation which involved a complex experimental design and a combination of 2-D DIGE and mass spectrometry needed over 2 years for step-by-step optimization and the generation of bioinformatics data about thermal stress tolerance of the opportunistic black yeast *Exophiala dermatitidis* (Tesei et al. 2015a).

The improved proteomics workflows could be recruited for experiments with similar samples, with adjustments needing to be assessed case by case. Despite the optimization work, melanin still represents the main bottleneck and melanin-contaminated extracts aggravate stubbornly all proteomics approaches with black fungi (Moreno et al. 2018) (Fig. 12.3b). Besides the sample-related drawbacks, 2-DE remains itself a very time-consuming and laborious technique. The available image analysis delivers many mismatches, which are to be manually improved. The resolution of 2-DE is a point of concern, since there are spots, which contain multiple proteins. Despite typical disadvantages and limitations, 2-DE however represents a unique methodology due to the capability to generate visible protein maps and images after separation of proteins. Images, which can serve proteome comparative analysis and maps, can be directly used for spot picking and can therefore undergo mass spectrometric analyses.

12.2.3.2 Gel-Free Approaches: SHOTGUN Proteomics

As compared to gel-based approaches, mass spectrometry (MS)-based proteomics such as shotgun proteomics allows a comprehensive study of the proteome involving a multitude of samples in complex experimental designs and combines the qualitative and quantitative study of the proteome with an enhanced efficiency of separation and sensitivity of protein identification (Fernández et al. 2014; Marcotte 2007). Such properties can potentially serve different applications within the study of extremotolerant and extremophilic species, including, among others, the investigation of the stress survival and of the evolution in extreme environments as well as the elucidation of the mechanisms involved in fungal infection. If shotgun proteomics often entails a quicker workflow for sample processing due to the possibility of simultaneous analysis of multiple samples, it however requires complex

downstream analyses aiming at the biological interpretation of the results (Sinitcyn et al. 2018). Statistics, computational technologies, and bioinformatics are indeed paramount to proteomics data mining, especially since large amount of data are involved. Moreover, the integration of proteomics data with other OMICS data has been increasingly gaining importance (Kohl et al. 2014).

Peptide-based shotgun proteomics, also called bottom-up proteomics, is most often the method of choice for the analysis of the fungal proteome. Bottom-up proteomics, in combination with either protein labeling or label-free techniques (Huang et al. 2015), happens to be also the format currently most used in proteomics (Sinitcyn et al. 2018). Sample preparation for bottom-up techniques involves reduction alkylation steps followed by in-solution enzymatic cleavage (by a trypsin and LysC protease mix) of the protein extract into peptides, which are then subjected to liquid chromatography (LC)-based separation and MS/MS analysis. Proteolytic peptides can be analyzed in a data-dependent or a data-independent manner. In data-dependent acquisition (DDA) mode, only the peaks (i.e., peptides) with higher intensities at a given chromatographic elution time are chosen for fragmentation and subsequently identified through protein database search (Huang et al. 2015). In data-independent acquisition (DIA) experiments, all peptides within a certain m/z range undergo fragmentation and fragment ion spectral libraries, established beforehand, are used to mine the complete fragmentation maps (Gillet et al. 2012). The actual number of identified proteins depends on the sample complexity and the proteins' dynamic concentration range—namely the diverse abundance of different classes of proteins—as well as the availability of sequenced and annotated genomes (Rohrbough et al. 2007).

The earliest research works to apply bottom-up proteomics in black fungi and black yeasts aimed at getting an insight into the extracellular proteome, especially of opportunistic and pathogenic species. Albuquerque et al. (2008) used reversed-phase liquid chromatography-tandem mass spectrometry (LC-MS/MS) to identify proteins from purified extracellular vesicles from the clinically important melanotic dimorphic fungus *Histoplasma capsulatum*. Two hundred and six out of 283 proteins could be identified by sequence analysis, revealing their involvement on the onset of pathogenesis and host immune responses along with cell architecture and cell growth. Many of these proteins were also described in the proteome of vesicles from *Cryptococcus neoformans*, the causative agent of cryptococcosis, where a similar protocol for protein fractionation and identification by LC-MS/MS was applied (Rodrigues et al. 2008). Interestingly, the rate of protein detection among different strains varied considerably according to the presence of capsular structures surrounding the cell, suggesting that polysaccharides in extracellular fractions might interfere with protein digestion. The secretome of *Paracoccidioides brasiliensis*, the dimorphic ascomycete, and the causative agent of paracoccidioidomycosis were additionally inspected. The overall characterization of extracellular proteins in the supernatants of the yeast phase of *P. brasiliensis* was achieved by LC-MS/MS. The analysis of vesicle and vesicle-free fractions resulted in the identification of 85 and 140 proteins, respectively, with 35% of the sequences—most likely

vesicle-free proteins, which bound to vesicles during sample preparation steps—overlapping both fractions. Also in this case, several vesicle-associated sequences had orthologues in other fungal extracellular vesicles.

Along with protein identification, bottom-up proteomics allows the comparative quantitative analysis of complex protein samples by means of a great variety of approaches and instrumentations based on the methodology strength for a specific research aim. Relative protein abundance can be measured using stable isotopes or label-free methods. The label-based techniques isobaric tagging like iTRAQ (isobaric tags for relative and absolute quantification) and TMT (tandem mass tag) are among the most popular techniques in quantitative proteomics. Both iTRAQ and TMT use chemical labels, which bind to protein samples after proteolysis in a peptide-specific manner without altering peptides' chromatographic and ionization properties (Bianco and Perrotta 2015; Chahrour et al. 2015). In iTRAQ, isobaric mass labels are covalently linked to peptides and yield "signature" or reporter ions following peptide fragmentation that can be used to identify and quantify individual members within a multiplex set of samples using tandem mass spectrometry (Wiese et al. 2007). Similarly to iTRAQ, TMT reagents use isotopomer labels and release "daughter ions" (Chahrour et al. 2015). iTRAQ is available in 4-plex and 8-plex formats, while TMT is available in 2-plex, 6-plex, and 10-plex formats. Together with the samples, a reference sample, which is a pool of all samples included in the experiment, is also used. Protein samples are pooled, then separated in a first dimension by strong cation exchange (SCX)—separation by charge—or reversed-phase chromatography (RP)—separation by hydrophobicity—and thereafter analyzed by MS/MS (Rohrbough et al. 2007). The combination of the two separation techniques in a single chromatographic column is known as multidimensional protein identification technology (MudPIT) and is applied to the separation of complex biological mixtures.

Although all mentioned techniques show high potentials, their successful application in the study of black fungi is still in the early stages, mostly due to the difficulties posed by the sample. First studies of the fungal proteome resorting to iTRAQ were carried out in species of *Aspergillus* and *Fusarium*, to investigate alterations of the total proteome in response to antifungal drugs and mycotoxins (Cagas et al. 2011; Taylor et al. 2008). Similarly, iTRAQ found applications also in the characterization of the secretome of biotechnologically relevant strains such as *A. niger* and *Trichoderma reesei* (Adav et al. 2010, 2012). More recently, iTRAQ labeling and strong cation exchange in combination with ESI-Q-TOF MS/MS were reported for the study of the aluminum stress in the extremotolerant yeast *Cryptococcus humicola* (Zhang et al. 2015). In order to assess changes in total protein abundance between control and aluminum-treated samples, protein relative concentrations were calculated based on the reporter peak area. TMT labeling coupled with reversed-phase LC-tandem MS (MS/MS) was applied to the molecular characterization of the melanotic hyphomycete and human opportunist *A. niger* JSC, isolated from the International Space Station (ISS; Romsdahl et al. 2018). The comparison with a terrestrial reference strain allowed to get an insight into the adaptive mechanisms to space travel conditions at the protein level (total protein). Protein differen-

tial abundance especially affected proteins involved in the stress resistance, starvation response, and nutrient acquisition (Romsdahl et al. 2018). Through TMT approach, the existence of a distinct strain of *A. niger* onboard the ISS also showing a higher melanin content than its ground counterparts was revealed.

Label-free methods for quantitative proteomics have been also applied in fungi aiming at the discovery of processes and molecules governing the stress response. Although isotope labeling approaches are more accurate than label-free methods, the latter are relatively inexpensive and unaffected by labeling process-related technical bias (Bianco and Perrotta 2015; Huang et al. 2015). Moreover, there is no limit to the number of samples that can be compared. In a typical label-free experiment, samples are individually analyzed and compared after independent analyses, usually using spectral counting or peak intensity measurement, which approximate protein abundance (Wasinger et al. 2013). Spectral counting is a relatively simple procedure based on the foundation that a higher number of peptides can be identified from a more abundant protein (Washburn et al. 2001). The number of mass spectra recorded for a peptide in a sample thereby linearly correlates with its molar amount; therefore, the sum of spectral counts for peptides associated with a particular protein can be used to estimate protein amount (Bianco and Perrotta 2015).

Label-free quantitative proteomics based on sequential window acquisition of all theoretical fragment ion spectra (SWATH)-MS is currently the best known workflow for label-free proteomics. Quantitative proteomics using SWATH-MS provides good reproducibility, accuracy, and precision in quantification of proteins, and is suitable for detecting negligible protein differentiation (less than twofold) (Li et al. 2017). SWATH was reported for the study of the mechanism of formation and differentiation of sclerotia, a dormant form displayed by several fungal species in relation to extreme environmental conditions. Proteomes of both sclerotia and hyphae at different developmental stages were analyzed in the medicinal fungus *Polyporus umbellatus* (Li et al. 2017). A total of 1234 proteins were identified and quantified by LC-MS using SWATH in combination with DDA mode. The results of protein differential abundance analysis revealed the role of oxidative stress in triggering sclerotia formation from hypha and further highlighted the importance of antioxidant defensing for sclerotia growth. SWATH was used to achieve a comprehensive protein identification and regulation in the mycotoxin producer *Penicillium verrucosum* at different time points of the growth curve (Nöbauer et al. 2017). Notably, as no protein information was previously available for the organism, an "ab initio" translated database from the sequenced genome of *P. verrucosum* was applied for the identification of 3488 proteins. A SWATH setup was also applied for comparative quantitative analysis of *A. fumigatus* proteome aiming at the characterization of conidia's adaptation at different culture ages (Anjo et al. 2017). Information-dependent acquisition (IDA) was used in combination with SWATH to generate peptide fragmentation spectra for library creation. A time course evaluation of the proteome revealed how the metabolic state of conidia switched from very active—at the beginning of the cultivation—to dormant, as the availability of nutrients decreased. The increase levels of hydrolytic enzymes toward the end of cultivation in a 30-day-old conidia cell went hand in hand with cell autolysis.

Nano ultra-performance liquid chromatography coupled with tandem mass spectrometry (UPLC-MS^E) is another non-labeling approach for the quantitative analysis of proteins. UPLC-MS^E is a relatively new MS/MS technique for the simultaneous acquisition of precursor ion information and fragment ion data at low and high collision energy in one analytical run, and has been thereby shown to improve protein and proteome coverage compared to the conventional LC-MS/MS approach (Murad et al. 2011). In this technique, abundance values of proteins are assessed based on the average intensity value of the top three ionized tryptic peptides from a constitutive protein, detected in all replicates and with a low variance coefficient (Rodrigues et al. 2016). This internal standard protein is thereby used to normalize the protein expression levels in the samples. Informatics tools are additionally used for proper quantitative comparisons (Parente-Rocha et al. 2015). UPLC-MS^E has served a thorough characterization of *Paracoccidioides* sp. response to environmental stresses trying to get an insight into the mechanisms at the base of pathogenicity. De Silva Rodrigues et al. (2016) applied UPLC-MS^E to identify differentially expressed proteins during osmotic shock in *P. lutzii.* The results of this study suggest that the response to osmotic stress could help the fungus to cope with the host environment during dissemination to organs and tissues. Proteomic responses to carbon starvation were additionally investigated in *Paracoccidioides* sp. to simulate adaptation to host during infection. A total of 421 proteins were found to be differentially regulated by 1.5-fold change, suggesting a metabolism reprogramming during carbon starvation in favor of gluconeogenesis and ethanol production (Lima Pde et al. 2014). Further proteomics investigations of *P. lutzii* and *P. brasiliensis* were carried out to shed light on the survival mechanisms of human pathogenic fungi toward nitrosative stress, as the main defensive strategies applied by immune cells during infection (Parente et al. 2015). Among the 66 downregulated proteins, proteins related to carbohydrate energy conservation and the mitochondrial electron transport chain were found. Proteins showing increased expression (i.e., 76) during nitrosative stress induced by adding GSNO (S-nitrosoglutathione) included those related to lipids and branched-chain amino acid metabolism as well as to the oxidative stress response, such as superoxide dismutase (SOD) and cytochrome c peroxidase (CCP). Further aspects of the infection were examined in *P. brasiliensis* (Parente-Rocha et al. 2015). The proteomic response of the dimorphic fungus to macrophage internalization was analyzed and, similarly to what is observed for nitrosative stress defense, the results of protein differential analysis revealed proteins involved in the oxidative stress response—i.e., thioredoxins along with SOD and CCP—to be upregulated. The rest of the 139 proteins found to be positively regulated out of the 7845 peptides identified were related to amino acid catabolism, cell rescue, defense, and virulence, suggesting that *P. brasiliensis* adapts to the macrophage milieu by reprogramming its metabolism to produce glucose and inhibiting protein synthesis.

The rapid advancement in bottom-up MS technologies has paved the way for faster analyses of larger number of proteins resulting in high amounts of data regarding protein IDs and quantitative peptide information. By relying on protein digestion, bottom-up techniques, however, can leave behind important information

regarding posttranslational modifications (PTMs) or sequence variants like those giving rise to protein isoforms. Moreover, alterations or sequence variations may occur on peptides, causing their relation to one another to be lost following digestion (Catherman et al. 2014). Top-down approaches were developed to compensate for the limits of bottom-up proteomics, by using MS to characterize intact proteins whose intact and fragment ion masses are both measured. Top-down is a promising tool for the detection of proteoforms originating from PTMs, alternative splicing, or genetic variations. Nevertheless, the technical effort of proteome-wide investigation at the intact protein level has caused top-down proteomics to lag behind bottom-up in terms of proteome coverage, sensitivity, and throughput (Catherman et al. 2014). Similarly, software for the interpretation of top-down has also been slower to develop and the protocols for accurate quantification are still under development (Collier and Muddiman 2012). The application of top-down proteomics in fungal analysis is therefore still very limited. Up to now, intact protein studies were carried out in filamentous fungi of agricultural and medical interest. In the work from Collier et al. (2008), whole-organism SILAC labeling was applied for qualitative and quantitative top-down proteomics in *A. flavus* to assess the biological effects of several growth parameters and antifungal agents.

Each of the methods here mentioned has its own merits and drawbacks; the choice of the optimal method should therefore be evaluated in accordance with the experimental design and downstream needs. Being microcolonial fungi and black yeasts at the same time emerging model organisms and challenging samples for biochemical analysis, label-based and label-free quantitative proteomics are hitherto far from being fully exploited in black fungi proteomic research, as revealed by the limited number of papers published in this field up to now.

12.2.3.3 Use of MALDI-TOF MS for the Identification of Fungal Species

Based on the UV irradiation of the sample while embedded in a matrix, MALDI-TOF MS (matrix-assisted laser desorption/ionization time-of-flight mass spectrometry) has several applications, ranging from the analysis of intact proteins to diagnostics. Over the last years, multiple studies have reported MALDI as a diagnostic technique in medical centers worldwide for the identification of bacteria, yeasts, and fungi (Panda et al. 2015; Paul et al. 2017, 2018; Putignani et al. 2011). The discrimination between microorganisms is based on highly specific peptide profiling (i.e., ribosomal fingerprinting) and has proven great precision, low costs, and speed of analysis (turnaround time of approximately 10 min) (Özhak-Baysan et al. 2015). MALDI has thus become a valid alternative to other identification techniques such as sequencing methodologies targeting ribosomal DNA (rDNA) genes (e.g., internal transcribed spacers, ITS), especially for the analysis of large numbers of isolates. Putignani et al. (2011) performed MALDI-TOF proteome phenotype profiling on more than 300 clinically relevant samples including several *Candida* species, by achieving a high analytical performance of yeasts and yeast-like identifications (IDs). Along with *Candida*, members of many fungal genera such as

Aspergillus, *Fusarium*, *Penicillium*, or *Trichoderma* have been successfully identified by MALDI-TOF MS (Chalupová et al. 2014; Del Chierico et al. 2012; Ranque et al. 2014).

MS-based species identification is especially relevant in black yeasts and black fungi, in view of the lack of reproductive cells, which hinders definitive identification through classical morphological, biochemical, and physiological methods (Özhak-Baysan et al. 2015). Nevertheless, a small number of studies have hitherto reported a MALDI-based identification of melanotic fungi, mostly due to the lack of a standardized protocol for protein extraction and a partial database availability (Borman et al. 2017; Kondori et al. 2015; Özhak-Baysan et al. 2015). More specifically, signal suppression was observed in darkly pigmented fungi due to the presence of melanin, resulting in poor fingerprint mass spectra containing few peaks of low relative abundance yield (Buskirk et al. 2011). The majority of the studies focus on the identification of black yeasts of the genus *Exophiala*, which includes agents of severe potentially fatal infections in both immunocompromised and immunocompetent individuals (Chalkias et al. 2014; Jeong et al. 2010; Kusenbach et al. 1992). To address the problems regarding the sample preparation and the lack of standardization, recently Paul et al. (2018) embraced an optimization work, which encompassed protein extraction as well as the creation of an in-house database for the rapid identification of melanized fungal isolates. Earlier, a broad in-house library was generated by Becker et al. (2014) by comparing MALDI-TOF MS with the classical identification methods, however only for filamentous fungi.

Based on these premises, MALDI-TOF MS will increasingly be applied in the future for the rapid diagnostic and detection of emerging clinically important melanized fungi.

12.3 Bioinformatics and Functional Analyses of Fungal Proteins

In the past, the analytical methodologies recruited for proteomics were based on conventional tools for protein characterization. The technical challenges comprised the overall coverage of physicochemical properties for a few thousands of proteins. Next-generation sequencing technology has represented the true milestones in science and paved the way for an upcoming challenge. In parallel proteomics involved interdisciplinary tools to evaluate the genes at the protein expression level.

Currently, proteomic analyses of extremophilic and extremotolerant fungi are challenged by various aspects, which have much to do with protein-related features such as protein identification, quantification, posttranslational modifications (PTMs), structure and function, and exploration of interactions and networks. The ultimate progress in fungal proteomics will be, however to achieve both protein identification and the understanding of protein function in the cell physiology.

In the last decade, we witnessed the generation of an extraordinary amount of proteomics and genomics data; however, the functional annotation leaves us waiting. The great ability of different proteomic separation tools such as gel-based and gel-free methodologies combined with high-resolution MS features makes data analysis using bioinformatics approaches and novel mathematical algorithms the major bottleneck for mass interpretation of obtained information.

The data generated in the field of black fungi and black yeasts are now increasing (Marzban et al. 2013). The genomic sequence data is progressively completing and the odyssey of homology searches in several available proteomic databases like UniProt (http://www.uniprot.org), Munich Information Center of Protein Sequences (MIPS) (http://www.helmholtz-muenchen.de/en/ibis) for plant pathogenic fungi, the Sanger Institute Fungal Sequencing (http://sanger.ac.uk/Projects/Fungi/), Central *Aspergillus* Data Repository (CADRE, http://www.cadre-genomes.org.uk/), Fungal Genome (http://fungalgenomes.org/), Fungal BLAST (https://www.yeastgenome.org/blast-fungal), FungiDB (http://fungidb.org/fungidb/), MycoBank (http://www.mycobank.org/), Fungal Annotation Project (https://www.uniprot.org/program/Fungi/), and Q Bank (http://www.q-bank.eu/fungi/) is becoming an exciting task. The global databases are gaining more efficiency for the homology searches (e.g., ExPASy (http://world-2dpage.expasy.org/repository/), PRoteomics IDEntifications database (PRIDE, www.ebi.ac.uk/pride/), MASCOT (http://www.matrixscience.com), and UNITE (https://unite.ut.ee/)). Additionally, different advanced platforms make the identification of fungal secretomics possible based on prediction of signal peptides, e.g., comparative fungal genomics platform (CFGP, http://cfgp.riceblast.snu.ac.kr/main.php) and SignalP 4.1 (http://www.cbs.dtu.dk/services/SignalP/). In both cases the correct genomic sequence data is the prerequisite for the prediction of secretory protein. Whereas CFGP encompasses secretome, transcription factor, and mitochondrial genome databases, among others, SignalP aids the prediction of signal peptide cleavage sites. Furthermore, the Fungal Secretome KnowledgeBase (FunSecKB and FunSecKB2 (Meinken et al. 2014); http://bioinformatics.ysu.edu/secretomes/fungi.php) and the Fungal Secretome Database (FSD; http://fsd.snu.ac.kr/) have been established to collect, manage, and use the data. FunSecKB collects secretomes from all available fungal protein data in the NCBI RefSeq database. The FSD is at present time the most accurate platform for putative secretory proteins, since it uses different databases like SigCleave, SigPred, and RPSP to screen those proteins not considered positive by SignalIP (Choi 2010). By increasing volume of data, the integration of more platforms using efficient algorithms must be developed to minimize the false-positive and false-negative results.

In the last years, a number of tools for the localization of intracellular proteins in fungi have been developed (e.g., WoLF PSORT, MultiLoc2, SherLoc2, MSLoc-DT, SCLpred) (Blum et al. 2009; Briesemeister et al. 2010; Horton et al. 2007; Mooney et al. 2011; Zhang et al. 2014). This aspect holds particular importance in black fungi where, as described earlier, the characterization of the subcellular proteome can be especially cumbersome. Along with pre-fractionation techniques, protein localization can be effectively demonstrated by means of fluorescent microscopy.

However, this requires fluorescent dyes, recombinant reporter proteins, or protein-specific antibodies, which might not be available for proteins not yet characterized as well as for unknown proteins. Bioinformatics tools can instead provide predictions of subcellular localization for a large number and a great variety of proteins, solely based on the amino acidic sequence. As protein localization and function are somewhat related, software-based predictions can additionally unravel protein potential functions and roles in biological processes.

In the example of black microcolonial fungi and black yeasts, however, we must still wait for the completion of annotation of genomics data, which will simplify the functional exploration of these still unknown living entities. Protein analysis is to a certain extent possible even when RNA-seq-based genome annotations are unavailable; however it requires resorting to a number of bioinformatics tools for the generation, in primis, of a database of predicted proteins. Currently AUGUSTUS is the best known tool for the "ab initio" translation of genome sequences based on training databases (i.e., annotated genome sequences from closely related species) (Hoff and Stanke 2013). Homology searches and PFAM (http://pfam.xfam.org/) analysis are then performed in order to obtain information about the biological function of the proteins (i.e., PFAM clan) (Nöbauer et al. 2017). By allowing the identification of proteins in yet not annotated organisms, "ab initio" translated databases ease the investigation of emerging model organisms and non-model-model organisms, thereby serving as basis for further and more detailed investigations.

The major challenge, however, will be the exploration of interactomics, biological networks, and PTMs by the means of epiproteomics, which are the key process regulators of extremotolerance and resistance.

12.4 Conclusions

The discovery of organisms like extremophilic and extremotolerant fungi and in particular black fungi influenced our knowledge about pathways and strategies that provide a biological systemic stubbornness against climate changes or sudden catastrophic environmental events. Primary efforts involved genomics and proteomics and more recently metabolomics and aimed at getting a more clear insight into the cell biology system as well as to obtain a comprehensive overview of the cellular processes under stress. However, the first ever step of the workflow, the sample preparation, has proven to be the real bottleneck for all of the analytical downstream approaches at present time. The standardization of extraction protocols will therefore be a foremost test for all future studies, in order for the extraction of fungal macromolecules and metabolites to be performed routinely or even be tailored for MS or DIGE, as it is already for plant or animal tissue.

The successful analyses of proteomic samples from extremophilic and extremotolerant fungal species carried out up to date have relied on the optimization of sample preparation workflows as well as on the availability of progressively improving mass spectrometry technologies and labeling protocols. Such approaches

showed to be adequate to deliver results and to characterize novel proteins or to explore already known pathways further. Despite the growing amounts of fungal functional data, genome annotation remains the main hindrance to the understanding of biological pathways leading to stress resistance. The application of pipelines for gene prediction, functional annotation, and comparative analysis as well as RNA-seq-based annotations to the study of extremophilic and extremotolerant fungi will therefore make the final breakthrough in the OMICS of these emerging model organisms.

Additional optimization work will be necessary in the field of fungal secretomics, which has hitherto proven to be the most challenging area in the investigation of adaptive capabilities of fungi in general and which still is in its early stages.

12.5 Future Perspective

A closer look to the habitats of the extremophilic fungi reveals a rare and desirable bioeconomy. The growing interest in the investigation of extremophilic fungi seems to have its roots in our time and in the challenges for our living space. The understanding of the evolutionary-based strategies of fungi to cope with harsh living conditions is of special interest for us.

We are currently witnessing climate change and global warming is undeniably underway. Both these aspects have had an influence on our own habitat, also having devastating effects on crop plants, which are essential for our existence. The urgency to counteract this state of things has sparked interest in alternative sources of energy, recycling of plastic materials, and pollution prevention, among others, consistently with the concept of sustainable living. The development of new ideas and the search for new products and biotechnological applications have at this point gained added value.

Fungi interactomics will therefore be in future the main challenge on the way to a full understanding of the system biology in a multidimensional network of genome, transcriptome, secretome, proteome, and metabolome. It seems clear that a cooperative functioning of all these levels motorizes the machinery of resistance to extreme environmental condition, while the organisms at the same time try to utilize and recycle the nutrients available as dead organic material. The future of extremophilic interactomics research looks mesmerizing and opens windows to technologies and strategies ranging from climate-resistant organisms and products on Earth to rapid transformation of Martian environment into a living space for humans.

Acknowledgements The authors would like to acknowledge the Austrian Science Fund (FWF-der Wissenschaftsfonds, Hertha-Firnberg Project T872-B22) and the BOKU Equipment GmbH as the founder of the VIBT-Extremophile Center for the technical and financial support of our research, whose outcomes widely contributed to this book chapter.

We also thank FWF for the project FWF-P24206, which allowed the initiation and the pioneering proteomics work on extremophilic black fungi.

The authors apologize to all researchers whose work could not be cited in this book chapter due to limits in manuscript dimensions.

Biotechnological Applications of Extremophilic Fungi

Chapter 13
Yeast Thriving in Cold Terrestrial Habitats: Biodiversity and Industrial/ Biotechnological Applications

Marcelo Baeza, Oriana Flores, Jennifer Alcaíno, and Víctor Cifuentes

13.1 Introduction

Environments with constant temperatures at 5 °C or below represent more than 80% of our planet, including polar regions, high mountains, glaciers, and deep oceans (Russell 1990). In spite of the fact that microorganisms are considered the primary organic matter recyclers in these cold environments, our current knowledge about them is still scarce, representing a pending challenge to microbiologists. Although yeasts are regarded as important nutrient recyclers due to their heterotrophic metabolism and ability to degrade organic macromolecules, their ecological role remains mainly unknown (Buzzini et al. 2012; Antony et al. 2016). Yeasts have evolved physiological adaptations to survive, grow, and successfully proliferate under the presence of several stress factors in cold environments, in addition to the low temperatures, nutrient deprivation, desiccation, and high UV radiation (D'Amico et al. 2006; Margesin and Miteva 2011; Wilkins et al. 2013; De Maayer et al. 2014). In addition to the ecological interest on cold-adapted microorganisms, the study of these microorganisms, especially of yeasts, has attracted the attention of researchers due to their potential applications in diverse industrial/biotechnological fields (Thomas-Hall et al. 2010; Tiquia and Mormile 2010; Buzzini et al. 2012; de Garcia et al. 2012; Buzzini and Margesin 2014a; Zalar and Gunde-Cimerman 2014; Tiquia-Arashiro and Rodrigues 2016). In this chapter, an actualized analysis of cold-adapted yeasts is presented that reveals the cold regions from which more studies and yeast species have been described. The identification of yeasts in the original works is contrasted to their current taxonomical classification, and according to the latter the yeast species that could be considered more ubiquitous in cold environments around

the earth is suggested. Furthermore, the incipient data referring to yeasts obtained in culture-independent approaches of cold environments and the novel or less reviewed elsewhere applied potential in diverse productive areas of cold-adapted yeasts is discussed.

13.2 Yeasts from Cold Environments

The study of cold regions is challenging because of their difficult accessibility and the need for substantial funds to perform accurate scientific research. For these reasons, the published works about isolation and identification of yeasts from cold environments are still limited and concentrated in areas of better accessibility of the earth, as can be observed in Fig. 13.1. Yeast species have been described from approximately 84 cold localities around the world, which according to the number of works reported from them and their geographic location can be mainly grouped in those from Shetland South Archipelago and Antarctic Peninsula, Patagonia, Alps, Apennines, and Italian glaciers, and sites close to Davis base and South Victoria Land at Antarctica. According to the current number of works reported, the most studied locations have been King George Island and South Victoria Land, 14 and 8 works, respectively. Concerning the yeast species identified from cold environments, in literature it is commonly stated that the vast majority of them belong to the genus *Cryptococcus*, an aspect that had changed profoundly in last years. The percentages of different genera of cold-adapted yeast species reported are shown in Fig. 13.2. The top five yeast genera described from cold environments, considering the reported identification in the original works (Fig. 13.2a), are by far dominated by *Cryptococcus* followed by *Rhodotorula*, and appearing in a minor proportion the genera *Candida*, *Mrakia*, and *Dioszegia*. However, the top five genera drastically change when the current taxonomical classification of yeasts is considered (Fig. 13.2b). In this case, *Mrakia* and *Naganishia* are the main genera, followed by *Rhodotorula*, *Candida*, and *Leucosporidium*, but all five species in similar proportions. As it can be observed, the most drastic change of genera when comparing the results from both taxonomical classifications is the proportion of the genus *Cryptococcus* that decreases from a 27% to only a 3%, and to a lesser extent in *Rhodotorula* that decreases from 15% to 7%. According to the current taxonomic classification of yeasts, the locations in which the greatest number of different yeast species have been reported (see Fig. 13.1) are King George Island (81), followed by du Geant-Miage Glacier (49), Kandalaksha (42), Nahuel Huapi Lake (34), Calderone Glacier (32), Kongsfjorden (31), South Victoria Land (29), Olsztyn (25), Nahuel Huapi Park (24), Ross Sea region (22), and Mount Tronador (20). The cold-adapted yeast species that have been isolated and identified from more cold environments around the world are *Debaryomyces hansenii*, *Rhodotorula mucilaginosa*, *Cystobasidium laryngis*, *Vishniacozyma victoriae*, and *Papiliotrema laurentii* (shown in triangles in Fig. 13.1). On the other hand, there is a high number of cold-adapted yeasts that have been isolated and identified from only one location, corresponding to 55% at the species level and 48% at the genus level of all the yeasts that have been isolated and identified from cold environments.

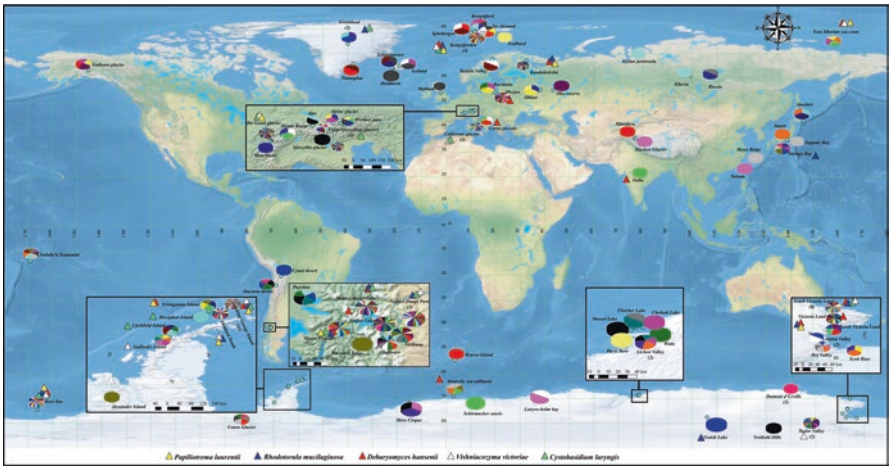

Fig. 13.1 Identified yeasts isolated from different cold environments on earth. The pie chart at each location represents the fraction of different species described. The number of yeast isolation/identification reports from each locality from which at least two works have been published is indicated in parenthesis. Yeast species that have been isolated from at least ten locations are indicated in triangles. Data considered only works where molecular taxonomical markers were used for yeast identification, such as the ITS or D1/D2 region of the rDNA, and was collected from literature revisions performed until January 2018 (di Menna 1966; Goto et al. 1969; Baharaeen and Vishniac 1982; Gounot 1986; Baublis et al. 1991; Ray et al. 1992; Babjeva and Reshetova 1998; Golubev 1998; Ma et al. 1999; Montes et al. 1999; Petrescu et al. 2000; Scorzetti et al. 2000; Nagahama et al. 2001; Bab'eva et al. 2002; Thomas-Hall 2002; Vishniac 2002, 2006; Birgisson et al. 2003; Libkind et al. 2003, 2009a, b; Guffogg et al. 2004; Nakagawa et al. 2004; Bergauer et al. 2005; Gilichinsky et al. 2005; Starmer et al. 2005; Arenz et al. 2006; Fell et al. 2006; Butinar et al. 2007, 2011; Chen et al. 2007; de García et al. 2007; Margesin et al. 2007; Sansone et al. 2007; Xin and Zhou 2007; Connell et al. 2008, 2009, 2010; Turchetti et al. 2008, 2011, 2013; Zalar et al. 2008; Bridge and Newsham 2009; D'Elia et al. 2009; Pavlova et al. 2009; Branda et al. 2010; Kachalkin 2010; Konishi et al. 2010; Pathan et al. 2010; Thomas-Hall et al. 2010; Brandão et al. 2011, 2017; Vaz et al. 2011; Carrasco et al. 2012; Singh and Singh 2012; Uetake et al. 2012; Zhang et al. 2012, 2013, 2017; Duarte et al. 2013, 2016; Godinho et al. 2013; Laich et al. 2013, 2014; Rovati et al. 2013; Tsuji et al. 2013a; Vaca et al. 2013; Ejdys et al. 2014; Furbino et al. 2014; Mestre et al. 2014; Selbmann et al. 2014a, b; Vasileva-Tonkova et al. 2014; Coleine et al. 2015; Jacques et al. 2015; Pulschen et al. 2015; Barahona et al. 2016; Martinez et al. 2016; Filipowicz et al. 2017; Hassan 2017; Martorell et al. 2017; Trochine et al. 2017)

13.3 Identification of Cold-Adapted Yeasts Using Metagenomic Approaches

Most of our current knowledge about the microbial diversity of cold environments is due to studies based on traditional culture-dependent methodologies. However, it is known that only a small proportion of viable microorganisms are recovered from diverse environmental samples using this strategy, estimated to be only a 17% in the case of fungi (Holdgate 1977). The environmental microbial ecology has been

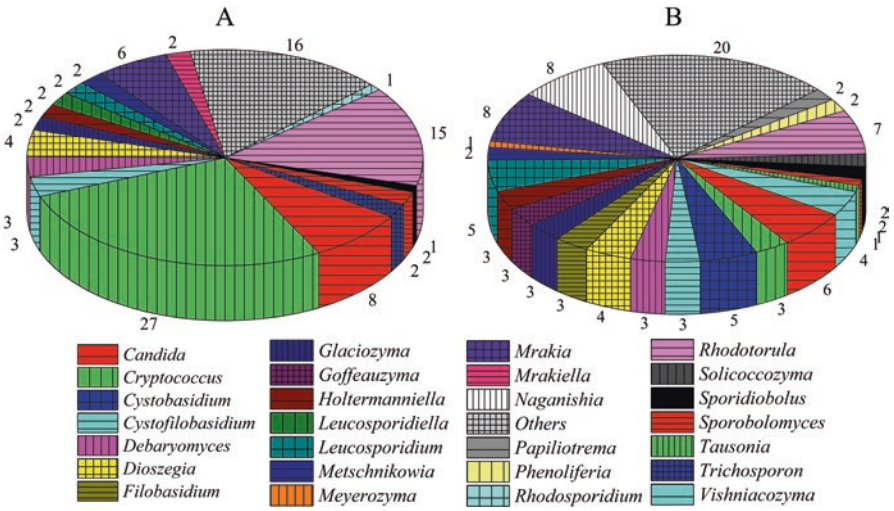

Fig. 13.2 Proportion of cold-adapted yeasts described at the genera level. The percentages of cold-adapted yeast species belonging to different genera are shown according to the description in the original publication (**a**) and to current taxonomical classification (**b**). Source: data as in Fig. 13.1

revolutionized by the development of culture-independent methodologies, especially by the use of metagenomics approaches that allow a more exhaustive exploration of the taxonomic composition and metabolic profiles of communities of diverse environments (Rondon et al. 2000). Initially, metagenomic libraries were constructed using total DNA purified directly from the environmental samples for sequencing analysis followed by functional characterization by heterologous expression methods (Rondon et al. 2000; Voget et al. 2003; Delmont et al. 2011). The advances of high-throughput DNA sequencing technologies, bioinformatic tools, and databases allowed a progressive discovery of novel genes, physiological pathways, and species from diverse environments (Simon et al. 2009; Berlemont et al. 2011; Pearce et al. 2012; Choudhari et al. 2014b; Culligan et al. 2014; Alves Junior et al. 2015; Rivkina et al. 2015), and also it has helped to compare the microbial composition in different environments (Varin et al. 2012; Choudhari et al. 2014a; Lee et al. 2015; Johnston et al. 2016). In metagenomic studies where eukaryotes have been identified, it has been observed that they are present in a lower proportion (less than a 10%) than prokaryotes. Taking into account microbial eukaryotes, they are mostly represented by ascomycetous and basidiomycetous fungi (Simon et al. 2009; Rogers et al. 2013, 2013; Baeza et al. 2017b).

The identification of microorganisms based on metagenomic data generated from metagenome analysis needs robust bioinformatic tools and databases; the latter has been more developed for prokaryotes (Kim et al. 2013). A fungi database was recently published from a metagenomic study on Antarctic soil samples, which was initially performed to search bacteria capable of degrading diesel oil

(Donovan et al. 2018). Another molecular approach used to identify microbial species is the "metabarcoding," which is based on the amplification by the polymerase chain reaction (PCR) of species-discriminating barcode genes or sequences followed by next-generation sequencing (Kim et al. 2013). This methodology has been successfully used in the identification of fungal species from Antarctic regions, using the internal transcribed spacers (ITS) and the D1/D2 domain of the large ribosomal DNA as barcode sequences (Kurtzman et al. 2015; Antony et al. 2016).

Metagenomic studies detecting fungi from cold environments are currently very limited and even more scarce for yeasts. In a study of permafrost in the high Canadian Arctic, it was found that the proportion of sequences belonging to fungi was 200- to 10,000-fold lower than the proportion of prokaryotic DNA sequences (Yergeau et al. 2010); a lower proportion of fungal sequences was also observed in samples obtained from ice core sections from Lake Vostok (Rogers et al. 2013). In a study of permafrost from Muot da Barba Peider (Eastern Swiss Alps), operational taxonomic units (OTUs) including lichenized fungi of the genera *Lecidea*, *Acarospora*, or *Umbilicaria* and yeasts of the genera *Rhodotorula*, *Cryptococcus*, *Mrakia*, and *Leucosporidium* were found (Frey et al. 2016). In an amplicon-metagenomic analysis of soils from islands of the South Shetland archipelago and Antarctic Peninsula, and from Union Glacier at Antarctica based on the D1/D2 rDNA region, OTUs corresponding to fungi were distributed in 87 genera and 123 species (Baeza et al. 2017b). Regarding yeasts, the highest fraction of them corresponded to basidiomycetes, which is according to data obtained from viable yeast studies. Also, 37 yeast genera were found that were not previously cultivated from Antarctic samples.

13.4 Applications of Cold-Adapted Yeasts

The best known potential of cold-adapted yeasts that can be applied in several fields lies in their hydrolytic enzymes, such as lipases, amylases, and proteases, which are valuable for industrial processes or for the generation of products that require enzymes highly active at low temperatures. These have been revised in previous reviews and book chapters (Gerday et al. 2000; Tutino et al. 2010; Cavicchioli et al. 2011; Buzzini et al. 2012; Feller 2013; Gerday 2013, 2014; Joshi and Satyanarayana 2013; Białkowska and Turkiewicz 2014; Buzzini and Margesin 2014a, b; Alcaíno et al. 2015; Sarmiento et al. 2015; Baeza et al. 2017a). Here, some newfangled or less revised applied potentialities of cold-adapted yeasts are briefly discussed.

The multiple health benefits of fermented foods are known (Marco et al. 2017), and currently low-temperature fermentations are valued to improve flavor, for example, in the production of dairy products, bread, and alcoholic beverages (Kanellaki et al. 2014). Another example is the wine industry, which is continuously evolving according to the consumer preferences. Currently, there is high demand for wines having a lower alcohol content (Schmidtke et al. 2012; Varela et al. 2012; van Bussel et al. 2018) as they have less negative impacts on flavor and aroma perception,

and on human health (Golddner et al. 2009; Kutyna et al. 2010). Even though there are physical-chemical techniques to reduce the alcohol content in wine, an alternative and promising tool to produce this kind of wines is the use of cold-adapted *Saccharomyces* and non-*Saccharomyces* yeasts to perform the must fermentation at lower temperatures. The psychrotolerant yeast *Candida sake* was tested in the fermentation of concentrated natural must from Spanish wineries (Tempranillo 2012) at 12 °C. By this approach, the typical cold-associated *S. cerevisiae* lag phase in the fermentation was avoided, and the obtained wine had a significantly lower ethanol content (a 30% fold reduction) and glycerol (50% fold reduction, but sorbitol was produced as a compatible osmolyte), and different aromatic features (Ballester-Tomás et al. 2017). A psychrophilic strain of *S. cerevisiae* immobilized onto apple cuts was successfully used in continuous wine fermentation at 5–15 °C. Under these conditions, the microbiological contamination was reduced, and the obtained wine was similar to dry wines considering total and volatile acids, but it had an overall improved quality (Kourkoutas et al. 2002). In beer brewing at 5 °C using domestic refrigerators, a freeze-dried immobilized format of a cold-adapted strain of *S. cerevisiae* (AXAZ-1) showed a good performance, obtaining beer of good clarity, with an acceptable amount of volatile compounds, and lower diacetyl and polyphenol contents than commercial beers (Gialleli et al. 2017).

Microorganisms are the primary organic matter recyclers in cold environments, displaying a wide range of metabolic activities, including the degradation of a broad range of hydrocarbons (Margesin 2007). For example, the use of phenol, n-hexadecane, and methanol as a carbon source was described in cold-adapted yeasts isolated from Antarctica (Fernández et al. 2017). Yeasts isolated from the Alps, including *Cryptococcus terreus* and species of *Rhodotorula*, also showed the ability to degrade phenol and phenol-related mono-aromatic compounds, in some cases using immobilized yeast cells on zeolite at temperatures as low as 10 °C and phenol concentration from 10 to 12.5 mM (Margesin et al. 2003; Bergauer et al. 2005; Krallish et al. 2006). For the treatment of other contaminant/refractory materials as wastewater containing cow's milk, an Antarctic yeast identified as *Mrakia blollopis* showed promissory results. This yeast showed a high biochemical oxygen demand (BOD) removal rate on a wastewater model at low temperature, an ability that was attributed to the production of cold-active lipase (Tsuji et al. 2013b). These examples, and surely many other similar ongoing works, support the potential of cold-adapted yeasts to be applied in bioremediation of contaminated soils and water.

In the field of postharvest fruits, vegetables, and grains, the biological control of pests is gaining space as an alternative to reduce the current chemical treatments (Liu et al. 2013; Sangorrín et al. 2014). Yeasts of different genera have been used for the biocontrol of fungal phytopathogens, in which the reported control mechanisms include competition for nutrients and space, production of cell wall-degrading enzymes and antifungal compounds, mycoparasitism, and induction of host resistance (El-Tarabily and Sivasithamparam 2006). Cold-adapted yeasts represent good candidates for postharvest biocontrol, especially for refrigerated products. Epiphytic isolates of *Aureobasidium pullulans* and *Rhodotorula mucilaginosa* obtained from

healthy pears from two Patagonian cold-storage packing houses were able to reduce to a 33% the fruit decay produced by *Penicillium expansum*, and the lesion diameter was reduced by an 88% after 60 days of incubation in cold (Robiglio et al. 2011). Similarly, cold-adapted yeasts isolated from soils of Tibet showed a high potential to be used in biocontrol. Isolates identified as *R. mucilaginosa* and *Cryptococcus laurentii* (now *Papiliotrema laurentii*) reduced the incidence of decay on cherry tomatoes due to *P. expansum* and *Botrytis cinerea* about a 65% and a 52%, respectively (Hu et al. 2015, 2017). A *Leucosporidium scottii* isolate from Antarctic soils showed to be a good biocontrol agent for blue and gray mold on two apple cultivars; moreover, the isolate was resistant to commonly used postharvest fungicides, which allows its use in combination to low-dose fungicides in an integrated management practice (Vero et al. 2013).

Another potential field for application of cold-adapted yeasts is in the development of alternative combustibles to fossil fuel, for example, through the fermentation of raw materials such as starch and lignocellulose (Tiquia-Arashiro and Mormile 2013). Advances in this area have included methods for the conversion of these feedstocks to fermentable sugars (ozonolysis, acid or alkaline hydrolysis), design of bioreactors, growth condition optimization, and immobilization of yeasts. However, a significant challenge is to simplify and reduce the cost of bioethanol production by the simultaneous saccharification and fermentation of raw sources rich in starch or cellulose (Petrovič 2015) by supplementing to the *S. cerevisiae* fermentation process amylases and/or cellulases. The enzymes currently available in the market are active at temperatures ≥50 °C; therefore, enzymes having high activity at lower temperatures to make the process more cost effective are needed. In this way, the amylases and cellulases produced by cold-adapted yeasts and fungi such as *Tetracladium* sp., *Cystofilobasidium capitatum*, *Rhodotorula glacialis*, and *Mrakia blollopis* (Hamid 2015; Carrasco et al. 2016, 2017; Daskaya-Dikmen et al. 2018) are attractive candidates to be applied in the bioethanol industry. Furthermore, the Antarctic yeast *M. blollopis* has a unique capacity to ferment cellulosic biomass, reaching up to 12 g L^{-1} of alcohol from Japanese cedar and Eucalyptus pulp (Tsuji et al. 2013c). Another attractive eco-friendly fuel is biodiesel, which is currently produced from plant oils or waste cooking oils/fats. However, these sources of biodiesel have the inconvenience of their inconsistent composition and quality, and a considerable formation of C_1–C_4 hydrocarbons, which limits the production capacity (Bateni et al. 2017; Mishra and Goswami 2018). Good alternatives are oleaginous yeasts such as *Yarrowia lipolytica* that produce lipids from various economical substrates by fermentation under aerobic conditions (Xie 2017). Oleaginous microorganisms with the potential to be used as biodiesel sources have been isolated from cold environments. Among yeasts isolated from Tibetan Plateau, *Cryptococcus* species accumulated more than 30% of lipid content (Li et al. 2012), and isolates of *Rhodotorula glacialis* a 68% lipid/biomass, reaching a lipid/glucose yield of 16% (Amaretti et al. 2010). Antarctic isolates of *Rhodotorula glutinis* and *R. glacialis* showed high lipid production and accumulation (5–7 g L^{-1}) and accumulated large amounts of lipids per gram of biomass (47–77% w/w) (Viñarta et al. 2016).

13.5 Conclusions and Future Perspectives

It is clear that our knowledge about yeasts living in cold environments is very limited because the majority of studies are based on culture-dependent methodologies and concentrated in some locations, in spite of the majority of earth's biosphere being cold. It is desirable to broaden the research to more cold regions, for example glacial areas more easily accessible. Along with that, the application of culture-independent methodologies is essential, since although efforts are being made to develop cultivation methodologies to emulate environmental conditions, this is a tough task because of the unknown macro- and micronutrient requirements and in many cases the yeasts grow only in association with other organisms. Culture-independent methodologies have advanced greatly, including the purification of nucleic acid directly from diverse environmental materials and high-throughput sequencing. However, a pending task in this direction is the availability of a robust sequence database of fungi/yeasts for correct identification, including the detection of genes. This will be an essential input to knowing the metabolic potential of fungal communities and to finding novel genes desirable for application in diverse areas.

Chapter 14
Pharmaceutical Applications of Thermophilic Fungi

Gurram Shyam Prasad

14.1 Introduction

Microbial life is not only restricted to specific environmental conditions like moderate temperature and neutral pH, where salinity, hydrostatic pressure, and ionizing radiations are low. Large group of microbial communities were also found in most diverse environments including extremes of temperature, pressure, salinity, and pH. The microorganisms thriving optimally under one or several of these diverse conditions for their growth are termed as extremophiles which include acidophiles, alkalophiles, halophiles, psychrophiles, thermophiles, hyperthermophiles, radioresistant microbes, barophiles, and endoliths. The term extremophile was used for the first time by MacElroy in 1974 (Gomes and Steiner 2004). The extremophiles that have been identified to date belong to the domain of the archaea. However, these have also been identified in eubacterial and eukaryotic organisms (Burg 2003). Among extremophiles, thermophilic fungi are a small group of mycota with an exceptional mechanism of growing at an elevated temperature of at or above 50 °C. Thermophily in these fungi is not as extreme as in eubacteria or archaea which are able to grow near or above 100 °C in thermal springs, solfatara fields, or hydrothermal vents (Brock 1995; Blohl et al. 1997). The fungi which grow at or above 20 °C and attain maximum growth at or above 50 °C are thermophilic while thermotolerant forms opt 20–55 °C for growth.

Thermophilic fungi form a diverse group of organisms reported from various natural habitats, viz. soils and in habitats where plant material decomposition takes place which includes compost, wood chip piles, nesting material of birds, and

animal and municipal refuse (Prasad et al. 2011). These are also reported from stored groundnuts (Ogundero 1981), forest soils (Sandhu and Singh 1985), mushroom composts (Ross and Harris 1983; Miller et al. 1990; Weigant 1992; Stratsma et al. 1994; Johri and Rajani 1999), desert soils (Mouchacca 1995), vermicomposts (Anastasi et al. 2005), hot springs (Lin et al. 2005), and alkalescent thermal springs (Pan et al. 2010). Tubaki et al. (1974) have also recorded thermophilic fungi even from aquatic environments. These fungi survive the stress such as oxygen and desiccation (Mahajan et al. 1986). Majority of the fungi were isolated from herbivore dung and bird nest materials (Mouchacca 1997, 1999). Thermophilic fungi are the principal components of the microflora that develops in heaped stacks of plant material, piles of agricultural and forestry products, and other accumulations of organic matter where the warm, humid, and aerobic environment provides the ideal conditions for their growth (Allen and Emerson 1949). In these habitats, thermophiles may occur as resting propagules or as active mycelium depending on the availability of nutrients and favorable environmental conditions (Khushaldas 2009). The exothermic reactions of the saprophytic mesophilic microflora raise the temperature of the substratum to 40 °C, resulting in a warm environment favoring the germination of spores of thermophilic microflora, and eventually the latter outgrows the mesophilic microorganisms. The thermophilic fungi constitute a heterogeneous physiological group of various genera in the Mastigomycotina, Ascomycotina, Deuteromycotina, and Mycelia Sterilia (Mouchacca 1997). Most significant natural habitats for saprophytic thermophilic fungi are the decomposing organic materials in which thermogenic conditions resulted in the activity of mesophilic microorganisms (Eggins and Coursey 1964). Thermophilic fungi are worldwide in distribution and most species do not show any geographical restrictions and their gene pool is still uncertain.

The first of the known thermophilic fungi, *Mucor pusillus*, was isolated from bread over a century ago by Lindt (1886). A little later, Tsiklinskaya discovered another thermophilic fungus, *Thermomyces lanuginosus*, growing on potato which had been inoculated with garden soil (Tsiklinskaya 1899). Several workers including Cooney and Emerson (1964), Chang (1967), Eggins and Malik (1969), Evans (1971), Crisan (1973), Ofosu-Asiedu and Smith (1973), Tansey and Brock (1978), Kuthubutheen (1983), Ito et al. (1992), Johri and Satyanarayana (1986), Sharma and Johri (1992), Maheshwari (1997), Niehaus et al. (1999), Kohilu et al. (2001), Cordova et al. (2003), Moloney et al. (2004), Fulleringer et al. (2005), Salar and Aneja (2007), Khushaldas (2009), Pan et al. (2010), and Sreelatha et al. (2018) have isolated these fungi from different ecological niches.

Though thermophilic fungi are recognized for wide biotechnological applications, their application in the pharmaceutical industry is unexplored. In this review, potential pharmaceutical applications of thermophilic fungi are discussed.

14.2 Pharmaceutical Applications of Thermophilic Fungi

14.2.1 Biotransformation of Organic Compounds for Bioactive Compound Synthesis

Biotransformation is the method by which an organism or its enzyme brings out minor chemical alterations on compounds that are not part of their metabolism and result in a novel or more useful product than its parent compound which is difficult or impossible to obtain by conventional chemical methods (Prasad et al. 2010). Almost all types of chemical reactions are made achievable by microbial transformations. Further, this process is hazard free, and minimizes the problems of isomerization, racemization, epimerization, and rearrangement that generally occur during the chemical process. Though biotransformation reactions employing mesophilic microbial cultures are well documented, such reactions employing thermophilic organisms are limited. Thermophilic enzymes show thermostability and offer many major advantages over mesophiles (Nguyen et al. 2013; Tiquia-Arashiro 2014). The main advantages of performing biocatalytic reactions using thermophiles are reduced risk of mesophilic microbial contamination, lower viscosity of the medium, improved transfer rates, and improved solubility of substrates (Bruce et al. 1991; Lasa and Berenguer 1994). They are also known to withstand denaturants of extreme acidic and alkaline conditions (Tiquia-Arashiro and Rodrigues 2016a). Thermophilic enzymes, when cloned and expressed in mesophilic hosts, are easy to purify by heat treatment. Their thermostability is also associated with higher resistance to chemical solvents (Pomaranski and Tiquia-Arashiro 2016; Tiquia-Arashiro and Rodrigues 2016b). These reactions are the subject of increasing interest in the pharmaceutical industry because of the demand for enantiomerically pure compounds (Schulze and Wubbolts 1999). Some of the examples of biotransformation reactions employing thermophilic fungi are reported in this section.

14.2.1.1 Biotransformation of Albendazole to Albendazole Sulfoxide by *Rhizomucor pusillus*

Albendazole is a benzimidazole carbamate with a broad-spectrum anti-helminthic activity. It is marketed as a prodrug and after administration; it is rapidly metabolized by oxidation in the liver to form its active metabolite albendazole sulfoxide (Prasad et al. 2008). Synthesis of albendazole sulfoxide chemically is difficult as it is site-specific reaction where oxidation has to take place at sulfur group while the process also leads to environmental pollution. Biotransformation is the best alternative to synthesize albendazole sulfoxide. The mesophilic fungal culture *Cunninghamella blakesleeana* NCIM 687 was reported to transform albendazole to albendazole sulfoxide in a single-step reaction with a yield of 16% at 27 °C (Prasad et al. 2008) while

thermophilic fungus *Rhizomucor pusillus* NRRL 28626 could transform albendazole to albendazole sulfoxide with a yield of 60% at an incubation temperature of 45 °C which is far more superior to mesophilic fungus (Prasad et al. 2011).

14.2.1.2 Biotransformation of Ferulic Acid to Guaiacol by *Sporotrichum thermophile*

Vanillic acid which is used as the starting material in chemical synthesis of oxygenated aromatic chemicals such as vanillin, one of the most universally used aromatic molecules in the pharmaceutical, food, and cosmetic industries, was produced from ferulic acid employing thermophilic fungal culture *Sporotrichum thermophile* at a temperature of 50 °C by propenoic chain degradation via an intermediate compound 4-vinyl guaiacol with very high levels of 4798 mg/L with a molar yield of 35% (Topakas et al. 2003). Initially, ferulic acid is decarboxylated to 4-vinyl guaiacol which is further converted to vanillic acid which later undergoes a nonoxidative decarboxylation to guaiacol. The thermophilic fungus *Sporotrichum thermophile* has a considerable potential in performing decarboxylation reaction and synthesis of high yields of vanillic acid compared to mesophilic fungal cultures *Paecilomyces variotii* 3.2 mg/L (Rahouti et al. 1989), *Aspergillus niger* 920 mg/l (Meessen et al. 1996), *Aspergillus niger* 357 mg/L (Meessen et al. 1999), *Schizophyllum commune* 0.13 mM (Ghosh et al. 2005), *Paecilomyces variotii* 115 mg/L (Ghosh et al. 2006), and *Aspergillus niger* K8 116mg/L (Motedayan et al. 2013).

14.2.1.3 Biotransformation of Steroids by Thermophilic Fungi

The most important group of pharmaceuticals are steroid drugs which are effective as antiphlogistics, progestational, male and female sex hormones, blood pressure-regulating agents (Sayanarayana and Chavant 1987), and anabolic, antitumor, sedative, as well as oral contraceptives (Zohri and Abdel-Galil 1999). They are also effective in allergic, dermatologic, and ocular diseases and in cardiovascular therapy (Zohri and Abdel-Galil 1999). Some of them are also used in veterinary medicine. Commercial production of steroids is very much needed whose chemical synthesis requires multistep reactions and is a costly affair. For example cortisone steroid can be synthesized chemically from deoxycholic acid which requires 37 steps and must be carried out under extreme condition of temperature and pressure resulting in high production cost. But, with microbial transformation, the number of steps both chemical and microbial was reduced to two with reduced production cost. Not only mesophilic microorganisms, but also thermophilic fungi are potential enough to synthesize steroid drugs in eco-friendly and economical manner with many more advantages. Cholestenone, which represents an important group of pharmaceuticals, is used against obesity, liver disease, and keratinization and also serves as a precursor for the synthesis of other drug intermediates like androst-4-ene-3,17-dione and androsta-1,4-diene-3,17-dione; it also serves as a major

starting material for production of anabolic drugs and contraceptive hormones (Wu et al. 2015). Chemical synthesis of cholestenone is a difficult task as the molecule consists of asymmetric centers and requires harmful chemical solvents. Sayanarayana and Chavant (1987) could efficiently transform cholesterol in a single step employing thermophilic fungi *Acremonium alabamensis* and *Talaromyces emersonii* to cholestenone in an eco-friendly and cost-effective way. Similarly, different biotransformation products of steroids produced by using thermophilic fungi are shown in Table 14.1.

14.2.2 Thermophilic Fungi in Predicting Mammalian Drug Metabolism

Biotransformation is the principal route of elimination of drugs from the body which is metabolized upon administration by a series of enzymatic conversions leading to chemical alteration to more polar and hydrophilic metabolites for easy excretion (Rowland and Tozer 1995). The products of the metabolism are called metabolites which may be inactive or they may have a similar or different degree of therapeutic activity or toxicity than the original drug. The liver is the principal site of drug metabolism and significant levels of drug-metabolizing enzymes also occur in other organs. The biotransformation reactions occur in the liver in two stages classified as phase I and phase II. Phase I reactions occur in microsomes and are catalyzed by a group of enzymes known as cytochrome P450 system that plays a significant role in drug metabolism. The common chemical reactions involved in phase I are aromatic hydroxylations, oxidative *N*-dealkylation, S-oxidation, reduction, and hydrolysis. Phase II reactions occur in liver cells where the parent or the metabolite from phase I gets conjugated by glucuronidation, sulfation, amino acid conjugation, acylation, methylation, or glutathione conjugation to facilitate elimination (Gunaratna 2000).

In the course of drug innovation, understanding drug metabolism and metabolite toxicity is very crucial. Prior to consent to use in humans, a wide range of studies to establish safety and efficacy are mandatory which can be known by drug metabolism studies. Different animal models, microsomal preparations, perfused organ systems, etc. are presently accessible for drug metabolism studies but are associated with some disadvantages. Further, for evaluating pharmacological and toxicological studies large quantities of metabolites are required which is difficult with animal or with in vitro models while chemical synthesis of metabolites in a laboratory is also a tedious and costly process. Microorganisms, especially most of the fungi, were found to possess cytochrome p450 enzyme (CYP450) system and oxidize organic compounds in the same way as mammalian hepatic CYP450 enzymes. Many mammalian phase I (introduction of a functional group) and phase II metabolic reactions (conjugation with endogenous compounds) also occur in microbial models (Abourashed et al. 1999). The filamentous fungi, especially of the

Table 14.1 Some of the examples of biotransformation reactions mediated by thermophilic fungi

Thermophilic fungi	Substrate	Transformation products	Reference

	Dehydroepiandrosterone	3β,7α-Dihydroxy-androst-5en-17one 3β,7β-Dihydroxy-androst-5en-17-one	

genus *Cunninghamella*, are well documented as a model of mammalian biotransformation (Sun et al. 2004). The use of fungi as microbial models in predicting mammalian models is associated with many advantages like low cost, ease of handling, scale-up capacity, and potential to reduce the use of animals (Zhang et al. 2006). Further, fungi can also be used as metabolic factories to produce huge quantities of metabolites which is not possible with other available models. This mode of drug metabolism studies with microbial models and producing metabolites in large quantities using fungi is very convenient and a preparative method for otherwise difficult-to-obtain ones particularly when the structure of metabolite is complex. This approach has been successfully employed by many researchers comparing drug metabolism using mesophilic fungal and mammalian systems (Sun et al. 2004; Zhong et al. 2003; Cha et al. 2001; Moody et al. 1999, 2000; Hezari and Devis 1993) but the potential thermophilic fungi are unexplored in this area. Very few researchers (Prasad et al. 2011, 2018; Sreelatha et al. 2018) studied drug metabolism employing thermophilic fungi.

14.2.2.1 Metabolic Studies of Losartan Using *Rhizomucor pusillus* NRRL 28626

Losartan is the first of new class of antihypertensive drugs (Siegl 1993) and substrate for CYP 2C9 and CYP 3A4 enzymes. It is metabolized in humans by oxidation of C5-hydroxy methyl to the active metabolite carboxylic acid by CYP450 3A4 and by CYP450 2C9 (Lee et al. 2003). The aldehyde metabolite is also observed in human as an intermediate in the oxidation of losartan to carboxylic acid metabolite (Stearns et al. 1995), which is excreted in urine and feces as a conjugate (Boris and Bernahard 2003; Yun et al. 1995). The other routes of metabolism include C-1′, C-3′ hydroxylations and *N*-2 tetrazole glucuronidation. Similarly, the thermophilic fungus *Rhizomucor pusillus* NRRL 28626 biotransformed losartan to five metabolites (Fig.14.1), viz. glucuronic conjugate of losartan (M1), 3-hydroxy-*N*-acetyl losartan (M2); the metabolite M3 was produced by oxidation and acylation of demethylated and dechlorinated parent compound losartan; the other metabolite of losartan produced by *Rhizomucor pusillus* was found to be *N*-acetylated carboxylic acid compound (M4); and the metabolite M5 of losartan produced by the fungus was by decarboxylation of a carboxylic acid metabolite of losartan (Prasad and Srisailam 2018). The metabolite M1 produced by *Rhizomucor pusillus* was also detected by Huskey et al. (1993) using liver microsomes of rat, monkeys, and humans while Krieter et al. (1995) reported in rat intestine. This metabolite was reported to catalyze by UGT superfamily of enzymes in animals (Prasad and Srisailam 2018). The metabolite M2 produced by *Rhizomucor pusillus* is by *N*-acetylation reaction catalyzed by *N*-acetyl transferase in mammals which is a well-known reaction (Prasad et al. 2018). The other metabolite M4 produced by thermophilic fungus was also recorded by Yun et al. (1995) in the mammalian metabolic pathway of losartan catalyzed by CYP3A4.

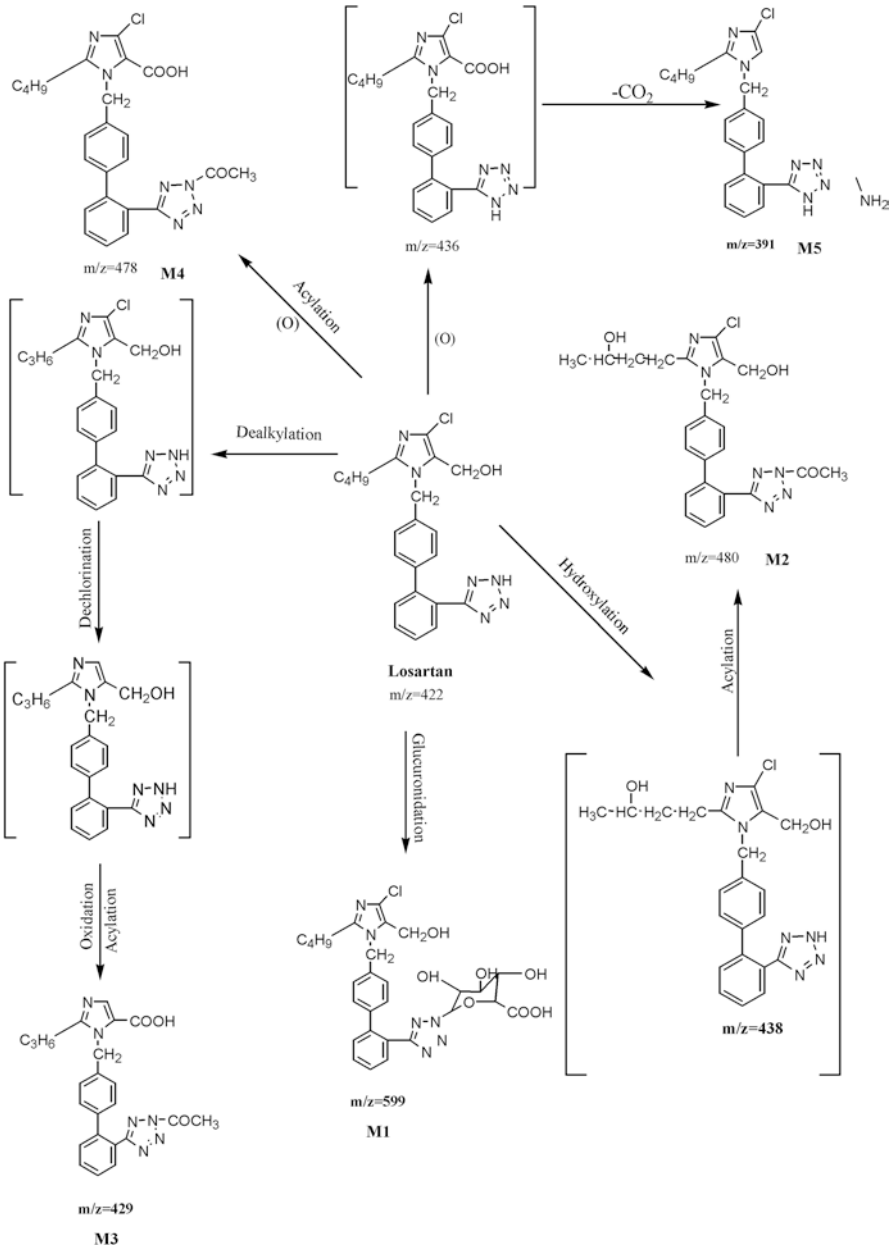

Fig. 14.1 Metabolic pathway of losartan by *Rhizomucor pusillus. Source* Prasad and Srisailam (2018).Copyright © International Research Journal of Natural and Applied Sciences (Associated Asia Research Foundation) Reproduced with permission

The fungus *R. pusillus* transformed losartan to five metabolites by oxidation, hydroxylation, acylation, dechlorination, dealkylation, and glucuronidation of losartan which clearly states that this thermophilic fungus *R. pusillus* NRRL 28626 has the ability to catalyze diverse reactions compared to mesophilic fungi. Similarly, the metabolites of losartan produced by the fungus are similar to metabolites of losartan reported in mammals which clearly states that similar type of enzyme system exists in mammals and this fungus.

14.2.2.2 Metabolism of Albendazole by *Rhizomucor pusillus* NRRL 28626

Benzimidazole anti-helminthics with a sulfide group are the most active against intestinal nematodes in humans, as well as in animals. Albendazole is a benzimidazole carbamate with a broad antiparasitic spectrum. The metabolic studies of albendazole have been shown to follow similar pathways in various mammals. These metabolic conversions included oxidation at sulfur alkyl and aromatic hydroxylation, methylation at both nitrogen and sulfur, and carbamate hydrolysis (Gyurik et al. 1981). Albendazole sulfoxide and albendazole sulfone were identified in plasma after oral administration in several species, viz., rat, human, porcine, ovine, bovine, caprine, and chicken (Penicaut et al. 1983; El Amri et al. 1987; Benchaoui et al. 1993; Lanusse et al. 1993; McKellar et al. 1993; Moroni et al. 1995; Csiko et al. 1996). The flavin-containing monooxygenases and cytochrome P-450 (CYP, mainly CYP3A in rat) appear to mediate the conversion of albendazole to albendazole sulfoxide, whereas the biotransformation of albendazole sulfoxide to albendazole sulfone is influenced by CYP only (CYP1A in rat) (Prasad et al. 2011). The drug is rapidly metabolized by oxidation in the liver to form its sulfoxide and sulfone. In animals after parenteral, oral, or intraruminal administration, albendazole is rapidly oxidized to the sulfoxide (Marriner and Bogan 1980); later, albendazole sulfoxide undergoes bioconversion to albendazole sulfone which is pharmacologically inactive (Lacey 1990). Similarly, the thermophilic fungus *Rhizomucor pusillus* NRRL 28626 was reported (Prasad et al. 2011) to biotransform albendazole to albendazole sulfoxide (M1), albendazole sulfone (M2), the major mammalian metabolites of albendazole reported previously and an *N*-methyl metabolite of albendazole sulfoxide (M3), and other metabolite (M4) which clearly states that metabolic pattern of mammals and the thermophilic fungus *Rhizomucor pusillus* NRRL 28626 are similar (Fig.14.2). Hence, this fungus can be used for studying mammalian drug metabolism and large quantities of metabolites can be produced for different pharmacological studies which are not possible with mammals.

14.2.2.3 Metabolism of Spironolactone by *Thermomyces lanuginosus* NCIM-1934

Spironolactone, a mineralocorticoid receptor antagonist and a potassium-sparing diuretic (Brunton et al. 2008), is used for the treatment of congestive heart failure, edema, and ascites in cirrhosis and primary hyperaldosteronism. It is reported to

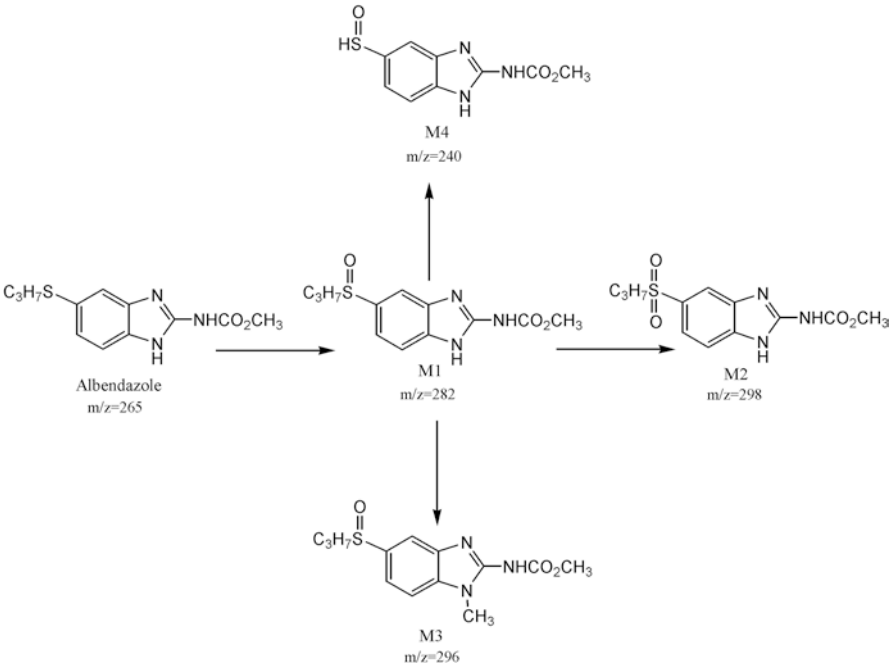

Fig. 14.2 Metabolic pathway of albendazole by *Rhizomucor pusillus*. *Source* Prasad et al. (2011). Copyright © Applied Biochemistry and Biotechnology (Springer Science + Business Media, LLC 2011) Reproduced with permission

biotransform in humans into 7α-thiomethylspironolactone, 6β-hydroxy-7α-thiomethyl spironolactone, and canrenone (IARC Monograph). On the other hand, Sreelatha et al. (2018) in their biotransformation studies employing thermophilic fungus *Thermomyces lanuginosus* reported four metabolites (Fig.14.3) of spironolactone, viz. 7-α thiospironolactone (M1), canrenone (M2), 7-α thiomethyl spironolactone (M3), 6β-OH-7α-thiomethyl spironolactone (M4), the major mammalian metabolites reported previously in different mammalian, and in vitro models. The metabolite (M1) was recorded earlier by Sherry et al. (1981) in microsomal preparations of guinea pig liver, adrenals, kidneys, and testes. However, Overdiek and Merkus (1987) recorded this metabolite (M1) in humans and Los et al. (1993) in plasma and organs of guinea pigs. The metabolite M2 produced by *Thermomyces lanuginosus* was also recorded earlier by many researchers in different models (Overdiek and Merkus 1987; Gardiner et al. 1989; LaCagnin et al. 1987; Albidy et al. 1997). The metabolite M3 was recorded by Overdiek and Merkus (1987) as a major metabolite of spironolactone in humans (Gardiner et al. 1989). LaCagnin et al. (1987), Los et al. (1993), and Albidy et al. (1997) also reported this metabolite (M3) of spironolactone in different systems. The metabolite 6β-OH-7α-thiomethyl spironolactone (M4) produced by *Thermomyces lanuginosus* was also detected by many researchers in various models (Overdiek and Merkus 1987; Karim et al. 1976;

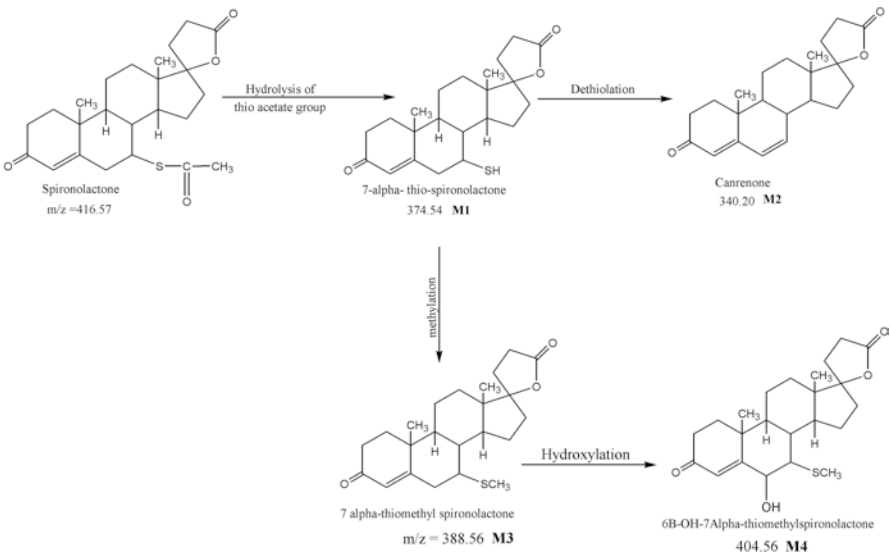

Fig. 14.3 Metabolic pathway of spironolactone by *Thermomyces lanuginosus*. *Source* Sreelatha et al. (2018).Copyright ©Steroids (Elsevier) Reproduced with permission

Albidy et al. 1997; Gardiner et al. 1989). The thermophilic fungi *T. lanuginosus* could generate four metabolites of spironolactone by hydrolysis, dethiolation, methylation, and hydroxylation, reactions which are also reported in mammals, while the mesophilic fungus *Cunninghamella elegans* could transform spironolactone into two hydroxylated derivatives (Marsheck and Karim 1973). On the other hand, *Chaetomium cochloides* could also produce three oxygenated metabolites of spironolactone (Mei et al. 2014). This clearly indicates that the metabolic pattern of *T. lanuginosus* is similar to mammals in contrast to mesophilic fungi reported previously in the biotransformation of spironolactone (Marsheck and Karim 1973; Mei et al. 2014).

14.2.3 Thermophilic Fungi in Novel Drug Discovery

Drug development is a huge challenging task from the laboratory scale to the market. The synthesized compound has to cross different biological assays, in vitro and in vivo drug metabolism, pharmacokinetic studies, and pharmacological and toxicological studies. After performing all the studies, compounds are to be ranked for clinical studies and those which satisfy all the chemical and biological assays will be further tested. Synthesis of compounds similar to that of the parent drug will have added advantage for the drug discovery program (Ravindran et al. 2012). In the case of failure, compounds with next best properties will be tested (Ravindran et al. 2012).

Hence, synthesis of compounds with structure and properties similar to that of the parent compound is crucial. Microbial transformation especially employing thermophilic fungi is a better alternative to generate compounds whose structure and properties resemble the parent compound or for the synthesis of compounds with novel structures similar to parent compounds with enhanced activity or with different therapeutic effects. Some of the examples of metabolites with novel biological activity generated by biotransformation employing thermophilic fungi are described below.

14.2.3.1 Novel Metabolites of Losartan as Human Peroxisome Proliferator Activated Receptor-Gamma (PPAR-γ) and Human Angiotensin Receptor (AT1R) Binders

Peroxisome proliferator-activated receptors (PPARs) are members of the nuclear hormone receptor superfamily of ligand-activated transcription factors which are related to retinoid, steroid, and thyroid hormone receptors (Murphy and Holder 2000). Among three PPAR isotypes PPAR-γ constitutes a prime target for the development of drug candidates to treat type II diabetes and PPAR-γ full agonists may even induce cell growth arrest, apoptosis, and terminal differentiation in various human malignant tumors (Guasch et al. 2012). Hypertension is a chronic disease affecting one-third of adult population worldwide and causing about half of the total mortalities, mainly due to stroke and heart problems. The main PPAR-γ synthetic full agonists studied to date are the thiazolidinedione (TZD) insulin-sensitizing drugs (e.g., rosiglitazone and pioglitazone) which were withdrawn from the market due to their pharmacovigilance and identified undesired adverse effects such as weight gain, edema, bone loss, and congestive heart failure (Ahmadian et al. 2013). Hence, there is a need for producing drugs with both hypertension and insulin resistance to treat simultaneously with the same pharmaceutical agent. Prasad et al. (2018), in his preliminary studies, reported human peroxisome proliferator-activated receptor-gamma (PPAR-γ) and human angiotensin receptor (AT1R) binding activity of novel metabolites of losartan, viz. M3 and M5 (Fig.14.1), produced by biotransformation process employing thermophilic fungi *Rhizomucor pusillus* NRRL 28626. Hence, thermophilic fungi are potential enough to produce novel value-added metabolites.

14.2.3.2 Hepatitis C Virus RNA-Dependent RNA Polymerase NS5B Inhibition Potentials of Albendazole and Its Biotransformed Metabolites

Hepatitis C virus (HCV) infection is a major public health problem, with nearly 3% of the world's population persistently infected with this virus (Fan et al. 2007) causing liver failure and responsible for the majority of liver transplants. The RNA-dependent RNA polymerase NS5B, in particular, has been the subject of intense

research for developing new drugs in the past decade because of its essential role in viral replication (Wei et al. 2016). Anti-helminthic drug albendazole and four of its metabolites (Fig.14.2), viz. albendazole sulfoxide (M1), albendazole sulfone (M2), and the two novel metabolites (M3 and M4), produced by albendazole biotransformation employing thermophilic fungus *Rhizomucor pusillus* (Prasad et al. 2011) when studied for hepatitis C virus RNA-dependent RNA polymerase NS5B inhibition in silico showed strong inhibition potentials. Albendazole sulfone (M2) which is an inactive metabolite of albendazole against helminths proved to be active against hepatitis C virus RNA-dependent RNA polymerase NS5B followed by the novel metabolite M3. Albendazole, the anti-helminthic drug and albendazole sulfoxide (M1), the active metabolite of albendazole, showed intermediate degree of inhibition against hepatitis C virus RNA-dependent RNA polymerase NS5B. However, the least inhibition was shown by the metabolite M4. However, inhibition potential of albendazole and four of its metabolites against hepatitis C virus RNA-dependent RNA polymerase NS5B was higher compared to the standard drug sofosbuvir (Prasad and Shravan 2018).

14.2.4 Thermophilic Fungi in Studying the Drug-Drug Interactions

The drug-drug interaction occurs when two or more drugs are administered where one drug affects the activity of the other by increasing or decreasing its activity. These interactions are a major public health concern estimating that approximately 5% of hospital admissions are affected by adverse drug interactions; other estimates are between 3 and 28% (Hutzler et al. 2011), causing unexpected side effects. The probability of interactions increases with other drugs taken (Cascorbi 2012). These interactions are perceptible in patients suffering from chronic ailments such as congestive heart failure, cancer, hypertension, rheumatic diseases, and human immunodeficiency which require multiple drug therapy and may result in unpleasant drug interactions manifest as a loss in drug efficacy (Doucet et al. 2002). Cytochrome enzymes play a major role in metabolizing drugs and the activity of this group of enzymes or a single CYP can determine patient's response to drug therapy. Therefore, modulation of the activity of CYPs by a given drug is a critical issue for assessing the safety and efficacy of a drug. Inhibition of CYP can increase systemic exposure leading to severe toxic side effects of the drug or another concomitantly given medication that is metabolized by the respective CYP(s) (Romet et al. 1994; Wandel et al. 1998). Progress in CYP enzymology and biochemistry in the recent past suggests that the drug interactions are based on enzyme inhibition.

Life-threatening ventricular arrhythmia was recorded when ketoconazole and terfenadine were co-administered (Manahan et al. 1990). Similarly, an interaction between sorivudine and fluorouracil also resulted in fatal toxicity (Watabe 1996; Sokuda et al. 1997). Astemizole and cisapride were withdrawn from the market for causing drug-drug interactions. Mibefradil which is a calcium channel blocker

caused rhabdomyolysis when combined with lovastatin and nephrotoxicity in combination with cyclosporine or tacrolimus (Hutzler et al. 2011). The best example of resulting of cardiac toxicity is when anti-histamine terfenadine and the antifungal ketoconazole or the antibiotic erythromycin are co-administered whereby inhibition of CYP 3A4 results in elevated terfenadine levels, resulting in prolongation of the QTc interval (VenkataKrishna et al. 2000). Similarly, on warfarin therapy, the increased bleeding in patients has been attributed to inhibition of its metabolism (Prasad et al. 2016). Many high-profile drugs were withdrawn from the market because of drug-drug interactions. Hence, addressing this issue is crucial. Drug-drug interactions are investigated in vitro with microsomes, expressed enzymes, or cell systems (Prasad et al. 2016). An understanding of the role of drug-metabolizing enzymes in the clearance of drugs and of drug-drug interactions caused by co-administered medications is a vital part of the drug discovery process and its therapeutics. To assess the potential of a drug in inhibiting different P450 enzymes in vitro, a variety of tools currently are available which include human liver tissue, cDNA-expressed P450 enzymes, and specific probe substrates where human liver microsomal preparations are of choice. For inhibition of enzyme selective studies, the utility of tissues from individual donors is limited by the adequacy of catalytic activity present in the tissue. Alternately, recombinant P450s can be used when a specific enzyme is to be investigated. Human liver microsomes and recombinant p450 enzymes are the most preferred test systems as they are readily available than human hepatocytes and p450 kinetic measurements are not confounded with other metabolic processes or cellular uptake. A major disadvantage of these test systems is that they do not represent the true physiological environment (e.g., not all phase II enzymes are present) if that is of interest to the study. Moreover, the process with these systems is a costly affair.

The best alternative would be microorganisms whose enzymes have proved to be versatile biocatalysts and are involved in the biotransformation of complex organic compounds. Most of the fungal cultures were reported to metabolize drugs similar to mammals; especially the fungus of the genus *Cunninghamella* is very well familiar as a model of mammalian biotransformation (Prasad et al. 2016) and as a microbial model in studying drug-drug interactions (Prasad et al. 2016). Thermophilic fungi especially *Rhizomucor pusillus* (Prasad et al. 2011, 2018) and *Thermomyces lanuginosus* (Sreelatha et al. 2018) are reported to possess drug-metabolizing enzymes. This process with the fungi is simple, hazard free, efficient, economical, and eco-friendly. Prasad et al. (2016) studied the metabolic inhibition of meloxicam using CYP2C9 inhibitors using mesophilic fungus *Cunninghamella blakesleeana* NCIM 687. Similarly, Srisailam et al. (2010) studied the prediction of drug interaction of clopidogrel on microbial metabolism of diclofenac. Though thermophilic fungi are reported to possess different drug-metabolizing enzymes (Prasad et al. 2011, 2018; Sreelatha et al. 2018) their use in drug-drug interaction studies remained unexplored. The use of thermophilic fungi in drug-drug interaction studies will be more advantageous compared to currently available in vitro test system and mesophilic fungi.

14.2.5 Thermophilic Fungi in Antibiotic Production

Antibiotic resistance is a global trouble with increased prevalence which showcases the need for drugs designed to overcome this epidemic. With increasing rates of bacterial drug resistance, the number of antibiotic unresponsive infectious diseases increased and the development of new antibiotics has become a crucial focus of the medical community. However, despite a push for new antibiotic therapies, there has been a continued decline in the number of newly approved drugs. Antibiotic resistance, therefore, poses a significant problem. As long as bacteria continue to develop resistance to the antibiotics, the continued isolation, screening, and evaluation of microorganisms from different habitats and their secondary metabolites can only be of benefit to all higher life forms on earth. Hence, search for new antibiotics effective against resistant pathogenic bacteria is currently required. Though thermophilic fungi are potential enough to produce novel antibiotics very few reports on antimicrobial agents are available (Kluepfel et al. 1971; Saito et al. 1979; Chiung et al. 1993). A new crystalline antifungal compound myriocin which is effective against *Candida* species and *Trichophyton granulosum*, *Microsporum gypseum* was isolated from thermophilic ascomycete *Myriococcum albomyce* (Kluepfel et al. 1971). Similarly, a thermophilic fungus *Malbranchea pulchella* var. sulfurea was also reported to produce an antibiotic Tf-26Vx (Saito et al. 1979) which was highly active against Gram-positive and obligate anaerobic Gram-negative bacteria. Chiung et al. (1993) also reported a novel quinine antibiotic named malbranicin from thermophilic fungus *Malbranchea cinnamomea* TAIM 13 T54 which exhibited toxicity against *Staphylococcus aureus* and *Bacillus subtilis*. In the same way, thermophilic fungi are also reported to produce other antibiotics like penicillin G, 6-aminopenicillanic acid, sillucin, miehein, and vioxanthin which are active against both Gram-positive and Gran-negative bacteria. Thermozymocidin was the other antifungal substance produced by thermophilic fungi (Mehrotra 1985; Satyanarayana et al. 1992). Hence, intensive research in this direction with thermophilic fungi is needed.

14.3 Conclusion and Future Prospects

Though thermophilic fungi are potential enough, they have not received required attention. They can be exploited commercially in the pharmaceutical industry and their application can be amplified by technologies such as immobilization which improve the stability (longevity, reusability) of biocatalysts and render continuous production process possible, recombinant DNA techniques which can be used to increase the production of the enzyme responsible for the desired biotransformation, and protein engineering (site-directed mutagenesis) which can help to increase the stability and/or improve the catalytic properties of the enzyme in question, or even to tailor an enzyme for specific purpose. Skillful application of these techniques in combination with conventional methods will certainly help in cost

reduction and further make industrial bioprocess feasible and attractive, from an economical point of view. Further, increasing pressure of environmental constraints will favor this process.

In view of nearly unlimited reservoir of thermophilic fungi existing in nature and the exciting achievements of modern biotechnology, there is still an enormous potential awaiting for further progress in pharmaceutical applications in drug discovery, drug-drug interaction, and drug metabolism studies. It is envisaged that biotransformations employing thermophilic fungi will be increasingly exploited as a useful and often unique tool in the pharmaceutical industry.

Chapter 15
Biotechnological Applications of Halophilic Fungi: Past, Present, and Future

Imran Ali, Samira Khaliq, Sumbal Sajid, and Ali Akbar

15.1 Introduction

Diverse hypersaline habitats are present globally such as in the form of saline soil, saline water, and salted foods. However, there is diversity in hypersaline soils and heterogeneity in their nature and composition comprising a wide range of minerals present at various depths (Gostinčar et al. 2011). Likewise, water from salterns, salt lakes, sea, oceanic water, and brackish water are all considered as saline but have diverse compositions; for example the concentration of salt in Dead Sea is 78% whereas that of the Great Salt Lake is 33% (Khan et al. 2017). Similarly, salted foods can be formed by the addition of different salts for the purpose of flavors and preservation or for the addition of minerals in the food, in varying concentrations.

The microbial community surviving in hypersaline habitats comes as a blessing in disguise due to their adaptability in these extreme conditions and production of extreme metabolites, which are in high demand in current changing environments and the challenges faced by biotechnological applications (Gunde-Cimerman et al. 2004). There are very few genetic and/or genomic studies on identification and relative abundance of various halophilic species isolated from different sources.

However, the few investigations that have been conducted are PCR-based strategies, targeting 16S small subunit ribosomal ribonucleic acid (16S rRNA) genes (Baati et al. 2010). The results indicate that some of the most commonly isolated and studied halophilic species may in fact not be significant in situ; for example genus *Haloarcula* only makes less than 0.1% of the in situ community; however, it usually appears in isolation studies (Bakke, et al. 2009). In other recent studies where comparative genomic and proteomic analyses were carried out, it is identified that halophiles have distinct molecular signatures coinciding with environmental adaptations. Using *Sulfolobus solfataricus* as a model, it is identified that halophiles rearrange their extrachromosomal replicons, which are rich in IS elements, at high frequency. However, their chromosomes are quite stable in contrast to non-halophiles and in fact contain a smaller number of transposable IS elements (Berquist et al. 2006). Characterization of the proteome of halophiles indicates low hydrophobicity, repetition of acidic residues, lower occurrence of cysteine, lower inclination for helix formation, and higher propensities for coil structure (Paul et al. 2008). It is often found that the core of most proteins isolated from halophiles is less hydrophobic; for example DHFR protein from halophiles has narrower β-strands as compared to similar proteins isolated from non-halophiles (Miyashita et al. 2017; Zusman et al. 1989). In a similar fashion, it is also observed that halophiles show distinct dinucleotide and codon usage (Paul et al. 2008).

Halophiles are mostly prokaryotes while some eukaryotes also make it to the list. Prokaryotic halophiles can further be divided into two main classes: (1) *Archaea* and (2) *Halobacteria*, which include the extreme halophiles like *Halomonas elongata sp.*, phototrophic halophiles such as *Saliiococcus hispanicus* sp., and methanogenic halophiles like *Methanosarcinales* sp. Likewise, eukaryotic halophiles also include photosynthetic halophiles such as green algae *Dunaliella salina* and heterotrophic halophiles like *Wallemia ichthyophaga* (Gunde-Cimerman et al. 2009). Depending on their ability to thrive on salt concentrations, halophiles may also be classified as slight, moderate, or extreme, and/or as obligate or facultative halophiles (Tiquia et al. 2007). On the contrary, halotolerant species are the ones which do not require salt but can survive in changes pertaining to external salt concentrations (DasSarma and DasSarma 2012). Slight halophiles prefer 0.3–0.8 M (1.7–4.8%—seawater is 0.6 M or 3.5%), moderate halophiles 0.8–3.4 M (4.7–20%), and extreme halophiles 3.4–5.1 M (20–30%) salt content (Sarwar et al. 2015).

Many halophiles accumulate compatible solutes in cells to balance the osmotic stress in their environment (Oren 2013). The aerobic halophilic archaea are famous for "salt in" strategy in which they accumulate high concentrations of K+ and Na+ ions in the cytoplasm by the help of ionic pumps and protein transportation at the expense of energy (Schafer et al. 1999). In "low salt in" strategy, the microorganisms maintain a low concentration of salts in the cytoplasm and instead survive in hypersaline conditions by the use of compatible solutes (Oren 2013). Some halophiles produce acidic proteins that function in high salinity by

increasing solvation and preventing protein aggregation, precipitation, and denaturation (Talon et al. 2014). The high salt survival mechanism in prokaryotes is different from eukaryotes, e.g., extremely halophilic archaea accumulate potassium, as high as molar levels, when exposed to high external salinity (Sarwar et al. 2015). In contrast, eukaryotic microorganisms such as fungi cannot tolerate such high intracellular ion concentrations and in such organisms the maintenance of positive turgor pressure at high salinity is mainly due to an increased production and accumulation of glycerol, trehalose, and other organic compatible solutes (Oren 2013). Moreover, metabolites from fungi, mostly being extracellular, are easily extracted as compared to bacteria (Gostinčar et al. 2011) and show better performance in terms of quality and quantity of biotechnological applications (Ali et al. 2016). Hence, investigating biotechnological potential of only prokaryotic halophiles does not do justice, and therefore this chapter is intended to highlight the importance of halophilic fungi in biotechnology which is aimed at attracting industry and academia to further explore the potentials of halophilic fungi for use in biotechnological applications.

15.2 Halophilic Fungi

Halophilic fungi were first reported in 2000 to be active inhabitants of hypersaline environments, when they were found in man-made solar salterns in Slovenia (Gunde-Cimerman et al. 2000). Since then, there are numerous reports of halophilic fungi around the globe. Recently, a criterion has been set for their consideration that the ones isolated from hypersaline habitats of 1.7 M salt concentration and can grow in vitro at or above 3 M concentration of salt should be considered as halophilic fungi (Gunde-Cimerman et al. 2009). Location, time of sampling, dissolved oxygen, water activity, and available organic and inorganic nutrients are found to be the important factors in the geographical distribution, growth, and viability of these fungi (Butinar et al. 2005a, b). The adaptation of halophilic fungi to hypersaline habitats is independent of salt concentrations and they can be found inhabiting any range of salt present, such as in hypersaline waters, and they can be found from freshwater to saturated natural or man-made salterns (Oren 2013). Halophilic fungi from hypersaline habitats have been recognized as either new species, previous ones which may not be recognized as halophilic earlier, or the ones having natural mutation(s), making them new strains. Phylogenetic analyses of these strains show interesting far distant relationships with the fellow species or genus (Gunde-Cimerman et al. 2009). The dominant representatives are different species of black yeast-like and related melanized fungi of the genus *Cladosporium*, different species within the anamorphic *Aspergillus* and *Penicillium*, the teleomorphic *Emericella* and *Eurotium*, certain species of non-melanized yeasts, and *Wallemia* spp. (Butinar et al. 2005a, b).

15.3 Genomes of Halophilic Fungi

Halophilic microorganisms have helped us understand the basics of life and survival in extreme conditions and are useful participants in major biogeochemical cycles of sulfur, nitrogen, carbon, and phosphorous operating in extreme conditions (Oren 2008). They also provide a better comparative understanding of the interactions amongst living organisms in simple versus extreme ecosystem, and contribute to the knowledge of survival in salt stress and selection of best suitable genes for white biotechnology (Gunde-Cimerman et al. 2009). For example, discovery and comparative analysis of the extremely halotolerant but adaptable fungus *Hortaea werneckii* (Lenassi et al. 2013) and the obligate halophile *Wallemia ichthyophaga* (Zajc et al. 2013) revealed novel molecular mechanisms used in combating high salt concentrations in distinct ways. In both of these fungi, the key signaling components are conserved; however, there are structural and regulatory differences.

It is interesting to note that there is a large genetic redundancy in *H. werneckii* and the genes coding for metal cation transporters have increased in number. Surprisingly, studies have revealed that it has also undergone a recent whole-genome duplication (Lenassi et al. 2013). In comparison, *W. ichthyophaga* has a very compact genome of 4884 protein-coding genes, which make up almost three-fourth of the sequence. Amongst this, a significant increase in the hydrophobin cell-wall proteins with multiple cellular functions is observed (Zajc et al. 2013).

Genomic analysis of 26.2 Mbp of the fungus *Eurotium rubrum* (Eurotiomycetes) isolated from Dead Sea reinstates the fact that there is gain in gene families related to stress response and losses with regard to transport processes (Kis-Papo et al. 2014).

15.4 Biotechnological Reports on Halophilic Fungi

Most of the research on halophilic fungi from year 2000 has been focused on morphological and molecular adaptations of these fungi in hypersaline environments (De Hoog et al. 2005; Gostinčar et al. 2011; Gunde-Cimerman et al. 2004, 2009; Oren 2013; Plemenitaš and Gunde-Cimerman 2005; Plemenitaš et al. 2008). However, there is no substantial information on biotechnological applications on halophilic fungi as compared to halophilic bacteria (Oren 2010; Tiquia 2010; Tiquia and Mormile 2010; Tiquia-Arashiro and Rodrigues 2016a, b); therefore, we have tried to summarize all reported applications of halophilic fungi herein.

15.4.1 Production of Bioactive Compounds by Halophilic Fungi

Sepcic et al. (2011) reported a total of 43 fungal species, isolated from various environments. These fungal species were tested for their ability to either metabolize or produce compounds with selected biological activities such as hemolysis, antibacterials, and acetylcholinesterase inhibition. Results indicate that the halophilic fungal species synthesize specific bioactive metabolites under conditions that represent stress for non-adapted species.

It was observed that increased salt concentrations resulted in higher hemolytic activity. This was reasoned to be due to the production of only organic metabolites, which can be dissolved in organic solvents, and hence these halophilic fungi do not produce proteins which can hemolyze erythrocytes. However, low water activity and colder conditions increase the hemolytic activity of most halophilic fungi suggesting the stress immune response.

The appearance of antibacterial potential under stress conditions was seen in a similar pattern for the fungal species with regard to hemolysis. The active extracts exclusively affected the growth of the Gram-positive bacterium tested, *Bacillus subtilis*. None of the extracts tested showed inhibition of acetyl cholinesterase activity. Hence, species such as *Aureobasidium sp.*, *A. pullulans*, *Var. melanogenum*, *H. werneckii*, *T. salinum*, and *Wallemia spp.* perform best for their hemolytic and antibacterial activities and these can be exploited for commercial applications.

Ravindran et al. (2012) highlighted the role of antioxidants and its related enzymes on adaption to salt stress by a halophilic fungus isolated from seawater collected from Dona Paula beach, Goa, India. The fungus was morphologically and molecularly identified as *Phialosimplex sp*. (though in publication authors only used the name of fungus as halophilic fungus, but the accession number at NCBI shows *Phialosimplex sp*., which could be a later modification). The growth characterization showed that this fungus preferred to grow at 15% of NaCl concentration. The aqueous extracts of *Phialosimplex sp*. exhibited different levels of antioxidant activity in all the in vitro tests performed, such as α,α-diphenyl-β-picrylhydrazyl (DPPH), hydroxyl radical scavenging assay (HRSA), metal chelating assay, and β-carotene–linoleic acid model system and it was concluded that increasing the salt concentration increases the antioxidant capacity of this fungi. Antioxidant enzyme assays such as superoxide dismutase assay, catalase assay, guaiacol peroxidase assay, and glutathione S transferase assay with extracellular and intracellular samples were separately analyzed for activity and it was concluded that the antioxidant enzyme activity was best at 15% of salt concentration. Hence, this species can be subjugated for the production of antioxidants in the presence of high salt concentrations for commercial viability.

Xiao et al. (2013) isolated the moderately halophilic fungal strain *Aspergillus sp*. nov. F1 from a solar saltern in Weihai, Shandong, China. The fungus was tested for its secondary metabolites (cytotoxic compounds) in the presence of salt

concentrations. It was found that the increase in salt concentration increased the production of cytotoxic compounds. Three compounds with cytotoxicity were isolated from the ethyl acetate extract of the whole broth and mycelia of *Aspergillus sp.* nov. F1, and identified as ergosterol, rosellichalasin, and cytochalasin E, respectively. The structure elucidation of isolated compounds was performed by 1H and 13C NMR spectral. In terms of quantity, cytochalasin E was the most isolated compound (985 mg), followed by rosellichalasin (712 mg) and ergosterol (346 mg). Bioassay of crude and purified cytotoxic compounds showed anti-cancerous potentials against many tumors. Crude extract was found effective against A549, Hela, BEL-7402, and RKO (data was not provided). The purified compounds showed high toxicity to human tumor cell lines A549, Hela, BEL-7402, and RKO. Ergosterol was found very potent against human colon cancer cell line RKO.

The antibacterial potentials of *Aspergillus flavus*, *Aspergillus gracilis*, and *Aspergillus penicillioides* were checked by plate screening method and by spectrophotometric analyses, against Gram-positive *Bacillus subtilis* and Gram-negative *Escherichia coli* (Ali et al. 2014c). The results showed that halophilic fungal strains were active in producing antibacterial compounds against both Gram-positive and Gram-negative bacteria tested. These results were different from earlier report of Sepcic et al. (2011), in which the halophilic fungi were not effective against *E. coli*. Antioxidant potentials of these halophilic fungi were checked by using thin-layer chromatography and total phenolic content assay. All obligate halophilic fungi showed positive antioxidant potential with *Aspergillus penicillioides* (sp. 2) showing most antioxidant capacity. Some hydrolases (amylase, cellulase, lipase, protease, and xylanase) were screened by using obligate halophilic fungi through plate screening studies and by enzyme assays. Except for *Aspergillus penicillioides* (sp. 2), all of the screened enzymes were found positive at least by one obligate halophile and vice versa. All crude fungal filtrates were obtained at 10% of NaCl concentration.

Zambelli et al. (2015) reported a brief study by taking lyophilized *Cladosporium cladosporioides*, which was previously isolated for fructooligosaccharide production from sucrose. Fructofuranosidase assays were performed by using sucrose as a substrate and dinitrosalicylic acid (reagent) was used to study the calculated amount of fructose obtained. The crude enzyme residual activity was studied at different temperatures which revealed that enzyme was heat stable with an increase in enzyme activity at temperatures from 50 °C to 60 °C and the highest activity was found at 50 °C. Substrate concentration of 600 g/L and the lyophilized mycelium of 40 g/L (at 50 °C) were found to have the highest fructooligosaccharide production (344 g/L after 72 h). By high-performance liquid chromatography, the fructooligosaccharide composition was found as 1-fructofuranosylnystose 22 g/L, 1-kestose 184 g/L, and 1-nystose 98 g/L. A nonconventional disaccharide, namely maltose, was also recovered (30 g/L). Since Fructooligosaccharides have many commercial applications such as their use for curing constipation, traveler's diarrhea, and high cholesterol levels as well as their use as prebiotics and artificial sweeteners; it can be easily deduced that these compounds isolated from the halophilic fungi can be of great commercial use.

Jančič et al. (2016) collected 30 strains of *Wallemia spp*. obtained from different culture banks isolated from various hypersaline environments. The strains were maintained and grown for production of secondary metabolites according to the need of required media and salt concentrations (NaCl and $MgCl_2$) and sugar (glucose). High-performance liquid chromatography-diode array detection was used for the detection of approximately 100 different compounds selected from overall 200 extracts of *Wallemia spp*. The machine learning analysis revealed that NaCl was the most influenced solute amongst all solutes tested. Mass spectroscopic results in this study showed that NaCl significantly affects the biological activity of some compounds. There was an increase in the production of toxic metabolites (wallimidione, walleminol, and walleminone) from strains when the NaCl concentration was increased from 5% to 15%. Since these toxic compounds are known to cause respiratory conditions like asthma, hypersensitivity pneumonitis, rhinosinusitis, bronchitis, and respiratory infections, and *Wallemia spp.* is commonly found in household dust and as a food contaminant, it would be interesting to further our knowledge in this regard.

15.4.2 Production of Enzymes

15.4.2.1 Proteases

Annapurna et al. (2012) collected soil samples from the coast of Mumbai and from the Sambhar Lake in Rajasthan, India. The samples were focused on screening for protease-producing species which were later identified. *Aspergillus flavus* was claimed to be a halophilic fungus (no details were presented for species apart from the addition of 10% NaCl in the production medium of protease) after molecular identification. During the characterization studies the protease from *Aspergillus flavus* was found to be slightly acidic (having optimum activity at pH 6), thermophilic (having highest activity at 57 °C but inconclusive, as the graph just carried an upward peak only), and showing inhibition by the use of $HgCl_2$ and activation by the use of $CaCl_2$. Further work in this direction could help isolate/develop a protease which is stable at higher salt concentrations and could be used in the food and leather industry.

15.4.2.2 Amylases

Ali et al. (2014a) reported an α-amylase from halophilic *Engyodontium album*. The crude enzyme was purified by column chromatography and the molecular mass of enzyme was found to be approximately 50 kDa by SDS-PAGE. The specific activity was found as 132.17 U/mg by enzyme assay. Through enzyme kinetic studies, the Vmax and Km values of 15.36 U/mg and 6.28 mg/mL were found, respectively. Enzyme characterization studies showed polyextremophilic properties of α-amylase

from *Engyodontium album*. The amylase was found alkalophilic by showing a steady increase up to pH 9 and even retaining over 95% of its percentage relative activity at pH 10. Thermophilic nature of enzyme was found by a steady increase in enzyme activity at higher temperature up to 60 °C. Enzyme activity was increased by the addition of salt in substrate. The optimum halophilic character was found at 30% (which is a saturation point of NaCl solution), but even at 35% of salt concentration (oversaturation point of NaCl solution) the enzyme retained almost 90% of the activity. $HgCl_2$, $CaCl_2$, $MgCl_2$, and $BaCl_2$ improved enzyme activity, while $FeCl_2$, $ZnCl_2$, EDTA, and β-mercaptoethanol were found to decrease the amylase activity.

Ali et al. (2014b) reported another amylase isolated from *Aspergillus gracilis* and purified by column chromatography. The molecular mass of enzyme was found to be approximately 35 kDa by SDS-PAGE. The specific activity was found as 131.02 U/mg by enzyme assay. Through enzyme kinetic studies, the Vmax and Km values of 8.36 U/mg and 6.33 mg/mL were found, respectively. Enzyme characterization studies showed polyextremophilic properties of α-amylase from *Aspergillus gracilis*. The amylase was found acidophilic by showing an optimum activity at pH 5 and even retaining over 95% of its percentage relative activity at pH 4. Thermophilic nature of enzyme was found by an increase in enzyme activity at higher temperature up to 60 °C. However, there was a sharp decline in enzyme activity after 60 °C. Amylase activity was increased by the addition of salt in substrate. The optimum halophilic character was found at 30%. There was a steady increase from 5% to 25% of salt concentrations, but there was a sharp increase in enzyme activity from 25% to 30% of salt concentration. The amylase was found retaining over 85% of percentage relative activity up to last tested concentration of 40% salt which is a supersaturation point of salt concentration. Unlike the amylase from *Engyodontium album* (Ali et al. 2014a), the α-amylase from *Aspergillus gracilis* was not found much affected by the addition of metallic salts. Only $FeCl_2$ was slightly found to inhibit the enzyme activity. The amylase from *Aspergillus gracilis* was tested for its saline wastewater remediation compared with the commercial-grade amylase from a normal fungus. Synthetic wastewater was made and added with 0–25% of NaCl concentrations. The enzymes were added, incubated, and compared for their performance by dissolved oxygen parameter. The percentage relative activity of amylase from *Aspergillus gracilis* was taken as control. The waste remediation ability of commercial amylase subsequently decreased by the addition of salt in the substrate.

In another study Ali et al. (2016) selected the obligate halophilic fungus *Aspergillus penicillioides* for the purification and characterization of α-amylase. The crude enzyme was purified by column chromatography. The molecular mass of enzyme was found to be approximately 42 kDa by SDS-PAGE. The specific activity was found as 118.42 U/mg by enzyme assay. Through enzyme kinetic studies, the Vmax and Km values of 1.05 mol/min·mg and 5.41 mg/mL were found, respectively. Enzyme characterization studies showed polyextremophilic properties of α-amylase from *Aspergillus penicillioides*. The amylase was found being alkalophilic by showing an optimum activity at pH 9, though the activity declined rapidly after

crossing pH 9. Amylase was found to have an increase in enzyme activity at higher temperature up to 80 °C (this by far is the highest temperature of α-amylase ever reported yet from halophilic fungi). Though there was a sharp decline in enzyme activity after 80 °C still the amylase was found to have an activity over 80% at 90 °C. Increase in salinity increased the amylase activity. The optimum halophilic character was found same at 30%. More likely as the amylase from *Engyodontium album* (Ali et al. 2014b), the α-amylase from *Aspergillus penicillioides* was affected by the addition of metallic salts. Only $CaCl_2$ was found slightly activating the enzyme activity, which suggests that this enzyme could be metalloenzyme being activated more by the divalent ions of Ca^{2+}. Enzyme was greatly inhibited by $ZnCl_2$, followed by moderate inhibition from EDTA and $FeCl_2$. Negligible inhibition was observed by the addition of 2 mM concentrations of $BaCl_2$, $HgCl_2$, $MgCl_2$, and β-mercaptoethanol. The compatibility of α-amylase from *Aspergillus penicillioides* was checked by the addition of three commercial detergents (A, B, and C, obtained from local market in Thailand) and incubated for 1 h at 40 °C. Residual enzyme activity was calculated. It was found that enzyme retained at least more than 80% of residual activity in comparison to the control in any tested detergent. The α-amylase from *Aspergillus penicillioides* was also tested for its performance in increasing salt concentrations (from 0% to 5% NaCl) with abovementioned commercial detergents as well as with commercial amylase from a normal fungus. The percentage relative activity results showed gradual decrease in the activities of commercial amylase and detergents in comparison to α-amylase of *Aspergillus penicillioides*, which was taken as control.

Hence these reported amylases which are much stable at higher salt concentrations as well as being thermostable could find their commercial applications in bioremediation of wastewater as well as food-, pharmaceutical-, and fermentation-based industries.

15.4.2.3 Cellulases

Gunny et al. (2014) isolated *Aspergillus terreus* and *Penicillium sp*. The fungal strains were tested for halotolerance by supplementing salt from 0% to 30% in growth medium (no results were provided). Both fungi were tested for their crude cellulases in increasing salt concentrations from 0% to 30%. *Aspergillus terreus* was found of having better hydrolysis capacity at higher salt concentration so was chosen for further studies. The crude cellulases from *Aspergillus terreus* were characterized for salinity, temperature, and stability in ionic liquids. Halostability of the enzyme was tested by incubating the enzyme for either 1 h or 24 h from 0% to 20% of salt concentrations. The enzyme stability was increased from 0% to 15% of salt concentration and was decreased further in both allotted times. The heat stability of enzyme was tested at different temperatures (0–80 °C) at various salt concentrations (from 0 to 3 M NaCl). There was an increase in enzyme stability at any temperature by the increase of salt concentration. At any salt concentration, the enzyme stability was almost found best until 40 °C, after which there was a gradual

decrease in enzyme activity. This step suggested that the increase in salt was increasing the thermostability of the enzymes. The cellulase activity was determined in the presence of different ionic liquids ([BMIM][Ac], [EMIM][Ac], and [BMIM][Cl]). The enzyme activity was found increased from 0% to 10% concentration of ionic liquids after which it declined gradually.

Gunny et al. (2015) carried same cellulases from *Aspergillus terreus*, which was found halophilic and halostable. In this study, production of halophilic cellulases from *Aspergillus terreus* was found positively influenced by the substrate (carboxymethylcellulose, i.e. CMC), salts ($FeSO_4 \cdot 7H_2O$, NaCl, and $MgSO_4 \cdot 7H_2O$), and peptone and physical factors such as size of inoculum and agitation speed. Contrarily, components like yeast extract, KH_2PO_4, KOH, and temperature were found negatively affecting the production of enzyme. Face-centered central composite design was applied on the most positively influenced components (CMC, $FeSO_4 \cdot 7H_2O$, and NaCl) to find the exact amount of optimization. The results showed that the fungus preferred the higher concentration of NaCl and CMC for the cellulase production. The overall optimization studies showed almost double-fold of increase in cellulase production from 0.029 U/mL to 0.0625 U/mL, which shows that by statistical approaches and good experiment designs the production cost of enzyme production can be minimized.

Since cellulases isolated from halophiles are much stable at high salt concentrations, they could be used in the textile, paper, and food industry which require a salt-stable cellulose for better results.

15.4.3 Application of Halophilic Fungi in Bioremediation

15.4.3.1 Phenol Degradation

Jiang et al. (2016) collected activated sludge from the pharmaceutical factory in Wuhan, Hubei, China. The fungus was selected from the microbial mixture on the basis of phenol tolerance. The growth media and all tests in this research were carried by supplementing 5% of NaCl concentration. The obtained colonies were morphologically and molecularly identified into *Debaryomyces sp.*, showing most close resemblance with *Debaryomyces hansenii* and *Debaryomyces subglobosus*. Phenol degradation ability was assessed by supplementing 100–1300 mg/L of phenol to the growth medium. The cultures were incubated at 30 °C at 160 rpm. The readings were obtained up to 72 h by spectrophotometric analysis through cell cultures and residual phenol concentration. The results show that lesser initial concentrations most relevantly up to 500 mg/L took shorter time for phenol degradation as compared to the higher concentrations. Over 900 mg/L of initial phenol concentration took 4 and more days to degrade all phenol in the media. Similarly there was a decrease in biomass of the organism due to increase in phenol concentration. The heavy metal tolerance along with phenol degradation was checked by adding 5 mM salts ($CoCl_2 \cdot 6H_2O$, $MnCl_2 \cdot 4H_2O$, $NiCl_2 \cdot 6H_2O$, and

$ZnSO_4 \cdot 7H_2O$) of metal ions with 500 mg/L of phenol for 48 h at 30 °C and 160 rpm. Control was taken with no heavy metal salt added. Presence of Mn and Zn hardly affected the phenol degradation. Phenol degradation was greatly inhibited by the presence of Co and Ni. The effects of different physical factors (pH, dissolved oxygen, and salinities) on phenol degradation were observed. The pH was checked from 3 to 11 ranges. Neutral pH was found to facilitate the growth of fungus. The optimum pH for phenol degradation was found to be 6.0 at 36 h. For dissolved oxygen the variation (from 50 rpm to 200 rpm) of shaking speed was tested for 48 h at 30 °C. The higher shaking speeds favored the phenol degradation where the most amount of phenol was degraded at 200 rpm. Salinity was checked from 0% to 17% of NaCl concentrations. The most amount of fungal growth and degradation of phenol were found best at 1% of NaCl concentration.

15.4.3.2 Remediation of Halite on Sandstones by Halophilic Fungi

Mansour (2017) collected sandstone samples from the Medamoud, Egypt, and halophilic fungi (*Aspergillus nidulans, Aureobasidium pullulans, Cladosporium sphaerospermum* and *Wallemia sebi*) were obtained from a local culture bank. Salinity tolerance was estimated by growing these fungi at 0% to 25% of NaCl concentration supplemented on potato dextrose agar. Results showed that 5% of NaCl was the best suited growth supplement for halophilic fungi. The fungal strains were also tested on liquid media where they showed better tolerance to salt as compared to the solid media. However, 25% of NaCl concentration was found to inhibit any fungal growth. Stones were cut into small pieces and the fungal media prepared was poured over them filling all the gaps on the surface. The analytical determination of resulted samples showed that the salt concentrations from the rocks treated by halophilic fungi were lower than those of untreated rocks. *Wallemia sebi*, which showed best halotolerance in these experiments, was found best in remediation test too. Hence, *Wallemia sebi* could be used for treatment and bioremediation of hypersaline soils as well as salt damage caused by dampness in building materials such as sandstone.

15.4.3.3 Removal of Heavy Metals by Obligate Halophilic Fungi

Bano et al. (2018) took *Aspergillus flavus*, *Aspergillus gracilis*, *Aspergillus penicillioides* (2 strains as sp. 1 and sp. 2), *Aspergillus restrictus*, and *Sterigmatomyces halophilus* and incubated them in 50 mL of potato dextrose broth supplemented with 10% of NaCl concentration and 1000 ppm of heavy metal salts [$CdCl_2 \cdot H_2O$, $CuCl_2 \cdot 2H_2O$, $Fe(NH_4)_2SO_4 \cdot 6H_2O$, $MnCl_2$, $Pb(NO_3)_2$, and $Zn(NO_3)_2$]. The filtrate and biomass obtained after 14 days were undertaken for acid digestion method. Both components were separately analyzed in atomic absorption spectroscopy. Proper controls and blanks were used for comparison of data. The results showed that on average at least 67% of all metals were removed by each obligate halophilic fungus.

Most of the metals were removed by *Aspergillus flavus* (85.6%), narrowly followed by *Sterigmatomyces halophilus* (83.3%). The least activity of metal adsorption (67%) was exhibited by *Aspergillus penicillioides* (sp. 1). In terms of overall metal adsorption at least 63% of each metal was absorbed by all obligate halophilic fungi. Fe and Zn were mostly removed metals of approximate 84% adsorption. Copper was least absorbed with 63.2% of absorption.

15.5 Past and Present Trends of Research in Halophilic Fungal Biotechnology

Considering that it is only very recently that fungi have been recognized as halophilic microorganisms, the amount of reports in this new field of research is considerably high but still a lot of further research in general biotechnology and microbiology of these strains could be carried out since most of the research on halophilic microorganisms has been focused on either halophilic bacteria or, in case of halophilic fungi, adaptation studies. This can be signified by the fact that the total number of publications reported till date is 18 whereas in consecutive years 2014 and 2015 four publications are reported per year. Hence, on average, a trend of approximately two publications per year is observed, regarding biotechnology from halophilic fungi. Most of the work (39%) on halophilic fungal biotechnology has been focused on enzymes, followed by multicovered studies (28%), bioremediation research (22%), and 11% of metabolite reports. It could be postulated that an interest on halophilic fungal enzymes could be due to the polyextremophilic nature of these enzymes. Some of the reports (Esawy et al. 2016; Geoffry and Achur 2017; Lenka et al. 2016; Liu et al. 2017; Sinha et al. 2017) have somewhat touched the coverage of halophilic fungal biotechnology but they do not completely fulfill the criteria due to either focus on other microorganisms or other than proper coverage of biotechnology.

15.6 Conclusions and Future Perspectives

Climate change and global warming are creating challenges for the humanity. Approximately, 25% of irrigated lands are comprised of saline soils and subsequently millions of hectares of land are getting unsuitable for agricultural purposes. Hence, research on halophilic fungi will no longer be a luxury but it will be a need of future biotechnology. One of the reasons of fewer reports on halophilic fungal biotechnology could be the lack of awareness amongst researchers about the tremendous potentials these fungi hold in terms of their metabolites. For example, the amylases from obligate halophilic fungi have been found to consistently provide polyextremophilic characteristics. Especially, the salinity in which the optimum amylase activities are

found is far above than the ones reported from halophilic bacteria (Ali et al. 2016). The nature of these amylases makes them perfect candidates to be applied in white biotechnology as most of the industrial operations are carried at extremes of pH, temperature, and low water activity. Similarly, as shown by reports these fungi can work in solving several environmental issues such as bioremediation (Bano et al. 2018; Jiang et al. 2015, 2016). Screening studies show that there is still a lot to be explored about biotechnology from halophilic fungi. The genes present in these fungi can be incorporated into food crops for making them utilize less amount of water. The human expedition on other planets such as Mars may need the aid from these fungi due to their adaptations and metabolite productions in extreme environments. This comprehensive coverage of biotechnology from halophilic fungi is expected to promote the research in this field.

Chapter 16
Sporotrichum thermophile Xylanases and Their Biotechnological Applications

Ayesha Sadaf, Syeda Warisul Fatima, and Sunil K. Khare

16.1 Introduction

Thermostable enzymes are highly desirable commodities for industrial bioprocesses (Karnaouri et al. 2016). The thermophilic fungi like *Thermotoga, Thermoascus*, *Scytalidium*, etc. which produce thermostable enzymes have been majorly exploited in industrial bioprocesses (Patel and Savanth 2015; Zeldes et al. 2015). *Sporotrichum thermophile* (syn. *Myceliophthora thermophile*) is a potential thermophilic mould belonging to the class ascomycetes (Singh et al. 2016). It has been extensively utilised as a platform for the production of large number of enzymes mainly cellulases, xylanases, phytases, esterases and mannoses (Bala and Singh 2016).

Lignocellulosic biomass is the most plentiful and rich source of renewable energy; hence its utilisation for the production of second-generation biofuels and platform chemicals has been perceived as an alternate strategy to meet the current alarm of fossil fuel depletion (Cherubini 2010; Tiquia-Arashiro and Mormile 2013; Gupta and Verma 2015). Lignocellulosics are mainly composed of three major components, viz. cellulose (40–55%), hemicellulose (20–30%) and lignin (15–20%) (Menon and Rao 2012; Tadesse and Luque 2011). For complete utilisation of biomass the most important process remains the removal of lignin so that the hemicellulose and cellulose portion are saccharified by hydrolytic enzymes like cellulases and xylanases (Ravindran and Jaiswal 2016). Thermostable cellulases and xylanases find great advantage since their hydrolytic rates are higher as compared to their mesophilic counterparts (Plecha et al. 2013; Watanabe et al. 2016). In this context, *S. thermophile* xylanase holds great potential to be used for efficient biomass utilisation. The xylanase from *S. thermophile* belongs to GH10 and GH11 families and has the ability to catalyse the hydrolysis of different types of substituted and

non-substituted xylans, respectively (Van Gool et al. 2012, 2013; Vardakou et al. 2003). The xylanase has been widely studied with a pH optima in the range of 5.0–7.0 and a temperature optima between 50 and 70 °C along with other desirable properties such as thermal, pH and ionic liquid stability (Bala and Singh 2016; Katapodis et al. 2006; Sadaf et al. 2016; Topakas et al. 2003). This xylanase has been produced by both submerged and solid-state mode of fermentation by employing a number of substrates like cotton seed cake, wheat straw and corn cobs (Bala and Singh 2017; Katapodis et al. 2006; Vafiadi et al. 2010). Xylanase as well as cellulase from *S. thermophile* have also been successfully used for biomass conversion processes. For example, xylanase and cellulase from *S. thermophile* namely CMCase and endo- and exo-β-1,4-glucanase have been used for hydrolysis of rice straw and waste tea cup paper yielding sugars of 578.12 and 421.79 mg/g substrate (Bala and Singh 2016). Similarly a thermophilic enzymatic cocktail containing cellobiohydrolase, endoglucanase, mannanase and xylanase activities was used for the saccharification of wheat straw, birch and spruce biomass (Karnaouri et al. 2016).

Hence *S. thermophile* xylanase is viewed as a potent accessory enzyme and holds great significance in the biofuel industry. To date there are few reports which have summarised the research update on *S. thermophile* as well as the different types of enzymes produced by it along with their industrial applications. This chapter encompasses for the first time the detailed description of *S. thermophile* xylanase, its biochemical characteristics and its production levels by different modes of fermentation and by utilising different lignocellulosic substrates. The chapter also sheds some light on the genetic organisation of *S. thermophile*. The proteomic and transcriptomic profiles have also been discussed with a view to gain an insight into the expression level of various lignocellulolytic enzymes.

The last part of the chapter deals with the latest research being conducted on *S. thermophile*. This includes gene editing protocols by CRISPR-Cas system and the ionic liquid stability of *S. thermophile* xylanase.

16.2 Xylanases

Xylan (β-1, 4-D-xylose polymer) is the major form of the polymer hemicellulose and contains wide linkages and branching points (Scheller and Ulvskov 2010). Xylan is basically a heteropolysaccharide consisting of arabinosyl, *O*-acetyl and 4-*O*-methyl-D-glucuronic acid substituents, ferulic and coumaric acids (Collins et al. 2005). Their distribution and composition vary among various plant genera and species. The xylans from dicots are acetylated to various degrees whereas xylans from monocotyledons like grasses, sorghum species and eucalyptus comprise ferulic acid esters attached to arabinofuranosyl and galactopyranosyl residues, respectively (Scheller and Ulvskov 2010). The functional properties of xylans like solubility, interaction with various polymeric substances present in the cell wall as well as degradability by enzymes are influenced by their substitution (Ebringerova and Heinze 2000). Due to the complex structure of the xylan and its various

substituents, its enzymatic hydrolysis becomes an important area of study. The hydrolases are required to cleave the glycosidic linkage of xylan as well as its branches. These enzymes include endoxylanase (EC 3.2.1.8), β-xylosidases (EC 3.2.1.37), α-arabinofuranosidases (EC 3.2.1.55), α-glucuronidase (EC 3.2.1.139), feruloyl esterases (EC 3.1.1.73) and xylan esterases (EC 3.1.1.72) (Manju and Singh Chadha 2011).

Xylanases fall under the category of xylanolytic enzymes with 4-xylanohydrolase, endo-1,4-xylanase, endo-1,4-β-xylanase, β-1,4-xylanase, endo-1,4-β-D-xylanase and 1,4-β-xylan xylanohydrolase activities (Goncalves et al. 2015). Major producers of xylanase are the fungal sources while bacteria, plants and actinomycetes are also good producers. For example xylanases from *Trichoderma reesei*, *Trichoderma longibrachiatum* and *Aspergillus niger* are being used commercially due to their high activity (Dhiman et al. 2008; Kumar et al. 2016).

Xylanases have been classified, based on their structure as well as their mechanism of action, into different glycoside hydrolase families, namely GH 5, 7, 8, 9, 10, 11, 12, 16, 26, 30, 43, 44, 51 and 62 (Moreira 2016). Among these the glycoside hydrolase families 10 and 11 are the most widely studied. GH 10 family consists of endo-1,4-β-xylanases (EC 3.2.1.8), endo-1,3-β-xylanases (EC 3.2.1.32) and cellobiohydrolases (EC 3.2.1.91) (Takahashi et al. 2013) whereas GH 11 family consists of 'true xylanases' as they are routinely referred, as these act on mainly D-xylose-containing substrates (Bai et al. 2015b). The endo-xylanase forms the most important class of xylanases as they have the ability to break the glycosidic linkages liberating xylooligosaccharides and hence find extensive applications in the food and feed industry (Harris and Ramalingam 2010). The other important applications of xylanases include pulp and paper processing, clarification of fruit juices, in the textile industry as well as in lignocellulosic biomass processing.

16.2.1 Xylanase from Extremophilic Sources

Extremophiles are microorganisms which possess the unique ability to thrive under extremes of temperature, pH, pressure, salts, etc. and hence the enzymes produced by these 'classified as extremozymes' are also able to function under the above-mentioned stringent conditions (Dalmaso et al. 2015). Alkaliphilic xylanases are required in the pulp and paper industry since the chemical pulping leads to increase in the pH values and hence alkali-stable xylanases are required in this regard (Lin et al. 2013; Weerachavangkul et al. 2012). As a representative example, xylanase from *Alkalibacterium* sp. SL3 was found to be stable in the alkaline pH range of 7.0–12.0 with optima at pH 9.0. The xylanase was also found to be halotolerant by maintaining 60% of its activity at 3 M NaCl. These features made it suitable for biobleaching of paper pulp as well as in the production of xylooligosaccharides (Wang et al. 2017). Similarly an alkalitolerant xylanase from *Bacillus* sp. SN5 has also been reported in a recent study (Bai et al. 2015a). Acidophilic xylanases find application in the food industry for the clarification of juices, baking as well as

biobleaching (Sharma et al. 2016; Yegin 2017). The acidic medium enhances the catalytic mechanism of xylan hydrolysis and also prepares the substrate for cleavage. For example, a novel acidophilic and thermostable xylanase has been isolated from the fungal strain, *Thermoascus aurantiacus* M-2 (Ping et al. 2017). The xylanase exhibited a pH and temperature optima of 5.0 and 75 °C and was stable in the broad pH range of 2.0–10.0. Apart from the above described xylanases, cold-adapted xylanases also have immense potential in the food industries since they function at low temperatures which minimises the chances for microbial contamination (Butt et al. 2008). The cold-adapted xylanase from *Penicillium chrysogenum* showed high activity between 2 and 15 °C and between pH 3.0 and 9.0. However, most demanded xylanases are those from thermophiles due to their thermostability at higher temperatures which result in better product as well as substrate solubility (Watanabe et al. 2016). The reactions taking place at higher temperatures reduce the time for hydrolysis as well as lower the viscosity of the medium. The details about thermophilic xylanases are discussed in the next section.

16.2.2 Thermophilic Xylanases

Thermophilic xylanases are produced by a variety of microorganisms including bacteria, fungi and yeasts though fungi have been the most potent producers of thermophilic xylanases (Kumar et al. 2016; Polizeli et al. 2005). Among the fungal sources, the most common producers include *Thermomyces lanuginosus*, *Thermoascus aurantiacus*, *Paecilomyces thermophile*, *Malbranchea cinnamomea*, *Chaetomium thermophilum*, *Sporotrichum thermophile*, etc. (Bala and Singh 2018). These thermostable xylanases find special applications in pulp-prebleaching, bioethanol industry as well as other biomass conversion processes. Table 16.1 enlists some representative thermostable xylanases and their industrial applications.

16.2.3 Structure of Thermophilic Xylanases

To gain an insight into the structure of thermophilic xylanases, their crystal structures have been resolved and studied in detail. An interesting study on structural features of a GH 10 xylanase from thermophilic *Caldicellulosiruptor bescii* revealed stable interactions between the loops of the catalytic cleft region by H-bonding (Zhang et al. 2016). This H-bonding network was found to be mediated by Arg^{314} and Lys^{306} residues. Moreover, the presence of an aromatic cluster of amino acids like Tyr^{17} and Phe^{20}, and Phe^{21} and Phe^{337}, was thought to increase the interaction between the N- and C-terminus. All these interactions helped in providing stability to the enzyme at high temperatures. Similarly the structure of another well-known xylanase from *Thermoascus aurantiacus* has also been determined (de Souza et al. 2016). It was found that the protein had a predominance of salt bridges. It also

Table 16.1 Thermostable xylanases and their industrial applications

Microorganism	Source	pH and temperature optima	Heat stability	Application	References
Rhizomucor miehei NRRL 3169	Fungus	pH and temperature optima between 5.56–6.0 and 65 °C	Completely stable between 70 and 75 °C for 60 min	Pulp bleaching	Fawzi (2011)

Table 16.1 (continued)

Microorganism	Source	pH and temperature optima	Heat stability	Application	References
Planococcus sp. SL4	Bacteria	pH and temperature optima of 7.0 and 70 °C, respectively	Completely stable at 55 °C for more than 60 min, retained 50% activity at 60 and 70 °C for 15 min and 2 min, respectively	–	Huang et al. (2015)
Geobacillus sp.	Bacteria	pH and temperature optima of 7.0 and 65 °C, respectively	Completely stable at 65 °C for 60 min at pH 10.0	Pulp and paper industry	Mitra et al. (2015)
Thielavia terrestris Co3Bag1	Fungus	pH and temperature optima of 5.5 and 85 °C	pH stability in the range of 4.5–10.0. Maintained 70–80% of its activity in the temperature range of 65–80 °C	Biofuel production	García-Huante et al. (2017)
Pleurotus ostreatus HAUCC 162 and *Irpex lacteus* CD2	Fungus	pH and temperature optima of 5.0 and 55 °C, respectively. Stable in the presence of Ca^{2+}, Cr^{3+}, Zn^{2+}, Na^{+} and $Al3^{+}$. Inhibited by Li^{+}, K^{+}, Cu^{2+}, Fe^{3+}, Ni^{2+}, Mg^{2+}, Cd^{2+}	–	Lignocellulosic hydrolysis	Zhuo et al. (2018)

consisted of a compact hydrophobic core and proline residues at the N-terminal which were thought to provide thermostability to the xylanase. Similarly the thermophilic xylanase from the ruminal fungus, *Neocallimastix patriciarum*, have also been studied structurally (Cheng et al. 2014). A uniquely present N-terminal region (NTR) comprising of 11 amino acid residues was found in this particular protein.

This N-terminal region was linked to the catalytic core by H-bonds, stacking forces and a disulphide bond. This NTR was confirmed to contribute significantly to the thermostability of the xylanase after a series of mutations in this particular region led to a loss in the thermophilicity of the enzyme. The structure of xylanase from the fungus *Thermomyces lanuginosus* showed the presence of disulphide linkages as well as many charged residues leading to the formation of a compact globular structure (Wang et al. 2012). The crystal structure of two thermophilic xylanases from *Chaetomium thermophilum* and *Nonomuraea flexuosa* also provided some interesting thermophilic features (Hakulinen et al. 2003). Both the xylanases were found to contain twisted β-sheets forming a cleft. The *C. thermophilum* xylanase showed the presence of sulphate and calcium ions. The sulphate ions were attached to the arginine residues whereas the calcium ions interacted with the threonine residues. The resultant packing of the enzyme molecule led to the appearance of a compact tetrameric structure. The *N. flexuosa* structure consisted of a large number of side chain-polar interactions as well as several salt bridges. Similarly the structural elucidation of the xylanase from marine bacterium *Geobacillus stearothermophilus* revealed the presence of glutamate residues in the catalytic core of the protein. Homology studies with the local *G. stearothermophilus* showed the presence of five important amino acid residues. These were Thr/Ala, Asn/Asp, Lys/Asn, Iso/Meth and Ser/Thr. These residues were analysed to be responsible for imparting thermostability to the enzyme (Saksono and Sukmarini 2010).

16.3 *Sporotrichum thermophile*

Sporotrichum thermophile (syn *Myceliophthora thermophila*) is a major thermophilic fungus which is known to produce a variety of enzymes having immense industrial potential. Various enzymes produced by this thermophilic mould are xylanases, cellulases, esterases, phytases, mannanases and glucosidases (Gopalan et al. 2015; Kumari et al. 2016). The fungus was classified under ascomycetes and has optimal growth temperature between 40 and 50 °C (L Bergquist et al. 2014). Recently the genome of *S. thermophile* has been sequenced and has provided some pertinent details about the lignocellulolytic and other enzyme machinery.

16.3.1 Sporotrichum thermophile *Xylanase*

S. thermophile produces major endo-1,4-β-xylanolytic activities. These types of xylanases majorly fall under two prominent xylanase families, i.e. GH10 and GH11. While the GH10 xylanases are efficient for the hydrolysis of various xylans as well as their substituted forms, GH11 is more specific and does not act on substituted xylans (Van Gool et al. 2012). In one study the efficiency of two GH10 xylanases of *S. thermophile* was investigated on different types of xylans. The degradation

pattern on the basis of substrate specificity of high and low-substituted xylans gave a possible indication about the difference in the protein structure of both xylanases (Van Gool et al. 2012). Further study revealed intra-family differences in the GH10 type of xylanases (Van Gool et al. 2013). The protein structure of both the xylanases showed specific variation in the amino acid sequence. On similar lines, a xylanase with a molecular mass of 25 kDa was purified from *S. thermophile* ATCC 34628 (Katapodis et al. 2003). The enzyme had a pH and temperature optima of 5.0 and 70 °C, respectively. By studying the degradation pattern of different types of xylans as well as the inhibition profile by ω-epoxyalkyl glycosides of d-xylopyranose, the xylanase was concluded to be part of the GH11 family. However a study conducted a little later showed the purification and characterisation of two types of xylanases from *S. thermophile* with a molecular mass of 24 kDa and 48 kDa, respectively. Both the xylanases had a pH and temperature optima of 5.0 and 60 °C and the peptide mass sequencing helped in identifying the xylanases to belong to GH10 and GH11 families, respectively (Vafiadi et al. 2010). A recent study on *S. thermophile* xylanases provided a clear insight into their structural parameters (Basit et al. 2018). Both the xylanases closely resembled a right-handed helix with minor differences occurring in the β-strand. Their main chain structures matched with those of GH11 xylanases of *Acremonium cellulolyticus* and *Trichoderma longibrachiatum*.

16.3.2 Production of Sporotrichum thermophile *Xylanase*

The xylanase from *S. thermophile* possesses various advantageous properties like thermal and pH stability which are of industrial significance; hence different methods to enhance its production level have been attempted by several research groups in the recent past. A representative study utilised corn cobs as carbon source for xylanase production. By using central composite design, 2.7% (w/v) corn cob and 0.7% (w/v) ammonium phosphate were found to yield maximum xylanase activity levels of 56 U/mL (Katapodis et al. 2006). In another study factors such as moisture content and carbon sources (wheat straw and bran) were varied to evaluate the xylanase production levels under solid-state fermentation (SSF). Quite high xylanase activity of 320 U/g was attained under finally optimised conditions (Topakas et al. 2003). Badhan et al. (2007) reported the production of xylanase by using rice straw as the substrate under SSF. A similar study reported xylanase activity levels under SSF by employing wheat bran and citrus pectin. Maximal xylanase activity (1900 U/g) was achieved after 4 days of fermentation at pH 7.0 and 45 °C with wheat bran and citrus pectin in a ratio of 1:1(Kaur and Satyanarayana 2004). Xylanase production has also been optimised by using *Jatropha curcas* seed cake (Sadaf and Khare 2014). Under the final conditions of pH, temperature, moisture level, carbon supplementation and inducers, high titres of xylanase (1025 U/g seed cake) were obtained. This study was advantageous in terms of utilisation of the seed cake which is otherwise underutilised as it is toxic even to animal feed.

16.3.3 Genomics of Sporotrichum thermophile *Xylanase*

Sporotrichum thermophile has emerged out to be a useful and well-characterised thermophilic strain while hunting for thermostable xylanases from filamentous fungi (Liu et al. 2017; Margaritis et al. 1986). The coupled cellulolytic activity has made it even more suitable for studying it genomic features (Wojtczak et al. 1987).

While deciphering the genomic makeup of this strain, it was noticed that genome size extended to 38.74 Mb containing seven telomere-telomere chromosomes comprising of TTAGGG repeats (Singh 2016). With most of the genes residing on chromosomes 2 and 4, main translocation events occurred extensively between chromosomes 1 and 6. The core of protein coding in the genome corresponded to 9110 genes, which were too small as compared to other closely related class of fungi, Sordariomycetes (Berka et al. 2011). It also shared similarity in organisation with *Thielavia terrestris*. The gene model statistics and assembly exhibited G + C content of 51.4% and the gene length of 1733 nt with two exons per gene. Higher GC content at the coding regions pointed towards greater thermal stability. Based on above facts, *T. terrestris* and *S. thermophile* have been placed under the family Chaetomiaceae as they share syntenic relationships (with over 6000 genes in a block between the pair ending with repetitive stretch of AT-rich contents) and orthologues (6279 three-way) (Berka et al. 2011). The genome of *S. thermophile* is further constituted of gene families of large transporters such as AAA, sugar, ABC and MFS along with signalling proteins like WD40 and protein kinases. Several other protein domains like Pfam and glycoside hydrolases of families GH61 and GH11 appeared to be expanded in the genome. Attempts have been made to clone xylanase genes MYCTH_56237 (672 bp) and MYCTH_49824 (693 bp) encoding proteins of 223–230 amino acids (Verma et al. 2013). The bioinformatics analysis matched with endo-β-1,4-xylanases which belong to GH11 family of glycoside hydrolases. Further sequence alignment of these xylanases showed high index of similarities in their primary and secondary structures. The insights of the tertiary structures also provided a clear picture for the mechanism of substrate binding.

Other relevant enzymes of the strain have also been retrieved by genomic analysis. These included polysaccharide lyases (PLs like pectate lyases), glycosyl transferases (GT), carbohydrate esterases, carbohydrate-binding modules and carbohydrate-active proteins (CAZymes): glycoside hydrolases (GHs-polygalacturonases) (Harris et al. 2010; Henrissat and Davies 1997). The diverse array of enzymes produced by *S. thermophile* having differential role eventually helps the fungus to effectively hydrolyse various types of biomass.

16.3.4 *Transcriptomic Profile of* Sporotrichum thermophile *Grown on Different Biomass*

Transcriptomic profile of *S. thermophile* was also studied for checking the decomposition pattern of polysaccharides. The growth of the fungus was analysed on glucose, starch, flax, canola, barley (monocot) and alfalfa straw (dicot) (Kolbusz et al. 2014; Xu et al. 2018). These substrates represent major differences in terms of cell wall constituents (cellulose, hemicellulose with a negligible amount of pectin in monocots; 15–20% pectin and xylan in dicots) (Dien et al. 2006; Pahkala et al. 2007). Based on significant differences in cell wall, the transcriptional profiles reflected the secretion of different classes of carbohydrate-active enzymes. The substrate composition influenced the secretion and expression of various enzymes. In case of barley, cellulolytic and xylanolytic enzymes were highly up-regulated, followed by arabinanases, mannanases and pectinases. However, in case of alfalfa there was down-regulated expression of xylanolytic enzymes (Berka et al. 2011). To conclude, the link between expression profiles and orthologues extended to many core lignocellulolytic proteins with the exception for pectinolytic enzymes.

16.4 Applications of *Sporotrichum thermophile* Xylanase

The *S. thermophile* xylanase finds large applications, in various food, biofuel and pulp and paper processes, apart from other uses. Since the *S. thermophile* xylanase is thermostable it can be used efficiently in the biomass conversion of lignocellulosics into fermentable sugars. It has been successfully employed in the saccharification of agrowaste like wheat straw, corn cobs, birch and spruce biomass. The applications of *S. thermophile* xylanases are summarised in Table 16.2.

16.5 Other Enzymes from *Sporotrichum thermophile* and Their Applications

S. thermophile is a thermophilic mould and hence various enzymes secreted by it are thermostable and advantageous from the industrial point of view especially the cocktail of lignocellulolytic enzymes. Apart from xylanase, cellulases (Bajaj et al. 2014), glycosyl hydrolases (Ye et al. 2014), phytases (Kumari et al. 2016), feruloyl esterases (Topakas et al. 2004) and polygalacturonases (Kaur et al. 2004) have also been worked out. *S. thermophile* has been reported to produce high activity of cellulase (42 U/g) by SSF using wheat bran and citrus pectin as substrates (Kaur and Satyanarayana 2004). Two cellobiohydrolases have been purified and characterised from this strain (Gusakov et al. 2007). One of the cellobiohydrolases was found to

Table 16.2 Industrial applications of *S. thermophile* xylanases

Mode of xylanase production	Process conditions	Xylanase characteristics	Application	References
SSF	Corn cob at pH 5.0, 50 °C for 4 days	K_m and V_{max} of 7.1 nm and 3.54 gL^{-1} h^{-1}, respectively	Xylan hydrolysis	Vardakou et al. (2003)
SSF	Corn cob at pH 5.0, 50 °C for 4 days	Molecular mass and pI of 25 kDa and 6.7, respectively. The pH and temperature optima of 5.0 and 70 °C, respectively	Hydrolysis of polysaccharides	Katapodis et al. (2003)
SSF	Rice straw, wheat straw, bagasse, corn cob, wheat bran each incubated for 5 days at 45 °C, pH 7.5	n.s.	Xylan hydrolysis	Badhan et al. (2004)
SSF	Wheat bran and citrus pectin in 1:1 ratio, pH 7.0 at 45 °C with moisture ratio of 1:2. for 4 days	n.s.	Treatment of fruit pulp for clarification of juices	Kaur and Satyanarayana (2004)
Submerged	Corn cobs at 2.7% (w/v) and ammonium phosphate at 0.7% (v/v) concentration for 5 days	pH and temperature optima of 5.0 and 70 °C, respectively	–	Katapodis et al. (2006)
Submerged	2.7% (w/v) wheat straw at pH 5.0, 50 °C for 7 days	pH and temperature optima of *St*Xyn1 *St*Xyn2 were 5.0 and 60 °C, respectively, for both the xylanases $t_{1/2}$ of 60 and 115 min for *St*Xyn1 and *St*Xyn2, respectively	Hydrolysis of xylan	Vafiadi et al. (2010)
SSF	De-oiled *Jatropha curcas* seed cake with a moisture ratio of 1:1.5, pH 9.5 at 35 °C with 1% (w/v) birchwood xylan as inducer	$t_{1/2}$ of 4 h at 45 °C and pH stability in the range of 7–11.0. K_m and V_{max} of 12.54 mg/mL and 454.5 U/mL/min, respectively	Xylooligosaccharide production	Sadaf and Khare (2014)

(continued)

Table 16.2 (continued)

Mode of xylanase production	Process conditions	Xylanase characteristics	Application	References
Submerged	Cane molasses at 8% (v/v) supplemented with ammonium sulphate at 0.5% (v/v) at pH 5.0	pH and temperature optima of 5.0 and 60 °C, respectively	Saccharification of biomass	Bala and Singh (2016)
SSF	Rice bran and rice straw (1:2 w/w), pH 8.9 at 44.16 °C for 7 days of incubation	pH and temperature optima of 12.0 and 50 °C, respectively	Xylooligosaccharide production	Boonrung et al. (2016)
Submerged	Emerson's medium containing soluble starch 15, yeast extract 4, K_2HPO_4 1.5, $MgSO_4$, 0.5 in g/L, at pH 9.0, 40 °C for 48 h	Stable at 50% (v/v) concentrations of [EMIM][OAc] and [BMIM][$MeSO_4$] for 72 h	In situ pretreatment and saccharification of wheat straw	Sadaf et al. (2016)
SSF	Cottonseed cake and wheat straw in 1:1 ratio, pH 5.0 at 45 °C for 96 h at a moisture level of 1:2.5	n.s	Xylooligosaccharide production	Bala and Singh (2017)
Submerged	Buffered minimal methanol medium	pH optima of MYCTH_56237 and MYCTH_49824 were 6.0 and 7.0, respectively, temperature optima of 60 °C for both the xylanases The V_{max} and K_m for MYCTH_56237 were 2380 U/mg and 8.80 mg/mL, respectively, V_{max} and K_m of MYCTH_49824 were 1750 U/mg and 5.67 mg/mL, respectively	Saccharification of biomass	Basit et al. (2018)

Protease	Submerged fermentation	Temperature and pH optima of 45 °C and 6.5, respectively. Molecular weight of 36.2 kDa	Food industry, leather, detergents and bioremediation	Neto et al. (2015)

be very active on Avicel and cotton. Table 16.3 summarises the other important enzymes from *S. thermophile*.

16.6 Current Trends in *Sporotrichum* Research

16.6.1 Genome Editing

With the advent of versatile technology such as genome editing, the revolutionary outlook has been shifted towards multifarious biotechnological applications (Liu et al. 2017; Singh 2016). The booming CRISPR/Cas9 system has manifested the underlying mechanism of metabolic pathways leading to enhanced thermostability (Karnaouri et al. 2014a). The genome editing/engineering has led to the efficient hydrolysis/degradation of lignocellulosic biomass (Viikari et al. 2007).

Previously, the CRISPR/Cas9 system for gene editing has been well established in yeasts and fungi like *Aspergillus* (Katayama et al. 2016; Nodvig et al. 2015), *Penicillium chrysogenum* (Pohl et al. 2016), *Trichoderma reesei* (Liu et al. 2015) and *Magnaporthe oryzae* (Arazoe et al. 2015). Using CRISPR-Cas interface via genomic engineering, a metabolic pathway of cellulase which in turn has been linked with xylanases and other extracellular hydrolytic enzymes has been edited in *S. thermophile* for higher production of enzymes. Consequently, a genome-wide engineering system for thermophilic fungi has been established based on multiplex-locus editing with the CRISPR/Cas9 technique, the main target locus being cre-1.

Similarly, gene editing-mediated enhanced production of enzymes by targeted mutations on desired gene via NHEJ-mediated events in a one-step transformation into *Myceliophthora heterothallica* strain CBS203 was successfully achieved (Hutchinson et al. 2016; van den Brink et al. 2012). The targeted gene of interest located at loci (amdS gene along with four other regions/constructs *cre-1, res-1, gh1–1* and *alp-1*) was mutated. These multigene disruptions were at different loci and selections of mutants were based on neomycin selection marker. The mutated strain exhibited hypersecretions of desired enzymes nearly 5 to 13-folds more than wild type (Liu et al. 2017).

16.6.2 *Ionic Liquid Stability of* Sporotrichum thermophile

The use of ionic liquids as green solvents for biomass pretreatment and saccharification has gained sufficient interest in the recent years (da Costa Lopes and Bogel-Łukasik 2015; Mahmood et al. 2016). Ionic liquids (ILs) are salts composed of an anion and cation moiety and hence are tuneable for desired applications (Marsh et al. 2004). This property of ILs makes them useful for biomass saccharification for enhanced bioethanol generation (Badgujar and Bhanage 2015). However, the sensitivity of biomass-saccharifying enzymes towards ILs limits the use of these solvents (Sadaf et al. 2018). ILs have been shown to exert inhibitory effect on the activity of many cellulases, xylanases and other hydrolytic enzymes (Thuy Pham et al. 2010; Turner et al. 2003). Xylanases are important for hydrolysis of hemicellulose portion of lignocellulosic biomass. The studies on the IL stability of xylanases are comparatively few as compared to those on cellulases. For example xylanase from *Thermoascus aurantiacus* retained its activity in the presence of 25% [EMIM][OAc] (Chawachart et al. 2014). Similarly xylanase from *Volvariella volvacea* retained only 50% activity in the presence of 20% [EMIM][DMP] (Thomas et al. 2011). *Amycolatopsis* sp. GDS was slightly more stable in the presence of 10% (v/v) HEMA (2-hydroxyethyl methacrylate) and retained 80% activity (Kshirsagar et al. 2016).

Detail study on IL stability of *S. thermophile* xylanase has been recently described by Sadaf et al. (2016). The crude xylanase was stable and active in the presence of 50% [EMIM][OAc] for as long as 72 h. This is a remarkable stability for any xylanases reported so far. The xylanase was exploited to hydrolyse IL-pretreated wheat straw without the removal of residual IL. The whole process led to the generation of 281 mg reducing sugars per gram wheat straw. The IL-stable xylanase thus enabled the development of one-pot IL pretreatment and simultaneous saccharification process.

16.6.3 *Proteomics of* Sporotrichum thermophile

The studies on secretomes and exo-proteomes of *S. thermophile* provided insights into its cellular, physiological and metabolic functioning (Ghimire and Jin 2017). In addition to extracellular CAZymes involved in the digestion of polysaccharide nutrients, the genomes of *S. thermophile* and *T. terrestris* encoded an assortment of hydrolytic and oxidative enzymes that possibly enhanced their ability to forage non-carbohydrate substrates. The secretome of *S. thermophile* was comprised of ~683 proteins. Out of these, 569 were predicted to be homologues consisting of 180 CAZymes, >65 oxidoreductases, 40 peptidases and >230 proteins with unknown functions (Berka et al. 2011). Based on this data more studies would be needed to decipher the role of these secreted proteins in lignocellulose degradation.

16.7 Conclusions and Future Perspectives

S. thermophile, a thermophilic mould, produces an array of enzymes like cellulases, xylanases, pectinases, mannanases and phytases. The battery of interesting enzymes hold promise for various bioprocesses in food, feed, textile, biofuel, etc. *S. thermophile* xylanase is an interesting enzyme with many novel characteristics such as broad pH, heat and ionic liquid stability. Owing to the above features, the mould holds promise in effective biomass saccharification for biofuel production. So far there are only few studies which have studied the extracellular proteome and transcriptome of *S. thermophile* when grown on different types of substrates giving an indication of the expression levels of various enzymes involved in lignocellulosic biomass hydrolysis. Hence in future intracellular proteomic studies are also required in order to gain a better understanding of the functioning of major metabolic pathways under various growth conditions of the fungus. The IL stability aspect of *S. thermophile* xylanase has been only reported by a single study; therefore further studies in this regard will help in the development of an efficient cost-effective enzyme system. The genome editing of this fungus has also led to the enhanced production of hydrolytic enzymes by targeted mutations. Therefore more genetic manipulations of this kind will assist in enhancing the enzyme levels to a larger industrial scale. Also, bioinformatics studies of *S. thermophile* xylanase are necessary in deciphering the structural integrity of the xylanase under various extreme conditions and will therefore benefit in designing potent and robust enzymes.

Chapter 17
Deep-Sea Fungi: Diversity, Enzymes, and Bioactive Metabolites

Muhammad Zain Ul Arifeen, Ya-Rong Xue, and Chang-Hong Liu

17.1 Introduction

Fungi are an important component of all ecosystems and are ubiquitous in nature because of their highly versatile physiological behavior (Gostinčar et al. 2009; Tedersoo et al. 2014). Fungi that inhibit deep sea and its sediments at a depth of more than 1000 m below the surface of the sea are called deep-sea fungi (Swathi et al. 2013). The deep-sea environment is one of the extreme environments for living organisms (Tiquia-Arashiro 2012). Absence of sunlight, usually lower temperature (some places like hydrothermal vents have an extremely high temperature up to 400 °C), extreme pH, and high hydrostatic pressure (up to 110 MPa) are the conditions which make deep sea an extreme environment (Damare et al. 2006; Burgaud et al. 2010; Nagano and Nagahama 2012). It has been documented that many environmental factors such as salinity, temperature, oxygen availability, hydrostatic pressure, substrate specificity, light, and availability of substrata significantly affect the abundance, diversity, activity, and distribution of fungi in the natural habitats (Nagano and Nagahama 2012; Batista-García et al. 2017). Despite these extreme living conditions, microorganisms, especially fungi, are found in abundance in deep-sea environments (Gadanho and Sampaio 2005; Nagahama et al. 2006; Wang et al. 2015; Xu et al. 2016; Nagano et al. 2017). It is believed that these fungi came from terrestrial environments, and adapted well to the deep-sea environment through evolution (Redou et al. 2015; Hassan et al. 2016). A recent estimate suggests that global fungal species are approximately 2.2–3.8 million (Hawksworth and Lücking 2017), around 120,000 species have been described by taxonomists (Mueller and Schmit 2006), and only a few species have been identified from the deep-sea

environments. The biodiversity and their application in biotechnology of deep-sea derived fungal species are not fully understood and need more research to explore their potential.

A wide range of bioactive molecules have been isolated from deep-sea fungal communities, which have the potential to perform different activities such as antibacterial, antiviral, antidiabetics, anti-inflammatory, and antitumor, and some can be used as in important enzymes (Tiquia and Mormile 2010; Shang et al. 2012; Mayer et al. 2013; Wang et al. 2015, 2017a).

The aim of this review is to explain the current research of deep-sea fungal diversity, and the tools and equipment used in the sampling, isolation, and identification of the deep-sea fungi. This review also discusses novel and industrially important enzymes and bioactive molecules recently isolated from deep-sea fungi.

17.2 Biodiversity of Deep-Sea Fungi

Although the deep-sea environment provides a habitat for a vast number of microbial lives, however, the origin, diversity, and distribution of deep-sea fungal community remain largely undiscovered. Höhnk (1969) for the first time reported about deep-sea fungi when he isolated fungi from shells collected at 4610 m depth below the sea. Roth et al. (1964) isolated fungi from surface to a depth of 4500 m from the subtropical Atlantic Ocean. However, these fungi were not able to culture in the lab. Until 1992, Raghukumar et al. (1992) firstly isolated various filamentous fungal strains from calcareous fragments collected from the Bay of Bengal at a depth of 300–860 m using culture-dependent method. After that, several numbers of fungal species have been isolated and identified from many deep-sea environmental samples, such as from the Mariana Trench at a depth of 11,500 m (Takami et al. 1997), the Chagos Trench 5500 m (Raghukumar et al. 2004), the Central Indian Basin 5000 m (Singh et al. 2011), Gulf of Mexico sediment 2400 m (Thaler et al. 2012), South China Sea 2400–4000 m (Zhang et al. 2013), East India Ocean 4000 m (Zhang et al. 2014), Canterbury Basin (New Zealand) 4–1884 mbsf (below the seafloor) (Redou et al. 2015), Okinawa 1190–1589 m (Zhang et al. 2016a), and the pacific ocean off the Shimokita Peninsula, Japan, 1289–2466 mbsf (Liu et al. 2017).

So far more than 120 fungal species have been isolated and identified from the deep sea, using culture-dependent technique (Gadanho and Sampaio 2005; Nagano and Nagahama 2012; Zhang et al. 2013) while culture-independent technique has also been useful for the identification of some strange and unknown fungi. It has been reported that Ascomycota was the dominant species in deep-sea environment representing 78% followed by Basidiomycota (17.3%), Zygomycota (1.5%), and Chytridiomycota (0.8%) while 2.4% was unidentified fungal isolates (Redou et al. 2015; Zhang et al. 2016a). The most diverse and common fungal species were reported to be *Aspergillus* sp., *Penicillium* sp., and *Simplicillium obclavatum*, while

Alternaria alternata, *Aureobasidium pullulans*, *Cryptococcus liquefaciens*, *Exophiala dermatitidis*, *Epicoccum nigrum*, and *Neosetophoma samarorum* were the rarest fungal species documented in the deep-sea environments (Zhang et al. 2014). Recently, Liu et al. (2017) obtained 69 fungal isolates belonging to 27 species from deep coal-associated sediment samples collected at depths ranging from 1289 to 2457 mbsf in the pacific ocean off the Shimokita Peninsula, Japan. Most of the isolated strains (88% to the total strains) belonged to Ascomycota dominated by *Penicillium* and *Aspergillus*, and only 12% of the strains belong to Basidiomycota.

Besides the richness of biodiversity, many novel fungal species were also reported recently. Six novel phylotypes of genera *Ajellomyces*, *Podosordaria*, *Torula*, and *Xylaria* were reported by Zhang et al. (2013) based on their investigation and identification of the obtained cultural fungal species from the sediment of the South China Sea at a depth of 2400–4000 m. One novel fungal phylotype, DSF-Group1, was discovered in deep-sea sediments at depths ranging from 1200 to 10,000 m by using three fungal specific primer sets, targeting the ITS1-5.8S–ITS2-28S rRNA regions (Nagano et al. 2010) and another environmental clade KML11, which strongly supported group of the parasitic genus *Rozella* in *Cryptomycota*, was also identified by using eukaryotic-specific primers EK-82F and EK-1492R (Lara et al. 2010). Similarly, the BCGI clade by using fungus-specific primers nu-SSU-0817 and nu-SSU-1536-39 was also reported (Nagahama et al. 2011). Since most fungal species isolated from deep-sea environments showed similar morphological characteristics to their terrestrial counterparts, molecular phylogenetic analysis played important role in the discovery and identification of the unknown fungi.

The biodiversity of deep-sea fungal communities has largely been dependent on the samples where they obtained, and the methods used for fungal detection. The great depths and high hydrostatic pressure in the deep-sea are the major factors severely constraining sample collection from those extreme environments. Several samplers such as box corer, gravity corer, piston corer, and a grab sampler have been used to collect samples from deep sea and sediments (Nagahama and Nagano 2012). A sampler is used according to the nature of the sample. For example, a grab sampler is used to collect samples from the surface of deep-sea floor which are soft and silt in nature; box corer is suitable for mud- and silt-natured samples but not for sand; the gravity corer and piston corer are used for sampling at various depths from the deep-sea floor. Another powerful and most advanced drilling instruments are used with deep-sea drilling vessel, CHIKYU, able to collect sediments samples from 7000 m below the deep-sea floor (Nagahama and Nagano 2012). Unfortunately, all these samplers cannot absolutely protect the samples from contamination during sampling process Therefore, with the development of novel techniques used in samples from deep-sea environments, more and more fungi will be discovered from the extreme deep-sea habitats in the future.

17.3 Enzymes Derived from Deep-Sea Fungi

The enzymes produced by deep-sea fungi are either unique protein molecules which are not isolated from any terrestrial organisms or it may be a known protein previously isolated from terrestrial source but with novel properties. However, so far only few enzymes with unique properties have been reported from the deep-sea fungal community. Barotolerant proteases were reported from two deep-sea strains of *Aspergillus ustus* (Raghukumar and Raghukumar 1998); alkaline and cold-tolerant proteases were isolated from the deep-sea fungi, *Aspergillus ustus*, were active at various temperatures, pH, and pressure, with an optimum activity at pH 9, and showed stability under high concentration of detergents and salinity (Raghukumar and Raghukumar 1998; Damare et al. 2006), thus allowing laundry under cold water and having the potential to reduce the energy requirement for a chemical reaction by increasing the hydrostatic pressure and decreasing the temperature. Enzymes like this would be very useful in future to lower the energy cost. Polygalacturonases (PGase) are enzymes usually used in the food industry for clarification of fruit juices. Two unique PGase were isolated from deep-sea (4500–6500 m) yeast strains, and showed activity at low temperature (0–10 °C) and high hydrostatic pressure (100 MPa) (Miura et al. 2001; Abe et al. 2006). These enzymes were also tolerant at high (50 mM) concentration of $CuSO_4$ and showed high activity of superoxide dismutase (superoxide radical scavenger) (Abe et al. 2001, 2006). Batista-García et al. (2017) reported three lignocellulolytic-halotolerant fungi (*Cadophora* sp. TS2, *Emericellopsis* sp. TS11, and *Pseudogymnoascus* sp. TS12) from deep-sea sponge samples, which displayed high CMCase and xylanase activities at an optimal temperature of 50–70 °C and optimal pH of 5–8; thus it could be possible to use these enzymes in future for the conversion of lignocellulosic biomass materials (Plecha et al. 2013). Dimethyl phthalate ester is an important environmental pollutant belonging to phthalate esters group which can cause toxicity in the endocrine system, is widely distributed in nature, and is commonly used in plastic preparation. A deep-sea fungus, *Aspergillus versicolor* IR-M4, can degrade dimethyl phthalate ester with the help of phthalate esterase (Wang et al. 2017b).

17.4 Bioactive Compounds from Deep-Sea Fungi

Deep-sea fungi survived in the extreme conditions of the deep-sea and are adapted well through evolution; therefore, scientists considered this group of fungi a novel and new source of medicinally important metabolites for new drug discovery. According to previous data, more than 200 new bioactive materials have been isolated so far from deep-sea fungi (Daletos et al. 2018). Table 17.1 shows some interesting bioactive compounds recently isolated from deep-sea fungi.

Table 17.1 Important bioactive compounds isolated from deep-sea fungi after 2015

Fungal species	Place	Depth (m)	Metabolite	Activity	Chemical formula	Reference

17.4.1 Antimicrobial Activity

Antimicrobial compounds, asperolides D and E, isolated from the deep-sea fungus *Aspergillus wentii* SD-310 showed moderate antimicrobial activity against *Edwardsiella tarda*, each with an MIC value of 16 μg/mL (Li et al. 2016a). Wang et al. (2016) isolated oxepine-containing alkaloids and xanthones, from the deep-sea-derived fungus *Aspergillus versicolor* SCSIO 05879, which showed antifungal activities against other plant pathogenic fungi especially versicoloids A and B, and exhibited significant antifungal activity against *Colletotrichum acutatum* with an MIC value of 1.6 μg/mL; thus they could be used as a potent candidate for antifungal-agrochemicals. Similarly another antibacterial compound, aspewentin D (Li et al. 2016b), and antifungal compound, wentinoids A (Li et al. 2017), have also been isolated from fungus *Aspergillus wentii* SD-310. Niu et al. (2017a) isolated antibacterial compounds (eutypellazine P, eutypellazine Q, eutypellazine R) from deep-sea fungus, *Eutypella* sp. MCCC 3A00281, which showed inhibitory effects against *Staphylococcus aureus* ATCC 25923 and vancomycin-resistant enterococci (VRE), with an MIC value of 16–32 μM. Chaetoviridides A–C, from deep-sea fungus, *Chaetomium* sp. NA-S01-R1, showed antimicrobial activities against strains of *Vibrio vulnificus* (MIC = 30.5, 7.4, and 15.7 μg/mL), *Vibrio rotiferianus* (MIC = 7.3, 31.3, and 15.3 μg/mL), and *Vibrio campbellii* (MIC = 32.7, 32.3, and NA μg/mL) (Wang et al. 2018a). Another novel compound, anthraquinone, 2-(dimethoxymethyl)-1-hydroxyanthracene-9,10-dione, isolated from the deep-sea fungus *Aspergillus versicolor*, showed strong inhibition against MRSA ATCC 43300 (MIC = 3.9 μg/mL) and MRSA CGMCC 1.12409 (MIC = 7.8 μg/mL) and moderate inhibitory activities against Vibrio strains (Wang et al. 2018b).

17.4.2 Anti-inflammatory Activity

Two new anti-inflammatory compounds (acremeremophilane B and acremeremophilane E) were isolated from deep-sea-derived fungal species, *Acremonium* TVG-S004-0211. These compounds showed inhibition activity against NO production in LPS-activated RAW 264.7 macrophages, with IC_{50} values of 8 μM and 15 μM, respectively, suggesting them to be new anti-inflammatory compounds (Cheng et al. 2016). A nitrophenyl trans-epoxyamides derivative compound, chrysamides C, isolated from the deep-sea fungus, *Penicillium chrysogenum* SCSIO41001, showed a suppressive effect against the production of pro-inflammatory cytokine interleukin-17 with the inhibition rate of 40% at 1 μM (Chen et al. 2016). Several bioactive compounds have been isolated from the deep-sea fungus, *Penicillium granulatum* MCCC 3A00475. Spirograterpene A, a compound isolated from this fungus, showed antiallergic activity against immunoglobulin E (IgE)-mediated rat mast RBL-2H3 cells with 18% inhibition at 20 μg/mL as compared to control one (Loratadine) which showed 35% inhibition at the same concentration (Niu et al. 2017b).

An anti-inflammatory compound called khusinol B isolated and purified from the culture broth of fungus, *Graphostroma* sp. MCCC 3A00421, showed significant anti-inflammatory effect with IC_{50} value of 17 mM; this compound also showed weak antiallergic activity with IC_{50} value of 150 mM and thus could be a good anti-inflammatory candidate (Niu et al. 2017c). Similarly, a new anti-inflammatory compound, graphostromanes F, recently isolated from the same fungi, *Graphostromanes F*, exhibited stronger anti-inflammatory response against lipopolysaccharide-induced nitric oxide in macrophages with IC_{50} value of 14.2 μM, proving to be a potent candidate for anti-inflammatory drugs (Niu et al. 2018a). Gao et al. (2017) isolated three antiallergic compounds (CDMW-3, CDMW-5, and CDMW-15) from a deep-sea fungal species, *Williamsia* sp. MCCC 1A11233 (CDMW), showing potent anti-allergic activity through induction of apoptosis in mast cells. The deep-sea fungi were also investigated for antifood allergic drugs. A polyketide compound reticulol was isolated from the deep-sea-derived fungus *Graphostroma* sp. MCCC 3A00421, which showed antifood allergic and anti-inflammatory effect. Reticulol showed significant inhibition of degranulation with an IC_{50} value of 13.5 μM (Niu et al. 2018b).

17.4.3 Antioxidant Activity

The deep-sea-derived microorganisms produced many extracellular polysaccharides with novel and unique properties and are considered as most promising and potent group of antioxidant compounds (Arena et al. 2009; Sun et al. 2009; Le Costaouëc et al. 2012). Currently used antioxidants are synthetic and taught to be carcinogenic and may cause damage to liver (Laurienzo 2010); therefore, it is important to find and utilize natural products as an antioxidant source. Yan et al. (2016) extracted N1 compound, a novel extracellular polysaccharide, from the deep-sea isolated fungus *Aspergillus versicolor* N2bc. Proper investigation of N1 compounds revealed that it is a potent antioxidant and could be used in future.

17.4.4 Antiviral Activity

The most unique and interesting compound isolated from the deep-sea fungi is the influenza virus inhibitor. A compound called spiromastilactone D can be a potent inhibitor of influenza A and B virus. This compound has the ability to bind to hemagglutinin (HA) protein which usually attaches to the host cell surface receptor called sialic acid (SA) making an HA–SA complex which is essential for the attachment and entry of influenza virus to the host (human) cell. In the presence of this compound, HA cannot attach to SA and thus prevents influenza virus from being entered into the host cell. This compound can also inhibit viral genome replication process by targeting viral ribonucleoprotein complex (Niu et al. 2016); through both these properties this compound could be used in future for the antiviral application.

Another compound called cladosin C, isolated from the deep-sea fungus *Cladosporium sphaerospermum* 2005-01-E3, also showed antiviral activity against influenza A virus (Wu et al. 2014). Anti-HSV1 bioactive compounds (Aspergilol H, Aspergilol I, and Coccoquinone A) have also been isolated from another fungal strain, *Aspergillus versicolor* SCSIO 41502, which showed potent antiviral activity against HSV-1 with EC_{50} values of 4.68 μM, 6.25 μM , and 3.12 μM, respectively (Huang et al. 2017).

17.4.5 Cytotoxic Activity

A cytotoxic compound, asperolides E, isolated from the deep-sea fungus *Aspergillus wentii* SD-310, showed significant cytotoxic effect against HeLa, MCF-7, and NCI-H446 cell lines, with IC_{50} values of 10 μM, 11 μM, and 16 μM, respectively (Li et al. 2016a). Another five cytotoxic compounds (Asperethers A–E) were also isolated from this fungus. All these compounds showed potent cytotoxic effects against A549 cell line with IC_{50} values of 20 μM, 16 μM, 19 μM, 17 μM, and 20 μM, respectively (Li et al. 2016c). Two new secondary metabolites acaromycin A and acaromyester A have been isolated from deep-sea fungal strain *Acaromyces ingoldii* FS121, which showed cell growth inhibitory activities against MCF-7, NCI-H460, SF-268, and HepG-2 with IC_{50} values less than 10 μM (Gao et al. 2016). An antiproliferative compound, chaetoglobosin E, isolated from deep-sea fungus *Chaetomium globosum*, showed good cytotoxic and antitumor activity against two cell lines LNCaP and B16F10, with IC_{50} values of 0.62 μM and 2.78 μM, respectively (Zhang et al. 2016b). Another cytotoxic compound, brevianamide C, extracted form a fugal strain, *Penicillium brevicompactum* DFFSCS025, showed cytotoxic activity against human colon cancer cell line (HCT116) with IC_{50} value of 15.6 μM (Xu et al. 2017). A cytotoxic compound, dehydrocurvularin, isolated from deep-sea fungus, *Penicillium sumatrense* MCCC 3A00612, showed potent inhibition effect against LPS-induced NO production in RAW 264.7 macrophages with IC_{50} value of 0.91 mM as comparable to that of control L-NMMA with IC_{50} vale of 41.91 mM (Wu et al. 2017). New cytotoxic metabolites, sarcopodinols A and B, isolated from deep-sea fungus *Sarcopodium* sp. FKJ-0025, showed cytotoxic activity against human cell lines. Sarcopodinols A exhibited cytotoxic effect against Jurkat cells with an IC_{50} value of 47 μg/mL, while Sarcopodinols B showed cytotoxic activity against HL-60 cells with IC_{50} value of 37 μg/mL, Jurkat cells with IC_{50} value of 47 μg/mL, and Panc1 cells with IC_{50} value of 66 μg/mL (Matsuo et al. 2018). A compound phenylspirodrimane, stachybotrin H, isolated from the deep-sea fungal strain, *Stachybotrys* sp. MCCC 3A00409, showed weak cytotoxic activity against human leukemia (K562), cervical adenocarcinoma (Hela), and promyelocytic leukemia (HL60) cell lines (Ma et al. 2019). Four novel chlorinated azaphilone compounds chaephilone, chaetoviridides A–C, were isolated from deep-sea-derived fungus *Chaetomium* sp. NA-S01-R1, and among these, chaetoviridides A and B showed cytotoxic activities against A549, HeLa, and Hep G2 cell lines, with IC_{50}

values of 15.2 μM, 12.3 μM, and 3.9 μM, and 16.3 μM, 5.6 μM, and 18.2 μM, respectively (Wang et al. 2018a). Another dimeric isocoumarin compound, bipenicilisorin, has also been isolated from fungus, *Penicillium chrysogenum* SCSIO41001, which showed strong cytotoxic activities against various cell lines such as K562, A549, and Huh-7 with IC_{50} values of 6.78 μM, 6.94 μM, and 2.59 μM, respectively (Chen et al. 2017). Another compound, roquefortine J, isolated from the fungus, *Penicillium granulatum* MCCC 3A00475, showed cytotoxic activity against HepG2 tumor cells with an IC_{50} value of 19.5 μM (Niu et al. 2018c).

17.4.6 Bioactive Compounds with Other Activities

A new isopyrrolonaphthoquinone compound isolated from deep-sea fungi, *Biscogniauxia mediterranea* LF657, showed the potential of inhibiting glycogen synthase kinase (GSK-3β) with an IC_{50} value of 8.04 μM as compared to positive control (4-benzyl-2-methyl-1,2,4-thiadiazolidine-3,5-dione) with IC_{50} value of 0.26 μM (Wu et al. 2016). Perylenequinone, a protein inhibitor compound, isolated from the deep-sea fungi, *Alternaria* sp. NH-F6, has the ability to inhibit bromodomain-containing proteins such as BRD4, which is an epigenetic code reader protein, with an inhibition rate of more than 80% at a concentration of 10 μM. Thus it was suggested that this compound has potent antitumoral, antiviral, and anti-inflammatory properties (Ding et al. 2017). A unique compound sesquiterpene methylcyclopentenedione named penicilliumin B was reported for the first time in the fermentation broth of the fungus *Penicillium* sp. F00120. This compound was examined for its reno-protective activities and showed substantial potential to inhibit renal fibrosis in vitro, through oxidative stress disruption mechanism, thus presenting a new type of promising reno-protective agent (Lin et al. 2017). Recently, two new chlorinated diphenyl ethers, chrysines B and C, dichlorinated xanthone, chrysoxanthone, dichloroorcinol, 2,4-dichloroasterric acid, methyl chloroasterrate, mono-chlorosulochrin, and geodin were isolated from deep-sea fungal strain, *Penicillium chrysogenum* SCSIO 41001. All these compounds showed good potential of inhibiting α-glucosidase with IC_{50} values of 0.35 μM, 0.20 μM, 0.04 μM, 0.16 μM, 0.15 μM, 0.09 μM, 0.14 μM, 0.14 μM, and 0.12 mM, respectively, in comparison to positive control (acarbose) with IC_{50} value of 0.28 mM (Wang et al. 2018c). Similarly, another α-glucosidase inhibitor compound called dichotocejpins A, isolated from fungus *Dichotomomyces cejpii* FS110, showed significant α-glucosidase inhibition activity with IC_{50} values of 138 μM (Fan et al. 2016). Liang et al. (2016) investigated deep-sea fungal strain *Simplicillium obclavatum* EIODSF 020, for peptide production and eight new linear peptides, simplicilliumtides A–H, were successfully isolated and purified from the culture broth. Among them, simplicilliumtides D showed best antifouling activity against *Bugula neritina* larva with the EC_{50} value of 7.8 mg/mL and LC_{50}/EC_{50} >100, indicating that simplicilliumtides D has the potential to be a natural antifouling candidate. Another antifouling compound, trichobotryside A, has also been isolated from another deep-sea fungus,

Trichobotrys effuse DFFSCS021, which showed significant antifouling activities against *Bugula neritina* and *Balanus amphitrite* larvae with EC_{50} values of 7.3, 2.5 μg/mL and $LC_{50}/EC_{50} > 40.5$, 37.4, respectively (Sun et al. 2016).

17.5 Conclusions and Future Perspectives

Even though deep-sea fungi have been extensively studied in recent researches, our understanding and scientific knowledge of deep-sea fungi is still very limited. So far the major focus was on deep-sea bacteria and regardless of the physiological adaptability to low temperature, elevated hydro pressure, and playing important roles in the ecosystem, deep-sea fungal taxa have not been discovered that much. The current known diversity of deep-sea fungi has demonstrated that it is just the tip of the iceberg and a vast extent of the unknown fungal community is yet to be discovered. Deep-sea fungi have revealed much promise in terms of interesting enzymes with novel properties, unique metabolics, and secondary metabolites. Many biotechnological important enzymes have been produced by deep-sea fungal community isolated from a variety of habitats. This diversity of deep-sea fungal products could be due to their genetic diversity based on taxonomy and adaptability to various extreme environmental conditions. Both cultural-dependent and cultural-independent techniques are essential for the investigation of deep-sea fungal diversity. However, cultural-independent techniques proved to be very useful in the discovery of various unknown fungal lineages in the deep sea, which were not able to grow under normal cultural conditions. There is still a very big scope to examine these fungi for other interesting and useful products and these fungi could be the source for novel products like extracellular polysaccharides, enzymes, and other secondary metabolites (Pettit 2011). Future studies should be focused on marine fungal biology to reveal interesting biochemical and physiological features useful to various new biotechnological processes. For example, the finding of new techniques to study uncultured and rare marine-derived fungi and knowing about its physiology and biochemistry will definitely pave the way for future deep-sea mycology.

Chapter 18
Bioactive Compounds from Extremophilic Marine Fungi

Lesley-Ann Giddings and David J. Newman

18.1 Introduction

Natural products are small molecules produced by organisms that are not required for development, growth, or propagation of a species. These secondary metabolites have evolved over billions of years to have high affinities for specific biological targets, making them a prolific source of structurally unique, bioactive compounds for industrial purposes and human health. In the search for new secondary metabolites, natural product chemists traditionally explored easily accessible terrestrial environments. However, by the 1990s we realized that all of the "low-hanging fruit" had been picked and natural product rediscovery rates increased. As such, underexplored environments, such as extreme ecosystems, are now being investigated for new bioactive compounds.

Chemical novelty is often found in underexplored environments, as their unique ecology impacts the availability of nutrients, such as heavy metals or salts, as well as the genes expressed in an organism at a given point in time. Many extreme ecosystems remain unexplored due to the costs and tremendous effort required to obtain samples. These environments are typically characterized as being "non-mesophilic" (either hot or cold), oligotrophic, or subject to osmotic stress, high salt concentrations, extreme pH, limited oxygen and light, severe radiation, high metal concentrations, and high pressures. To inhabit these ecosystems, organisms have mechanisms to regulate temperature, intracellular pH values, solute composition, biochemical redox reactions, and production of other biomolecules, as well as repair DNA,

protein, and lipid damage. Thus, there is potential to find new molecular structures and bioactivity in extreme environments.

The marine world represents some of the most underexplored extreme environments, as roughly 71% of the Earth's surface is covered with water, mainly oceans. For the purpose of this chapter, we define marine environments as oceans, seas, estuaries, polar sea ice, brine, as well as shallow, deep, and tidal water collections with salt concentrations equivalent to that of sea water (3% w/v). These ecosystems are quite diverse with variable temperatures (~−1.5 °C in sea ice to 400 °C in deep sea hydrothermal vents), pressure (1–1000 atm), light (complete darkness to photic zones), nutrients (nutrient-rich to -limited), and species. Marine environments harbor a wide range of organisms, such as marine (in)vertebrates, plants, algae and their associated microorganisms, as well as sediment-derived microorganisms (Tiquia-Arashiro 2012). Oceans represent the greatest biodiversity with 34 of 36 phyla represented (Donia and Hamann 2003). Such genetic diversity renders significant chemical diversity with new carbon skeletons, high levels of halogenation, and most importantly, novel bioactivity.

It took a long time for researchers to become interested in studying marine environments due to difficulty accessing these sites. Studying oceanic environments requires specialized sampling techniques (Mckindles and Tiquia-Arashiro 2012; Tiquia-Arashiro 2012) and equipment and let us not forget that <1% of these microorganisms are actually culturable on traditional nutrient agar. In the past when new compounds were reported from marine environments, they typically came from easily cultivable organisms. Until the invention of the reliable self-contained underwater breathing apparatus (SCUBA), the isolation of marine natural products lagged behind that of metabolites from the terrestrial world. However, in the 1960s and 1970s, SCUBA diving became an essential tool for collecting marine organisms from ocean depths ranging from 3 to 40 m (Cragg and Newman 2001) and although expensive submersibles and remotely operated vehicles were also developed for deep sea sampling. Since the 1970s, the number of "extremophiles" reported has increased and new sampling and culturing methodologies, journals, databases such as MarinLit, and international symposia are dedicated to the study of these organisms. Now there is a renewed interest in marine natural products, and each year, increasing numbers of new biologically active marine natural products are reported (some from fungal sources) and several of these compounds have entered the preclinical and clinical pipelines. Table 18.1 includes the names of drugs (**1**–**7**), either directly from the sea or with structural modifications, which have been approved for clinical use by the FDA and/or the EMA. Their "nominal sources," structure numbers, bioactivities in brief, and relevant reference numbers are also provided. This will be the format used throughout this chapter, so readers interested in specific metabolites may consult the appropriate reference(s).

At least five clinically approved marine drugs are produced by microbial symbionts, which is not surprising as microbes primarily occupy 70% of marine biomass. As such, there is significant interest in bioprospecting marine microbes for natural

Table 18.1 Biological activities of compounds **1–38**

Name	Source	#	Bioactivity
Cytarabine	Sponge/bacterium?	**1**	Antitumor

products, especially because in time, it may be possible to use these, or surrogate hosts of the biogenetic clusters (BGCs), to sustainably produce large quantities of bioactive metabolites. While most microbial secondary metabolites reported from the marine world have been isolated from prokaryotes, fungi are rich sources of natural products, with at least 30–40 BGCs coding for secondary metabolites in a single genome. Fungi are metabolically, morphologically, and phylogenetically diverse. The chemo-diversity of marine fungi from underexplored environments is of even more interest as these environments have a range of ecological factors that impact natural product biosynthesis. In this chapter, we discuss marine-derived fungi from different aspects of marine environments, including shallow-sea isolates, deep sea environments, including sediments and hydrothermal vents, which are unique settings for life due to the increased pressures, temperatures, and presence of toxic elements, then finishing by covering the "Polar Seas." In these areas, and their functional subdivisions, we cover metabolites produced by fungi associated with marine invertebrates, predominantly sponges, and those associated with algae and cyanobacteria, noting that in the latter two cases, these are almost certainly epiphytic organisms in contrast to those in sponges. Chemical structures (**123**) are shown in detail in five figures, and in order to save space, we have used five tables to report compound names, the producing fungus, and any up-to-date biological details available in the reference(s). This review differs from others by our use of geographic and physical extremes to discuss fungal chemical diversity, corresponding bioactivity, and strategies to identify bioactive metabolites from marine environments. We also highlight the occasional occurrence of the same chemistry produced by (micro)organisms from terrestrial and marine environments.

18.2 Definition of Marine Fungi

Since the 1980s, more researchers have published the structures and bioactivities of a number of marine fungal metabolites as can be seen on inspection of the yearly review on marine natural products published in Natural Product Reports (Blunt et al. 2018). Why the delayed interest in marine fungi? To begin to understand why, one must recognize the fact that the mere definition of a marine fungus continues to be debated in publications and at international meetings. In fact, it took marine mycologists almost two decades after the first published study on marine fungi (Barghoorn and Linder 1944) to provide the first comprehensive definition of a marine fungus, Johnson and Sparrow (1961) followed by Kohlmeyer and Kohlmeyer (1979). The latter paper defined obligate marine fungi as growing and sporulating in marine or estuarine environments, whereas facultative marine fungi grow and possibly sporulate in marine, freshwater, or terrestrial habitats. Yet, different definitions are still used to classify fungi within the marine mycology and natural products communities (Overy et al. 2014).

Many marine mycologists only use microscopic techniques to study obligate marine fungi. These investigators consider facultative marine fungi to be (1) dormant spores that may be blown or rained into the ocean and (2) ubiquitous fungi metabolically active in marine environments. Others disagree with the treatment of facultative fungi and continue to advocate for these microorganisms to be included in the definition of marine fungi. These nominally marine facultative fungi elaborate different secondary metabolites from their terrestrial counterparts; thus natural product chemists often use the term "marine-derived" to classify fungi collected from marine environments, as the emphasis is on the bioactive metabolites, rather than the "correct" identification and characterization of the fungal producer. For the purpose of this chapter, we define marine fungi as microorganisms that can (1) reproducibly grow or sporulate in marine environments; (2) be found as symbionts of other marine organisms; or (3) adapt and evolve to thrive in marine environments.

18.2.1 Marine Fungal Sources

Fungi occupy various marine environments, such as the deep sea, hydrothermal vents, polar systems, sediment, sand, and symbiotic environments found in driftwood, algae, marine (in)vertebrates, or plants (i.e., mangroves). Even oceanic air harbors a diverse fungal population (Fröhlich-Nowoisky et al. 2012). Early studies on marine fungi focused on those isolated from macroalgae or seaweeds, submerged wood, and seagrass, followed in the 1970s by more published studies on fungal morphology and taxonomy due to significant technological advances made in microscopy. Three decades later, high-throughput genomic sequencing methods were developed and are now frequently used to classify taxa from marine sources. Distinct and highly divergent phylotypes have been identified in these studies,

suggesting that there is a great potential to find more chemical diversity in these environments (Singh 2012). Furthermore, metatranscriptomic sequencing is now revealing some of the following important roles fungi play in marine communities: biogeochemical cycling; decomposition/mineralization of organic matter; functioning as parasites, pathogens, mutualists, and endobionts in host organisms; and playing roles in chemical defense or as attractants.

As of 2015, a total of 1112 documented marine fungi were reported (Jones et al. 2015), but this number may be misleading due to confusion around whether an organism is even a marine fungus or a member of new taxa. Nevertheless, with increasing numbers of marine fungi reported, the number of publications on new bioactive secondary metabolites has increased. Culture-dependent and -independent techniques have been used to identify and characterize new bioactive compounds from these fungal isolates. Here, we will discuss representative bioactive metabolites produced by culturing fungi isolated from specific marine environments, such as the deep sea, hydrothermal vents, driftwood, and polar systems.

18.3 Culture-Based Approaches

18.3.1 Serendipitous Discovery of the First Natural Product Discovered from a "Marine-Derived" Fungus

The clinical use of penicillin marked the beginning of the "Golden Age of Antibiotics" in the 1940s, resulting in the extensive investigation of microbes as sources of new therapeutics. While searching for new antibiotic-producing organisms in 1945, Brotzu examined the microbial flora of sea water near a sewage outlet in Cagliari, Sardinia and isolated a fungus that inhibited the growth of Gram-positive and -negative bacteria. This fungus was identified as *Cephalosporium acremonium* in a 1948 report (Brotzu 1948). That year, a culture was sent to Oxford University for further investigation and over the next 20 years, active components, such as cephalosporins C (**8**) and N (now penicillin N) (**9**), were identified. Cephalosporin C (**8**) had a wide range of bioactivities against a number of penicillin-resistant and -sensitive strains of *Staphylococcus aureus* (Newton and Abraham 1955). Although its bioactivities were weak, cephalosporin C (**8**) was not susceptible to β-lactamases and therefore had potential bioactivity against penicillin-resistant microbes (Abraham and Newton 1956; Newton and Abraham 1956). These results encouraged Lilly to expand upon the 7-aminocephalosporanic acid scaffold to produce many cephalosporins to treat penicillin-resistant infections, and today there are five generations of these agents.

The genus *Cephalosporium* was later renamed *Acremonium* and several marine species have been reported to produce bioactive compounds. Jang et al. reported the new dibenzofuran derivative, awajanoran (**10**), from *Acremonium* sp. AWA16-1, isolated from sea mud at Awajishima Island, Japan (Jang et al. 2006a). The same

strain was later shown to produce the γ-lactone-δ-lactam, awajanomycin (**11**), two derivatives, a hydrolyzed ester (**12**) and a reduced carboxyl group (**13**) (Jang et al. 2006b). From *A. persicinum* SCSIO 115 three new cycloheptapeptides, cordyheptapeptides C–E (**14**–**16**), were isolated from a marine sediment sample collected in the South China Sea (Chen et al. 2012). A number of other bioactive compounds have been reported from predominately symbiotic *Acremomium* species of marine invertebrates and algae.

Several cytotoxic metabolites have been isolated from marine fungi. Hayakawa et al. reported efrapeptin J (**17**), a new downregulator of GRP78, from a *Tolypocladium* sp. isolated from sea mud in Japan (Hayakawa et al. 2008). Such downregulators exhibit antitumor activity against solid tumors (Fernandez and Tabbara 2000). Efrapeptin J (**17**), a linear pentadecapeptide with a hexahydropyrrolo-[1,2-*a*]-pyridinium moiety, and other efrapeptins (efrapeptins F–G, **18**–**19**) with a one- or two-amino acid difference have been isolated from marine-derived *Tolypocladium* sp. with similar bioactivities. Efrapeptins (efrapeptins A–I; structures not shown) are known from terrestrial species of *Tolypocladium* (Gupta et al. 1992; Krasnoff and Gupta 1991, 1992). Thus, osmotic stress may result in differential expression in this genus, and unpurified extracts of efrapeptins exhibit insecticidal, anti-parasitic, and antimicrobial activities (Bandani et al. 2000).

In 2013, Vansteelandt et al. isolated a new fumagillin analogue, ligerin (**20**), from *Penicillium* sp. MMS351 collected from seawater (Vansteelandt et al. 2013). Despite the abundance of chlorine in marine environments, there are very few secondary metabolites from marine-derived *Penicillium* strains containing this atom in their chemical structures. The chlorohydrin and C-6 substituents are essential for cytotoxic activity (Blanchet et al. 2014). Although of scientific interest, no antitumor clinical trials of any fumagillin derivative have proceeded beyond phase II.

18.3.2 Bioactive Compounds from the Deep Sea

The deep sea is a unique marine ecosystem that harbors some of the most diverse fungi and potentially unique molecules/structures. Deep sea environments are defined to be water at depths beyond the euphotic zone (200–300 m) (van Dover et al. 2002). These represent some of the most extensive and remote ecosystems on the planet, as 95% of the Earth's oceans are greater than 1000 m deep (Skropeta and Wei 2014) with hydrostatic pressures increasing by 1 atm with every 10 m increase in depth, to as high as 1100 atm in the Challenger Deep (10,897 m) (Takami et al. 1997). In addition, these environments have temperatures down to ~2 °C, darkness at depths greater than 250 m, sparse nutrients, and low oxygen levels (Skropeta and Wei 2014). The deep-sea microbes mainly inhabit the sediment substratum and obtain nutrients from the sediment or remote surface waters. Yet less than 5% of the deep sea has been explored and only 0.01% of the deep-sea floor has been sampled (Ramirez-Llodra et al. 2010).

Major limitations to exploiting the biodiversity of the deep sea have been developing effective sampling methods and access to this ecosystem. ZoBell coined the term "barophile" (now known as piezophile) to describe microorganisms that thrive under high-pressure conditions (ZoBell and Johnson 1949). Fifteen years later, Roth and coworkers published the first report of deep sea fungal piezophiles isolated from the Atlantic Ocean at a depth of 4450 m (Roth et al. 1964). With the advent of manned submersibles, it was now feasible to identify two new species of organisms a month at depths > 10,000 m (Fisher et al. 2007), and inexpensive collection methods, such as the "mud missile" were developed by Fenical et al. at Scripps Institution of Oceanography (Fenical et al. 2013). Techniques are now available to cultivate deep sea fungi using conditions that mimic the in situ natural environment (Rédou et al. 2015). Using these specialized tools and methods, microbes that live greater than 5000 m below sea level, irrespective of their classifications, can sometimes be cultured.

While some of the deep sea fungal phylotypes are novel, a number of them have "relatives isolated from terrestrial, fresh water, and salt water environments" (Nagano et al. 2010). Thus, it is not surprising that a number of bioactive compounds have been isolated from more cosmopolitan and universal fungi. There are numerous reports on diketopiperazine alkaloids produced from the *Aspergillus fumigatus* BM929 strain isolated from sea sediment 760 m deep. The two tryprostatins A (**21**) and B (**22**) isolated from this strain have different bioactivity profiles (Cui et al. 1995, 1996a, b, 1997; Usui et al. 1998). These compounds also reversed the resistance phenotype in selected cell lines (Woehlecke et al. 2003). Other tryprostatin A and B enantiomers and stereoisomers were evaluated for cytotoxic activity against human carcinoma cell lines, with the diastereomer of tryprostatin B (i.e., ds2-try B, **23**) being more potent than etopside (Zhao et al. 2002). Further synthetic work modeled on tryprostatins yielded multiple compounds with increased cellular cytotoxicity, but none entered clinical trials (Jain et al. 2008).

In 1997, Cui et al. reported the diketopiperazine derivatives, cyclotryprostatins A–D (**24**–**27**), from the same *A. fumigatus* strain (Cui et al. 1997). These compounds are pentacyclic with structural differences shown in the relevant figures. All inhibited the cell cycle progression of mouse tsFT210 cells at the G2/M phase, with cyclotryprostatin A (**24**) being the most potent, suggesting that the methoxy group and C-12 stereochemistry are important. A variant, cyclotryprostatin E (**28**), with an isopropyl alcohol group at the C-21 position sans the isoprene unit, was isolated from the mycelia of *A. sydowii* SCSIO 0035 (symbiont of the gorgorian coral *Verrucella umbraculum*) but lacked cytotoxic activity in the tested cell lines (He et al. 2012).

Cui et al. had earlier reported the production of a new diketopiperazine, demethoxy fumitremorgin C (**29**), in a companion paper to the initial report on the tryprostatins (Cui et al. 1996b). During a scale-up fermentation of strain BM939, they isolated the bioactive spirotryprostatins A (**30**) and B (**31**) (Cui et al. 1996c, d). They contain a spiro ring system with (**30**) having a C-6 methoxy group and lacking the C-8, C-9 double bond found in (**31**). Other related compounds, prenylcyclotryprostatin B (**32**),

20-hydroxycyclotryprostatin B (**33**), 9-hydroxyfumitremorgin C (**34**), 6-hydroxytryprostatin B (**35**), and spirogliotoxin (**36**), were reported from the *A. fumigatus* YK-7 strain isolated from the intertidal zone in Yingkou, China, but only prenylcyclotryprostatin B (**32**) and 9-hydroxyfumitremorgin (**34**), both with C-6 methoxy groups and C-18 prenyl groups, were active (Wang et al. 2012). Thus, the tryprostatin scaffold appears to be a valuable pharmacophore and several computational and synthetic studies have been published since this study to find other mammalian cell cycle inhibitors (Fani et al. 2015; Yamakawa et al. 2011).

Deep sea fungi have produced compounds that have entered early (pre)clinical trials. For example, in 1985, Japanese researchers at Sankyo laboratories identified the antifungal agent zofimarin (**37**) in the culture broth of *Zopfiella marina* SANK21274, isolated from mud at 120 m in the East China Sea (Ogita et al. 1987; Sato et al. 1985). Zofimarin (**37**) is a sordarin derivative, and the sordarins are a desired class of antifungal agents because they selectively inhibit fungal protein synthesis by inhibiting elongation factor 2 (Domínguez and Martín 1998). Though it had in vitro activity against various fungi and little toxicity in mice (Biabani and Laatsch 1998), it failed in in vivo studies. In 2002, two reports were published on derivatives, with R-135853 (**38**) being selected for further preclinical evaluation (Kaneko et al. 2002a, b). Although active against resistant *C. albicans* strains, and demonstrating in vivo efficacy in various experimental murine models of candidiasis, it was inactive against *C. parapsilosis*, *C. krusei*, and *Aspergillus* spp. (Kamai et al. 2005). Currently, analogs and sordarin-inspired scaffolds are still being investigated for in vivo efficacy against a spectrum of susceptible species (Chakraborty et al. 2016; Wu and Dockendorff 2018).

While several terrestrial strains of *Zopfiella* have been isolated, none produced zofimarin (**37**), highlighting the important impact of the *Z. marina* marine habitat on metabolism. However, it was identified in cultures of terrestrial fungi belonging to the following families: *Microascaceae* (*Graphium putredinis* F12210), soil in the UK (Kennedy et al. 1998); *Xylariaceae* (strain F-064,188), a plant epiphyte from Mauritius (Vicente et al. 2009); *Xylaria* sp. Acra L38, an endophyte isolated from the Thai medicinal plant *Aquilaria crassna* (Chaichanan et al. 2014; Wetwitaklung et al. 2009); *Diatrypaceae* (likely *Eutypa tetragona*), isolated from the fruitbody of *Phellodon melaleucus* in Spain (strain F-081,165); and *Sarothamnus scoparius* from France (strain F-247,493; CBS 284.87) (Vicente et al. 2009). It is still unclear how evolution leads to different species from distinct environments to produce the same natural product. Yet, this phenomenon has been observed with metabolites from sponges and tunicates that are also produced by terrestrial bacteria (Newman 2016). Specifically, unculturable microbes tend to be the true producers of several natural products from marine invertebrates, suggesting that the common denominator is microbes that share similar BGCs. So, many unanswered questions remain. Why are microbes producing the same metabolites in completely different environments? How do these BGCs evolve? A deeper understanding of (1) the ecological roles of secondary metabolites and (2) the influence the environment has on their production will provide more insight into these questions (Fig. 18.1).

18.3.3 Bioactive Compounds from the Hydrothermal Vents

Within the deep sea are hydrothermal vents, which are metal- and sulfur-rich, high-pressure and -temperature environments that form along continuous mid-ocean ridges (~60,000 km-long). The hot fluids (400 °C) that exit from deep-sea vents are enriched with transition metals, silica, sulfide, and dissolved gases, and the mixing

water springs to have abundant communities of benthic organisms. A number of large and unusual marine invertebrates, such as bivalve mollusks and crabs, were photographed by the manned submersible Alvin near these plumes. From 1979 to 1982, expeditions to hydrothermal vents led to the discovery of chemoautotrophs and symbiotic sulfide-oxidizing bacteria in invertebrates. These microbes play important roles in hydrothermal vents by being the primary producers driving the

food chain (van Dover 2000; van Dover et al. 2002). Furthermore, the steep physical and chemical gradients of these remarkable ecosystems influence the biogeographical patterns of species distribution. Several complex fungal communities in hydrothermal vents have been characterized, with the sediment being more phylogenetically diverse than the overlaying seawater (López-García et al. 2003). Molecular surveys of the small subunit ribosomal RNA in autochthonous eukaryotic communities have revealed that vent sediment is comprised of anaerobic fungi as well as those from known eukaryotic lineages (Zhang et al. 2014).

Marine fungi have been isolated from a variety of endemic animals, such as crabs, in hydrothermal vents and reported to produce a number of structurally diverse, bioactive metabolites. Pan et al. reported versicomides A–C (**39**–**41**), an oxepin containing quinazoline (versicomide D, **42**) and four cyclopenin derivatives (7-methoxycyclopeptin, 7-methoxydehydrocyclopeptin, 7-methoxycyclopenin, and 9-hydroxy-3-methoxyviridicatin, [**43**–**46**]) produced by *A. versicolor* XZ-4 isolated from a Taiwan Kueishantao hydrothermal vent crab (Pan et al. 2017). With the exception of (**44**), (**43**, **45**, and **46**) were active against *Escherichia coli*, suggesting that these structural scaffolds may be worth investigating to fine tune their antibacterial activity. The same group also reported a new verrucosidin derivative, methyl isoverrucosidinol (**47**), isolated from *Penicillium* sp. Y-50-10 from the same vent that inhibited *Bacillus subtilis* (Pan et al. 2016). Compound **47** is an unusual isomer of the potent neurotoxin verrucosidin (**48**) (Burka et al. 1983; Whang et al. 1990), based on its conformational isomerization between C-8, C-9 and the C-10, C-11 double bonds (Fig. 18.2; Table 18.2).

18.3.4 Bioactive Compounds from Fungi Associated with Marine Invertebrates, Cyanobacteria, and Algae

Several culture-dependent and -independent studies have shown that marine sponges, mollusks, tunicates, algae, and other invertebrates are a rich source of marine fungi (Debbab et al. 2010). These findings are not surprising as fungi often

Table 18.2 Biological activities of compounds **39**–**48**

associate with various marine organisms or substrata, assisting with nutrient cycling and the decomposition of organic matter. Marine fungi can be parasitic, commensal, or mutualistic. Ultimately, the interplay between microbe and host produces chemical responses that have profound effects on host microbiomes. These highly evolved responses often result in the production of unique molecular scaffolds that do not bear any resemblance to the chemical space occupied by synthetic compounds and therefore may have clinical potential in human medicine (Boot et al. 2006; Boufridi and Quinn 2018; Debbab et al. 2010; Gonzalez-Medina et al. 2016).

Sponges are the most studied marine habitat for fungi, as they comprise a significant proportion of the benthic community, and 40–60% of their biomass is comprised of associated microbes. Interestingly, abundant amounts of "terrestrial" taxa, such as *Acremonium* and *Penicillium*, are found in these invertebrates, some of which have specifically adapted to the marine environment and some are halogen sensitive, suggesting that some were recently acquired from terrestrial sources (Gal-Hemed et al. 2011). Thus, the highly oxygenated, tricyclic metabolite from a new structural class, acremostrictin (**49**), was produced by a strain of *Acremonium* (now *Sarocladium strictum*) from an unidentified Choristid sponge from Korean waters (Julianti et al. 2011). An unprecedented base, acremolin (**50**), was later isolated from the same strain of *Acremonium*. Acremolin (**50**), a modified guanine base attached to an isoprene unit via a 1H-azirine moiety, exhibited weak cytotoxic activity (Julianti et al. 2012). Its structure was revised later in the year removing the azirine ring, and the revised tri-ring system is shown as structure (**50**) (Banert 2012). *N*-methylated linear octapeptides, RHM1 (**51**) and RHM2 (**52**), were isolated from an atypical strain of *Acremonium* sp. (strain number 021172c) cultured from an *Axinella* sp. collected in Papua New Guinea (Boot et al. 2006). A year later, RHM3 and 4 (**53**–**54**) as well as the new linear pentadecapeptides efrapeptins Eα and H (**55**–**56**) were isolated from *Acremonium* sp. (Boot et al. 2007). Efrapeptin Eα (**55**), composed of 15 canonical amino acids, was significantly cytotoxic. However, as shown earlier, efrapeptin H isolated from terrestrial sources was quoted to be bioactive (cf Table 18.1).

Acremonium species associate with other marine organisms in addition to sponges, such as sea cucumbers and algae. Strains of *A. striatisporum* KMM 4401 isolated from the sea cucumber *Eupentacta fraudatrix*, collected in the Sea of Japan, produce derivatives of the virescenosides, though virescenosides A–C (**57**–**59**) were originally isolated from the terrestrial strain *A. luzulae* (Bellavita et al. 1970; Moussaief et al. 1997). A series of papers from the Elyakov group and his successors in Vladivostok published from 2000 through 2006 describe several of these compounds, including virescenosides M–X (**60**–**71**), from the same nominal organism, *A. striatisporum* (Afiyatullov et al. 2000, 2004, 2006). Virescenosides V–X (**69**–**71**) have different unsaturated carbons, either a proton or hydroxyl group at C-6, and either a proton, keto, or hydroxyl group at C-7. There are no reports of their bioactivity.

Structurally unique classes of compounds have been produced by endophytic *Acremonium* strains isolated from marine algae. For example, the novel antioxidant hydroquinone derivatives, 7-isopropenylbicyclo[4.2.0]octa-1,3,5-triene-2,5-diol (also known as acremonium A, **72**) and 7-isopropenylbicyclo[4.2.0]octa-1,3,5-triene-2,5-diol-5-beta-D-glucopyranoside (acremonium A-5-β-D-glucopyranoside, **73**), containing an unusual ring system, were isolated from *Acremonium* sp. isolated from the brown alga *Cladostephus spongius* collected in Spanish waters (Abdel-Lateff et al. 2002). Interestingly, this ring system can only be chemically synthesized from a butane solution of 3-methyl-1,2-dihydronapthalene in the presence of UV light (245 nm), and the mode of cyclization used by *Acremonium* sp. in its biosynthesis is unknown. The same *Acremonium* strain also produced new dihydronapthalenones and acyclic carbocyclic derivatives (structures not shown) with no reported bioactivities. Nevertheless, these are examples of the wide capabilities of this fungus' biosynthetic capabilities.

From the culture broth and mycelia of an *Acremonium* sp. strain cultured from the Caribbean tunicate *Ecteinascidia turbinata* (the source of the EMA and FDA-approved antitumor agent ET743), Belofsky and coworkers isolated the new oxepin-containing pyrimidines, oxepinamides A–C (**74**–**76**), and the new fumiquinazolines H and I (**77**–**78**) (Belofsky et al. 2000). The cyclic pentadepsipeptide zygosporamide, composed of α-hydroxyleucic acid and D- and L-amino acids (**79**), was isolated from the culture broth of *Zygosporium masonii* isolated from a marine cyanobacterium collected off the island of Maui, Hawaii (Oh et al. 2006).

Marine fungi have been isolated from "sea hares" (mollusks), and compounds from these have been reported to exhibit (potent) bioactivity. The pericosines A–E (**80**–**84**) are cyclohexenoids produced by *Periconia byssoides* OUPS-N133 isolated from the gastrointestinal tract of the sea hare *Aplysia kurodai* (Numata et al. 1997; Yamada et al. 2007). Mice inoculated intraperitoneally with P388 followed by *ip* pericosine A (**80**) survived as long as non-treated control mice. Since the initial 1997 report of these unique carbasugar-type metabolites, several syntheses have been published, especially as other bioactive compounds containing a pericosine moiety have been reported (Babu et al. 2014; Boyd et al. 2010; Donohoe et al. 1998; Li and Hou 2014; MuniRaju et al. 2012; Reddy et al. 2012; Tripathi et al. 2011; Usami et al. 2017).

Aside from the FDA-approved cephalosporins, plinabulin (NPI-2358, **85**) is currently the only marine-derived fungal metabolite at a phase III clinical trial (under NCT02504489) against NSCLC cancers. It is a synthetic *tert*-butyl analog of the diketopiperazine halimide (**86**), also known as (−)-phenylahistin, produced by *Aspergillus* sp. CNC-139 isolated from the alga *Halimeda copiosa* collected near the Philippines (Fenical et al. 1999, 2000). This compound was also produced by two terrestrial strains of *A. ustus*, further demonstrating how BGCs may not be unique to an organism and their habitat (Kanoh et al. 1997, 1999a). Kanoh et al. determined that its cytotoxicity originates from its inhibition of tubulin polymerization by interacting with the colchicine-binding site (Kanoh et al. 1999b). To remove chirality and optimize cytotoxic activity, Nereus Pharmaceuticals developed a series of synthetic derivatives, ultimately leading to plinabulin (**85**) (Nicholson et al. 2006) (Fig. 18.3; Table 18.3).

18.3.5 Bioactive Compounds from Driftwood

Marine fungi inhabit wood substrata and play an important role in nutrient regeneration by decomposing dead and decaying organic matter, particularly lignocellulose. Driftwood is rich in carbohydrate polymers and a habitat for grazing organisms tolerating variations in the saline environment. Importantly, driftwood is a stable nutrient source for xylophages, substrata for microbial growth, as well as a point of attachment, facilitating its habitation. Driftwood is relatively unique, as tidal variations change its location over time and vary its exposure to sunlight and the atmosphere.

Fungi that secrete an abundance of lignin-degrading enzymes commonly inhabit driftwood (Kameshwar and Qin 2018a, b). Submerged wood substrata are breeding grounds for members of the orders Halosphaeriales and Lulworthiales, as these environments facilitate the passive release of ascospores and the floatation and attachment of appendaged ascospores (Overy et al. 2014). Additionally, the geographic source of driftwood influences fungal community structure within these types of substrates. Thus, driftwood from the eastern and western regions along the Norwegian coast of the Barents Sea harbors different fungal communities (Rämä et al. 2016). While terrestrial fungal communities that colonize wood have been extensively studied usually due to the economic importance of their "preferred homes," the converse is the case in the corresponding marine environment.

Corollospora, a genus known for rapidly degrading cellulose, has been isolated from driftwood and found to produce bioactive compounds. In 1998, Alvi and coworkers reported the production of a new lactam, pulchellalactam (**87**), from *Corollospora pulchella (*ATCC 62554) isolated from a driftwood sample collected from Peleliu, Palau using a bioactivity screen looking for CD45 phosphatase inhibitors (Alvi et al. 1998). The new phthalide derivative corollosporine (**88**) isolated from *Corollospora maritima* collected from driftwood in the North Sea exhibited antibacterial activity against *S. aureus* SG 511 (Liberra et al. 1998). Since this first report of corollosporine (**88**), other amide derivatives that are more active against

Plinabulin	*Aspergillus* sp. CNC-139	**85**	Phase III clinical trial against NSCLC
Halimide	*Aspergillus* sp. CNC-139	**86**	Active in vivo against P388

different bacterial strains than their non-amide counterparts have been synthesized using a fungal laccase-based system (Mikolasch and Schauer 2009).

Structurally unique cytotoxic compounds have been reported from wood substrata collected from marine environments. These include the trichothecene sesquiterpene verrol-4-acetate (**89**) isolated from *A. neo-caledoniae* (Roquebert et Dupont n. sp.) in New Caledonia (Laurent et al. 2000). Another new member of the cytotoxic roridin class of trichothecenes, 12,13-deoxyroridin E (**90**), was later isolated from *Myrothecium roridum* TUF 98F42 obtained from submerged wood in Palau (Namikoshi et al. 2001). Further work with the same strain identified the cytotoxic trichothecenes 12′-hydroxyroridin E (**91**) and roridin Q (**99**). In addition, 2′,3′-deoxyroritoxin D (**100**) was also isolated and found to exhibit antimicrobial activity against *S. cerevisiae* (Xu et al. 2006).

Interestingly, the antiviral naphthalenone compounds balticols A–F (**94**–**99**) were reported from an unspeciated Ascomycete from inshore driftwood in the Baltic Sea (Shushni et al. 2009). These metabolites differ structurally by different degrees of oxygenation and/or methylation. Two years later the same group reported the 12-membered macrolide balticolid (**100**) from the same fungus. Only one paper describing the synthesis of this compound has been published since that initial report (Krishna et al. 2012). Of interest is that balticol A (**94**) and other naphthalene derivatives were later reported from the plant fungal endophyte *Biatriospora marina* cultured from the European white elm *Ulmus laevis* in the Czech Republic (Stodůlková et al. 2015).

Mangrove or tidal swamp fungi are often found on driftwood in intertidal zones. One example is *Fusarium heterosporum* strain CNC-477 from driftwood in the Bahamas. From this, Fenical et al. reported two new related classes of cytotoxic sesterterpenes, the neomangicols A–C (**101**–**103**) (Renner et al. 1998) and the mangicols A–G (**104**–**110**) (Renner et al. 2000). Since the identification of these compounds, several syntheses assembling the novel mangicol core have been published (Araki et al. 2004; Chen et al. 2013; Ying and Pu 2014).

The examples shown demonstrate the multiplicity of different structures found produced by “driftwood fungi” but there are many other substrates in the sea that have still yet to be investigated, including volcanic pumice, metal, and even plastics that should be investigated in the search for novel chemistry and accompanying bioactivity (Fig. 18.4; Table 18.4).

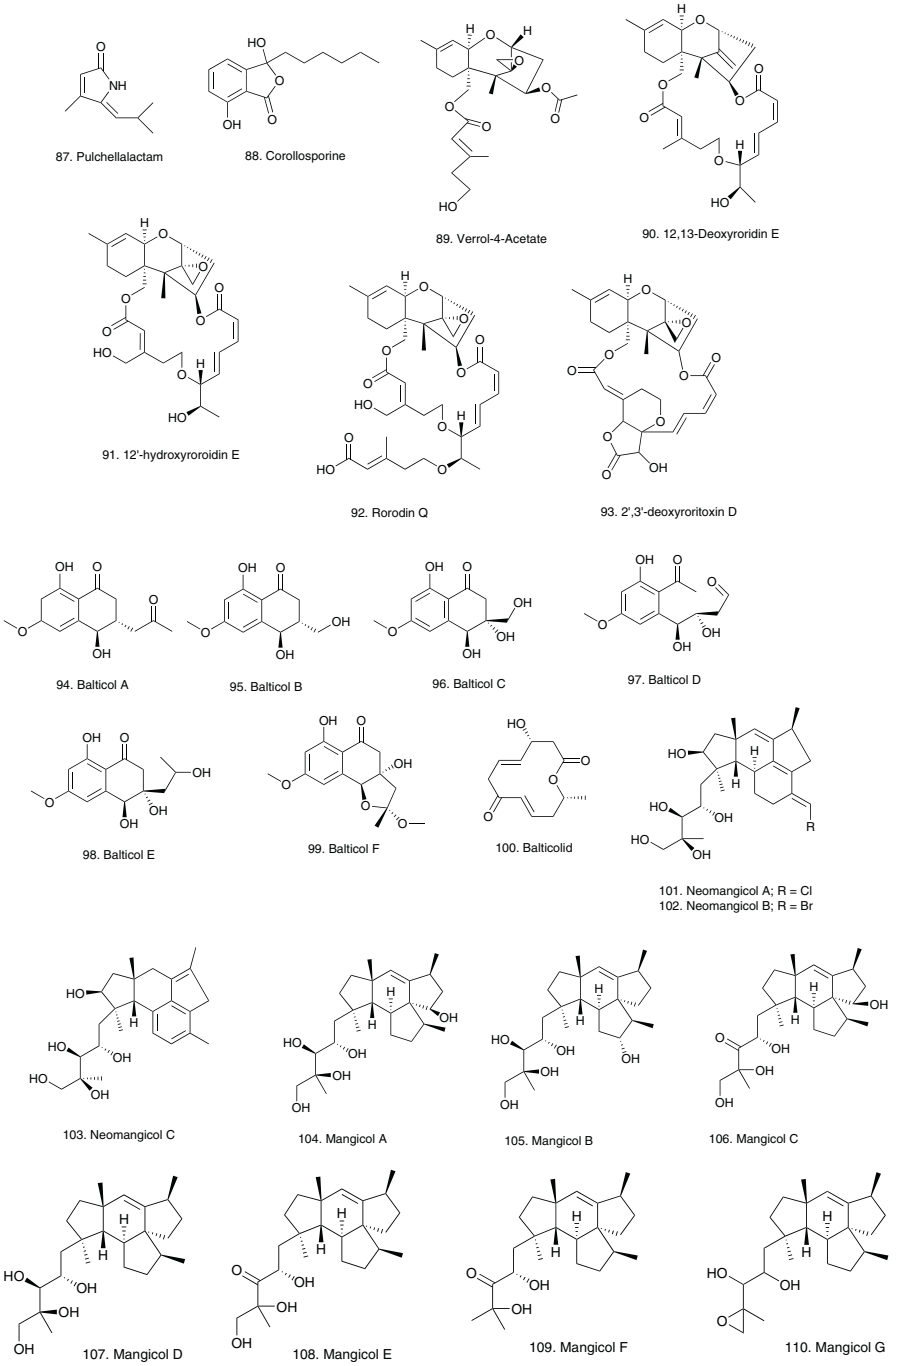

Fig. 18.4 Compounds **87–110**

Table 18.4 Biological activities of compounds **87–110**

Name	Source	#	Bioactivity
Pulchellalactam	*Corollospora pulchella* (ATCC 62554)	**87**	CD45 phosphatase inhibitor
Corollosporine	*Corollospora maritima*	**88**	Antibiotic activity against *S. aureus*
Verrol-4-acetate	*Acremonium neo-caledoniae*	**89**	Cytotoxic against KB cells
12,13-Deoxyroridin E	*Myrothecium roridum* TUF 98F42	**90**	Cytotoxic against L1210 and HL-60 cell lines
12′-Hydroxyroridin E	*Myrothecium roridum* TUF 98F42	**91**	Cytotoxic against L1210 cell line
Roridin Q	*Myrothecium roridum* TUF 98F42	**92**	Cytotoxic against L1210 cell line
2′,3′-Deoxyroritoxin D	*Myrothecium roridum* TUF 98F42	**93**	Antifungal (*S. cerevisiae*)
Balticol A	Ascomycete	**94**	Active against influenza A and HSV-1
Balticol B	Ascomycete	**95**	Active against influenza A and HSV-1
Balticol C	Ascomycete	**96**	Active against influenza A and HSV-1
Balticol D	Ascomycete	**97**	Active against influenza A and HSV-1
Balticol E	Ascomycete	**98**	Active against influenza A and HSV-1
Balticol F	Ascomycete	**99**	Active against influenza A and HSV-1
Balticolid	Ascomycete	**100**	Anti HSV-1
Neomangicol A	*Fusarium heterosporum* strain CNC-477	**101**	Cytotoxic MCF-7, H-60
Neomangicol B	*Fusarium heterosporum* strain CNC-477	**102**	Cytotoxic MCF-7, H-60; *B. subtilis* active
Neomangicol C	*Fusarium heterosporum* strain CNC-477	**103**	Potential decomposition product
Mangicol A	*Fusarium heterosporum* strain CNC-477	**104**	Cytotoxic in human lines; anti-inflammatory
Mangicol B	*Fusarium heterosporum* strain CNC-477	**105**	Cytotoxic in human lines; anti-inflammatory
Mangicol C	*Fusarium heterosporum* strain CNC-477	**106**	Cytotoxic in human tumor cell lines
Mangicol D	*Fusarium heterosporum* strain CNC-477	**107**	Cytotoxic in human tumor cell lines
Mangicol E	*Fusarium heterosporum* strain CNC-477	**108**	Cytotoxic in human tumor cell lines
Mangicol F	*Fusarium heterosporum* strain CNC-477	**108**	Cytotoxic in human tumor cell lines
Mangicol G	*Fusarium heterosporum* strain CNC-477	**110**	Cytotoxic in human tumor cell lines

18.3.6 Bioactive Compounds from Polar Marine Environments

The chemical diversity of polar regions is understudied due to a number of factors, including inaccessibility and the challenges faced when cultivating microbes from psychrophilic sources to obtain enough compound for biological evaluation. Yet, these regions could well be of extreme importance to the industrial and pharmaceutical industries, particularly for novel bioactive chemistry and psychrophilic enzymes (Tiquia and Mormile 2010). These environments have low to ultra-low surface temperatures, strong winds, limited nutrients, frequent freeze-thaw cycles, limited water access, high UV radiation, or combinations of these factors. The Arctic and Antarctic regions are surrounded by the Arctic and the Southern Oceans, respectively. The Arctic Ocean is a basin surrounded by continental land masses, whereas the Southern Ocean is a mixture of all of the world's oceans that surrounds a single isolated land mass. Thus, these polar oceans differ significantly based on their proximity to land and human populations.

Psychrophiles and psychrotolerant microbes have evolved modified gene regulatory systems and metabolic pathways for survival under extreme ecosystems. Fungi in particular play an essential role in this environment, functioning as decomposers, parasites, and mutualists. Fungi are commonly associated with large organisms, such as plants, macroalgae, their woody components, and animals, which are limited in polar environments. These organisms create protected microhabitats that help fungi survive harsh environmental conditions, with an example being the "Lichenosphere" as described by Santiago et al. (2015). Unique natural products have also been found, as organisms chemically adapt to these harsh conditions. For example, an increase in antibiotic activity was observed in the organic extracts of Arctic fungal cultures as the salt concentrations increased, though we should point out that these organisms originate from saline environments, including cold salterns (Sepcic et al. 2011).

The Arctic region is effectively a water basin with an ice covering, with the Arctic Ocean mostly surrounded by the United States (Alaska), Denmark (Greenland), Iceland, Norway, Russia, and Canada. Thus, land and the variable human population have a significant impact on this ocean. Permanent sea ice covers most of this region year-round and sea water temperatures vary from −1.9 °C in winter to 5 °C in summer, a wider temperature range than the Antarctic. These waters are highly stratified into three major water masses with the upper shallow layer being low-salinity layer and the intermediate layer being high-salinity layer with temperatures < 1.5 °C, and the deep salty layer has warmer Atlantic Ocean water (2–4 °C). Thus, the water columns and layers are quite different, and the microbial community is probably quite diverse. The shallow layer is typically frozen for most of the year; the intermediate layer receives water from the ocean inflow from the North Atlantic Current, as well as through the Bering Strait. This environment is strongly influenced by patterns of atmospheric and oceanic circulation that are driven by latitudinal temperature gradients, with seasonal depletion of nutrients.

Given these unique environments, a marine strain (KF970) belonging to the Lindgomycetaceae family, obtained during the 1991 expedition of RV Polarstern to the Greenland coast and the Arctic, was reported to produce the antimicrobial lindgomycin (**111**). Interestingly, another strain (LF327) isolated from a sponge *Halichondria panacea* collected from Kiel Fjord in the Baltic Sea (Germany) also produced the same compound (Wu et al. 2015). The Wu paper states twice that the original microbe (KF970) came from an Antarctic expedition by the Polarstern. From the cruise itinerary, the expedition was from Kiel to the East coast of Greenland and then to Jan Mayen Land, so it was an Arctic microbe. For more information on natural products from the Arctic in general, the publications coming out of the Marbio research group at the Arctic University of Norway are examples of what can be accomplished (Kristoffersen et al. 2018). Also, though they are entitled "from cold water," the two reviews by the Baker group at the University of South Florida, both include small sections on bacteria and fungi, are also indications of what can be found in these "extreme" ecosystems (Lebar et al. 2007; Soldatou and Baker 2017).

The Antarctic marine system is defined by the Southern Ocean, bounded by the Polar Frontal Zone and the frozen continent of Antarctica. Unlike the Arctic, no rivers discharge into the Southern Ocean and it is a major site for the formation of deep-water masses. The Southern Ocean has twice the oceanic surface of the Arctic Ocean, deep, narrow continental shelves, and thinner sea ice, which is expanding, unlike the disappearing ice in the Arctic (Hobbs et al. 2016; McBride et al. 2014). The ocean averages 3000–4000 m depth, to a maximum of 7236 m, with an area of 34.8 million km^2 wide (McBride et al. 2014; Waller et al. 2017). In the summer, a minimum of 7 million km^2 surface ice remains, with greater light exposure than that of the Arctic Ocean. Closer to the seafloor, Antarctic waters are warmer and higher in salinity, but the water column is not as stratified as that of the Arctic Ocean (Downey et al. 2012; Griffiths 2010). Salinity, not temperature, governs its stratification, and there is high nutrient availability. While both the Arctic and Southern Oceans have water temperatures close to freezing (~−1.9 °C), the Southern Ocean has less variation (0.5–1.5 °C) even in periods of limited ice covering, making this a more thermally stable environment than the Arctic, and in addition, oxygen levels in these waters (> 320 μmol/kg at 50 m) are higher than those of most regions (Orsi and Whitworth 2005).

A number of compounds have been reported from fungal sources isolated from Antarctic marine environments. Penilactones A and B (**112–113**) were reported from a deep sea sediment-derived *P. crustosum* PRB-2 (−526 m in Prydz Bay) (Wu et al. 2012). Their structures, which have opposite stereochemistry, were confirmed in a biomimetic synthesis published a year later (Spence and George 2013). Wu et al. later reported new sesquiterpenes from *Penicillium* sp. PR19N-1 isolated from Prydz Bay sediment (−1000 m) (Wu et al. 2013). These were 1-chloro-3β-acetoxy-7-hydroxy-trinoreremophil-1,6,9-trien-8-one (**114**) and three eremophilane-type sesquiterpenes (**115–117**). This fungal strain was later reported to produce five new eremophilane-type sesquiterpenes (**118–122**) and a new, rare lactam-type eremophilane (**123**) (Lin et al. 2014).

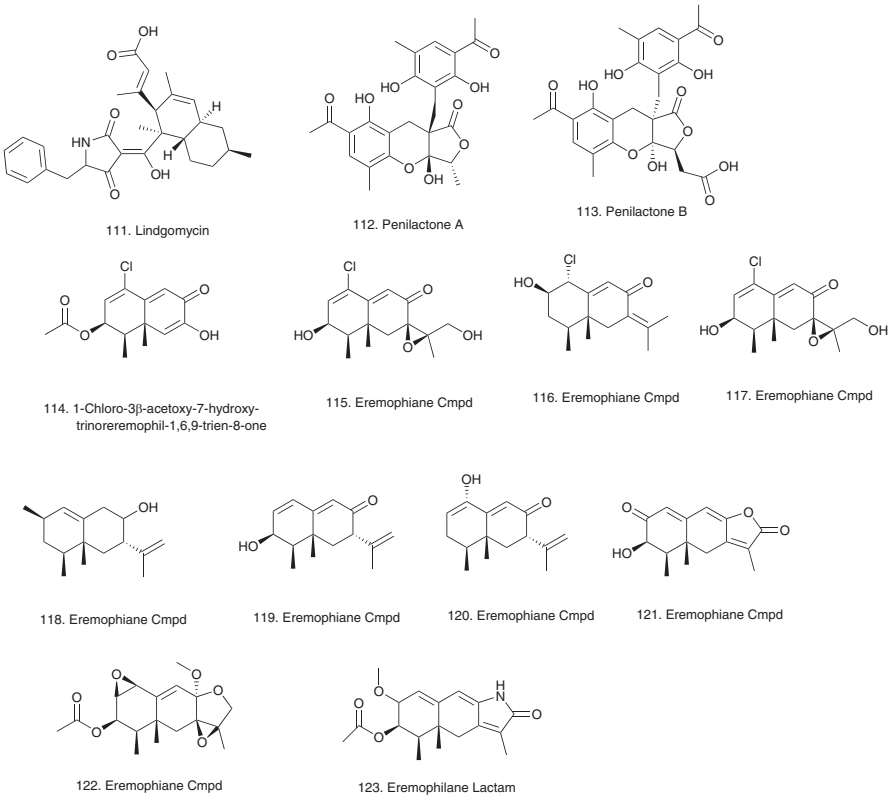

Fig. 18.5 Compounds **111–123**

Before it is too late, we hope to see more fungal products isolated from this area, which is undergoing significant anthropogenic climate change. Antarctica has more endemic species than the Arctic and, with increasing temperatures, will likely be a "hot spot" for species turnover, invasion, and extinction (Griffiths et al. 2017; Smith et al. 2017) (Fig. 18.5; Table 18.5).

18.4 Challenges and Strategies to Discovering Novel Bioactive Molecules from Extremophilic Marine Fungi

There are several reasons why more bioactive secondary metabolites have not been reported from marine fungi (Imhoff 2016). Fungi are morphologically diverse and there are no standardized procedures for their taxonomic identification, which is important for industrial and pharmaceutical applications. Molecular methods have been helpful when there is complete small subunit ribosomal sequence data. Yet, other than sequencing regions of internal transcribed spacers (e.g., ITS1–ITS2)

Table 18.5 Biological activities of compounds **111–123**

Name	Source	#	Bioactivity
Lindgomycin	Lindgomycetaceae family	**111**	Antimicrobial activity
Penilactone A	*P. crustosum* PRB-2	**112**	Weak NF-κB inhibitor
Penilactone B	*P. crustosum* PRB-2	**113**	No bioactivity reported
1-Chloro-3β-acetoxy-7-hydroxy-trinoreremophil-1,6,9-trien-8-one	*Penicillium* sp. PR19N-1	**114**	Cytotoxic; HL-60 and A-549 cell lines
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**115**	No bioactivity reported
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**116**	No bioactivity reported
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**117**	No bioactivity reported
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**118**	Cytotoxic; HL-60 and A-549 cell lines
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**119**	No bioactivity reported
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**120**	No bioactivity reported
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**121**	No bioactivity reported
Eremophilane-type sesquiterpene	*Penicillium* sp. PR19N-1	**122**	Cytotoxic; HL-60 and A-549 cell lines
Lactam-type ereophilane	*Penicillium* sp. PR19N-1	**123**	No bioactivity reported

or both ribosomal RNA and protein-coding genes, a species assignment can be unclear when there are no complete ribosomal sequences or verified reference databases. Some researchers use morphology and molecular data to identify a fungal species since the morphological plasticity caused by environmental cues, such as light and temperature, can lead to species exhibiting similar morphotypes. Yet, only a small fraction of marine fungi has been identified on a species level. Morphotypes can be misleading due to hybridization, cryptic speciation, and convergent evolution (Raja et al. 2017). To avoid confusion, post December 31, 2012, a fungus is now only given one name regardless of the stages in its life cycle, and as a result all fungal nomenclature prior to 2013 has to be reconsidered, further confusing taxonomic identification, and leading to problems when the natural products chemistry community attempts to rationalize compound sources. This can lead to the same compound being considered as novel, when in fact it, or close chemical relatives, was reported from terrestrial sources, further compounding the problems involved.

To increase the discovery of more fungal natural products from marine environments, we need high-throughput analytical methods to chemically profile fungal extracts in parallel. To screen numerous isolates, high-throughput metabolomic workflows using liquid chromatography and mass spectrometry have been designed, but they generate large amounts of data. These workflows have even started to incorporate different variables, such as time, genus, and species. While molecular networking sorts through these data to highlight new chemical scaffolds, scientists could also be more targeted in the search for chemical diversity by correlating environment with chemodiversity. More studies are using mass spectrometry to obtain molecular profiles over environmental gradients revealing chemodiverse and phylogenetic "hot spots" (Li et al. 2018; Luzzatto-Knaan et al. 2017). The integration of chemical and spatial data sets have led to the discovery of new metabolites

(Luzzatto-Knaan et al. 2017), and could be extremely useful when looking at fungi in different marine environments. It is all about *location, location, location*. Apparently, environmental factors, such as depth oxygen and nitrate, correlate with the composition of marine fungal communities and explain more variance than geographic distance (Tisthammer et al. 2016). These factors have a 4-dimensional space (season/time, longitudinal and latitudinal dimensions, and depth), and their variation could reveal unique chemical scaffolds. With the explosion of fungal genomes (approximately 8175 organisms sequenced according to the Genomes Online Database in August 2018), we should be able to also connect molecular and geographical information to genomic data (Mukherjee et al. 2017), enabling us to target new fungi instead of continuously isolating the dominant *Penicillium* and *Aspergillus* isolates.

These chemical programs also have to be linked to functional screens for bioactivity rather than a few random screens (those available to the chemist), and bioactivity-driven isolation programs are also required to identify fungal metabolomes of interest. Over 10,000 marine fungal species have been identified, but less than a quarter of those species have been explored for bioactive metabolites.

We also need to target both plentiful and rarer marine fungi, using single-cell genomic sequencing and metagenomic and metatranscriptomic sequencing primers that target the most variable regions of the ribosomal RNA gene. This way, publications are not always on the "easy-to-culture" *Penicillium*, *Aspergillus*, *Fusarium*, and *Cladosporium* strains, and we have a more balanced representation of other genera. Importantly, in order to develop systematic methods, the mycologists, ecologists, and natural products research community need to work together. For more information on how natural products chemists and ecologists can share language, resources, and information, one should consult the excellent 2017 review by Reich and Labes (2017).

18.5 Conclusions

Marine natural products are some of the most complex, structurally diverse molecules in chemical space, as they are influenced by their surrounding ecology. Over the last 30 years, there has been an explosion in the number of reports of bioactive compounds from marine fungi due to improved methods for sampling, cultivation, and identification. Examples can be seen in the annual reviews published in Natural Product Reports, initially by Faulkner and then by Blunt et al. (2018).

Due to the limited screening and the sheer time and money required to develop a lead compound, the increase in reports of novel active agents will not become "drug candidates" for a significant number of years. The bottleneck in such programs is the problem of producing enough of a bioactive agent to move through structural characterization and screens to initially develop a viable preclinical candidate. This may well require significant investment in synthetic chemistry as well as large-scale fermentation of precursors. The scientific community, including ecologists, marine

mycologists, and (bio)chemists, also needs to come together and decide on how to taxonomically identify fungi. Improved communication will lead to more impactful genomic, metabolomic, bioactivity, and geographic data. Nevertheless, we are hopeful because scientists are now forming fruitful collaborations across disciplines, and there are more research programs centered around marine natural products, from fungi, isolated from both "regular and extreme environments."

Chapter 19
Synthesis of Metallic Nanoparticles by Halotolerant Fungi

Sonia M. Tiquia-Arashiro

19.1 Introduction

Halotolerance is the adaptation of living organisms to conditions of high salinity. Halotolerant organisms tend to live in hypersaline environments, along with halophilic organisms. However, they are different from halophilic organisms in that they do not require elevated concentrations of salt to grow. Microbial diversity studies of hypersaline environments including saltern ponds worldwide (Gunde-Cimerman et al. 2000; Butinar et al. 2005; Diaz-Munoz and Montalvo-Rodriguez 2005; Cantrell et al. 2006; Nayak et al. 2012), the Great Salt Lake (Baxter et al. 2005), the Dead Sea (Buchalo et al. 1998; Kis-Papo et al. 2003a, b; Wasser et al. 2003; Bodaker et al. 2010; Nazareth et al. 2012), saline lakes in Inner Mongolia (Pagaling et al. 2009), African soda lakes (Jones and Grant 1999), deep-sea brines (van der Wielen et al. 2005), salt pans or salt marshes (Setati 2010), Mono Lake in California (Steiman et al. 2004), coastal environments of Arctics (Gunde-Cimerman et al. 2005), saline soils of Soos in the Czech Republic (Hujslova et al. 2010), and many others have led to the isolation of halophiles and halotolerant microorganisms.

Fungi hypersaline environments are mostly halotolerant (Gunde-Cimerman et al. 2009; Zajc et al. 2012) rather than halophilic. Thus, they constitute a relatively large and constant part of hypersaline environment communities. Well-studied examples include the yeast *Debaryomyces hansenii* and black yeasts *Aureobasidium pullulans* (Gunde-Cimerman et al. 2009). Surprisingly, more and more cases are being reported of the isolation of halophilic and halotolerant microorganisms from low-salinity environments (Abdel-Hafez et al. 1978; Tiquia et al. 2007; Gunde-Cimerman et al. 2009; Tiquia 2010; Gonsalves et al. 2012). Halophilic and halotolerant fungi

S. M. Tiquia-Arashiro (✉)
Department of Natural Sciences, University of Michigan-Dearborn, Dearborn, MI, USA
e-mail: smtiquia@umich.edu

S. M. Tiquia-Arashiro, M. Grube (eds.), *Fungi in Extreme Environments: Ecological Role and Biotechnological Significance*,
https://doi.org/10.1007/978-3-030-19030-9_19

are often found in unexpected environments such as domestic dishwashers and polar ice, and even on spider webs in desert caves (Gunde-Cimerman et al. 2009).

Halotolerant fungi represent a versatile reservoir of bioactive metabolites and potential source of halotolerant genes that could be used in biotechnology (Tiquia 2010; Tiquia and Mormile 2010). They are a valuable resource of enzymes and other metabolites with stability in harsh conditions of pH, temperature, and/or ionic strength (Margesin and Schinner 2001; Oren 2010). Hence, their use as biocatalysts in the presence of novel nanomaterials is attractive. Combining these bioactive molecules with various nanomaterials like thin layers, nanotubes, and nanospheres results in novel compounds harboring both biological properties of biomolecules and physicochemical characteristics of nanomaterials. While the biosynthesis of nanoparticles in bacteria is well understood (Rai et al. 2012), very few fungal (halotolerant) species have been investigated so far for nanoparticle biosynthesis. In general, the microbiology of fungi is much less investigated, mainly because fungi are difficult to characterize, as their structure complicates the microscopic and mechanistic studies that are required for nanoparticle characterization in it. However, fungi may have some advantages over bacteria for bioprocess, including nanoparticle biosynthesis. Fungi also harbor untapped biological diversity and may provide novel metal reductases for metal detoxification and bioreduction. This review focuses on halotolerant fungi that have been exploited for nanomaterial synthesis; the mechanisms in the nanomaterial fabrication; and possible applications.

19.2 Synthesis of Nanoparticles by Halotolerant Fungi

Reports on nanoparticle synthesis by halotolerant fungi are mostly confined to metallic nanoparticles. These halotolerant fungi capable of synthesizing metallic nanoparticles include *Penicillium fellutatum* (Kathiresan et al. 2009); *Aspergillus niger* (Kathiresan et al. 2009); *Pichia capsulata* (Manivannan et al. 2010); *Yarrowia lipolytica* (Bankar et al. 2009; Pawar et al. 2012); *Rhodosporidium diobovatum* (Seshadri et al. 2011); *Schizosaccharomyces pombe* (Kowshik et al. 2002a, b); *Thraustochytrium* sp. (Asmathunisha and Kathiresan 2013); *Schwanniomyces occidentalis* (Mohite et al. 2016); and *Williopsis saturnus* (Mohite et al. 2017).

Metallic nanoparticles have fascinated scientists for over a century and are now heavily utilized in biomedical sciences and engineering. They are a focus of interest because of their huge potential in nanotechnology (Tiquia-Arashiro and Rodrigues 2016a). Metallic nanoparticles have possible applications in diverse areas such as electronics, cosmetics, coatings, packaging, and biotechnology (Tiquia-Arashiro and Rodrigues 2016b, c). For example, nanoparticles can be induced to merge into a solid at relatively lower temperatures, often without melting, leading to improved and easy-to-create coatings for electronics applications. Typically, nanoparticles possess a wavelength below the critical wavelength of light. This renders them transparent, a property that makes them very useful for applications in cosmetics, coatings, and packaging. Metallic nanoparticles can also be attached to single

strands of DNA nondestructively, which opens avenues for medical diagnostic applications (Tiquia-Arashiro and Rodrigues 2016c).

19.2.1 Synthesis of Gold (Au) Nanoparticles

Gold nanoparticles (AuNPs) have attracted attention in biotechnology due to their unique optical and electrical properties, high chemical and thermal ability, and good biocompatibility and potential applications in various life sciences-related applications including biosensing, bioimaging, and drug delivery for cancer diagnosis and therapy (Jiang et al. 2013). Covalently modified gold nanoparticles have attracted a great deal of interest as a drug delivery vehicle. Their predictable and reliable surface modification chemistry, usually through gold-thiol binding, makes the desired functionalization of nanoparticles quite possible and accurate. Recently, many advancements have been made in biomedical applications of AuNPs with better biocompatibility in disease diagnosis and therapeutics (Tiquia-Arashiro and Rodrigues 2016b). AuNPs can be prepared and conjugated with many functionalizing agents, such as polymers, surfactants, ligands, dendrimers, drugs, DNA, RNA, proteins, peptides, or oligonucleotides. Overall, AuNPs is a promising vehicle for drug delivery and therapies.

Yarrowia lipolytica, a halotolerant yeast (Gunde-Cimerman and Zalar 2014), is known to synthesize AuNPs (Apte et al. 2013a; Nair et al. 2013; Tiquia-Arashiro and Rodrigues 2016d). Melanin (a dark-colored pigment from this yeast) plays an important role in its ability to synthesize nanoparticles. Since the inherent content of melanin in *Y. lipolytica* is low, the yeast is induced to overproduce melanin by incubation with a precursor, L-3,4-dihydroxyphenylalanine (L-DOPA). This process mediates the rapid formation of AuNPs. The AuNPs display antibiofilm activity against pathogenic bacteria (Apte et al. 2013a). They also display effective antifungal properties (Apte et al. 2013b). In addition to AuNPs, some strains of *Y. lipolytica* (e.g., *Y. lipolytica* NCIM 3589) can also synthesize CdO and CdS nanostructures in a cell-associated and extracellular manner (Pawar et al. 2012).

19.2.2 Synthesis of Silver (Ag) Nanoparticles

Silver nanoparticles (AgNPs) are already being commercially used as antimicrobial agents. For example, silver NPs are currently found in surgically implanted catheters to reduce the infections caused during surgery, in toys, personal care products, and silverware. The reason for using silver for antimicrobial applications is because silver possesses antifungal, antibacterial, anti-inflammatory, and anticancer effects (Li et al. 2010, 2014; Chernousova and Epple 2013; Tiquia-Arashiro and Rodrigues 2016c; Zhang et al. 2016).

The halotolerant fungus *Penicillium fellutanum* (De Hoog et al. 2005) can produce AgNPs at a faster rate by extracellular means (Kathiresan et al. 2009). Silver nanoparticles are synthesized within 10 min of silver ions being exposed to the *P. fellutanum* culture filtrate. The increase in color intensity of culture filtrate corresponds to the increase in number of nanoparticles formed by reduction of silver ions (Wang et al. 2009). The AgNPs obtained from this assay has a good monodispersity, with maximum synthesis occurring at pH 6.0, temperature of 5 °C, 24 h of incubation time, and silver nitrate concentration of 1 mM and 0.3% NaCl. Most of the AgNPs generated by *P. fellutanum* are spherical in shape with size ranging from 5 to 25 nm. In this study, the enzyme nitrate reductase is secreted by the *P. fellutanum* biomass and is involved in the reduction of the silver ions (Wang et al. 2009).

Other halotolerant fungi capable of synthesizing AgNPs include *Pichia capsulata* (Manivannan et al. 2010), *Aspergillus niger* (Zomorodian et al. 2016), *Yarowinia lipotyca* (Bankar et al. 2009), *Thraustochytrium* sp. (Asmathunisha and Kathiresan 2013), and *Schwanniomyces occidentalis* (Mohite et al. 2016).

19.2.3 Synthesis of Cadmium Sulfide (CdS) Nanoparticles

Cadmium sulfide (CdS) is a II–VI semiconductor which has been synthesized by microorganisms (Prasad and Jha 2010; Kowshik et al. 2002a). It is insoluble in water but soluble in dilute mineral acids. CdS has a bandgap energy of 2.42 eV (Zhang et al. 2007), at room temperature, and it shows great potential for uses in photochemical catalysis, solar cells, nonlinear optical materials, and various luminescence devices (Ma et al. 2007; Tiquia-Arashiro and Rodrigues 2016c). CdS nanocrystals have generated great interest due to their unique size-dependent chemical and physical properties (Zhao et al. 2006). Thus, extensive research has focused on the synthesis of various CdS nanostructures. In the classical studies by Dameron et al. (1989), it was shown that the halotolerant yeasts *Schizosaccharomyces pombe* can produce of CdS nanocrystallites when challenged with cadmium in solution. Short chelating peptides of general structure (γ-Glu-Cys)*n*-Gly control the nucleation and growth of CdS crystallites to peptide-capped intracellular particles of diameter 20 Å. These quantum CdS crystallites are more monodisperse than CdS particles synthesized chemically. X-ray data indicate that, at this small size, the CdS structure differs from that of bulk CdS and tends towards a six-coordinate rock-salt structure (Dameron et al. 1989).

19.2.4 Synthesis of Lead Sulfide (PbS) Nanoparticles

Semiconductor PbS nanoparticles have attracted great attention in recent decades because of their interesting optical and electronic properties (Bai and Zhang 2009). *Rhodospiridium diobovatum* synthesizes PbS nanoparticles intracellularly with the help of nonprotein thiols (Seshadri et al. 2011). The nanoparticles are in the range

of 2–5 nm. Elemental analysis by energy dispersive X-ray (EDAX) reveals that the particles are composed of lead and sulfur in a 1:2 ratio, and that they are capped by a sulfur-rich peptide. Quantitative study of lead uptake through atomic absorption spectrometry reveals that 55% of lead in the medium accumulated in the exponential phase, whereas a further 35% accumulated in the stationary phase; thus, the overall recovery of PbS nanoparticles is 90%. The lead-exposed *R. diobovatum* displayed a marked increase (280% over the control) in nonprotein thiols in the stationary phase. A sulfur-rich peptide is suggested to be the capping agent. In the presence of lead, *R. diobovatum* produces increasing amount of nonprotein thiols during the stationary phase, which are possibly involved in forming the nanoparticles (Seshadri et al. 2011). *Schizosaccharomyces pombe* is another halotolerant fungus capable of synthesizing PbS nanoparticles (Kowshik et al. 2002b).

19.2.5 Synthesis of Zinc Oxide (ZnO) Nanoparticles

Zinc oxide (ZnO) NPs have unique optical and electrical properties. As a wide bandgap semiconductor, they have found more uses in biosensors, nanoelectronics, and solar cells. These NPs are being used in the cosmetic and sunscreen industry due to their transparency and ability to reflect, scatter, and absorb UV radiation and as food additives. Furthermore, zinc oxide NPs are also being considered for use in next-generation biological applications including antimicrobial agents, drug delivery, and bioimaging probes (Jayaseelan et al. 2012). The potential ability of the halotolerant fungi *Pichia kudriavzevii* (Cai et al. 2014) in the synthesis of zinc oxide nanoparticles (ZnO-NPs) was explored recently (Boroumand Moghaddam et al. 2017). The ZnO nanoparticles synthesized by *P. kudriavzevii* possess hexagonal wurtzite structure with an average crystallite size of ~10–61 nm. They are less toxic and displayed antioxidant and antibacterial activities and show strong 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical effect with a dose-dependent activity. The synthesized ZnO nanoparticles also displayed antibacterial activity against both Gram-positive (*Staphylococcus aureus*, *Bacillus subtilis*, and *Staphylococcus epidermidis*) and Gram-negative (*Escherichia coli* and *Serratia marcescens*) bacteria.

19.3 Nanoparticle Formation Mechanisms in Fungi

The nanoparticles are produced either intracellularly or extracellularly. In case of intracellular synthesis, the nanoparticles are produced inside the cells by the reductive pathways. The synthesis occurs when the metal (e.g., Au^{3+}) concentration available is high and when the membrane integrity is compromised to allow for metal ion diffusion within the cell. In extracellular synthesis, the nanoparticles are produced extracellularly when the cell wall reductive enzymes or soluble secreted

enzymes are extracted outside the cell and are involved in the reductive process of metal ions. The extracellular biosynthesis of metallic nanoparticles is similar to the enzymatic machinery required for metal detoxification. Overall, nanoparticle biosynthesis is essentially a reduction process followed by a stabilization step (capping). There is no evidence available yet showing that fungi use biosynthetic nanoparticles for their metabolism. The biosynthesis of metal NPs by fungi is a function of heavy metal toxicity resistance mechanisms, whereby toxic metals are converted to nontoxic species and precipitated as metal clusters of nanoscale dimension and defined shape (Narayanan and Sakthivel 2010). Resistance mechanisms include redox enzymes that convert toxic metal ions to inert forms, structural proteins that bind protein. It is proposed that such mechanism works to coordinate synthesis.

One of the enzymes involved in the biosynthesis of metal nanoparticles is the nitrate reductase which reduces the metal ions (Me^{1+}) to the metallic form (Me^{0}). This enzyme is a NADH- and NADPH-dependent enzyme. Some fungi are known to secrete cofactor NADH- and NADH-dependent enzymes that can be responsible for the biological reduction of Me^{1+} to Me^{0} and the subsequent formation of nanoparticles. This reduction is initiated by electron transfer from the NADH by NADH-dependent reductase as electron carrier during which the metal ions gain electrons and are therefore reduced to Me^{0}. Synthesis of silver nanoparticles using α-NADPH-dependent nitrate reductase and phytochelatin in vitro has been demonstrated by Anil Kumar et al. (2007). The silver ions are reduced in the presence of nitrate reductase, leading to the formation of a stable silver hydrosol 10–25 nm in diameter and stabilized by the capping peptide. Nitrate reductase is suggested to initiate nanoparticle formation by many fungi including *Penicillium* species, while several enzymes, α-NADPH-dependent reductases, nitrate-dependent reductases, and an extracellular shuttle quinone, are implicated in silver NP synthesis for *Fusarium oxysporum*. Jain et al. (2011) indicated that silver NP synthesis for *Aspergillus flavus* occurs initially by a 33 kDa protein followed by a protein (cystein and free amine groups) electrostatic attraction which stabilizes the nanoparticle by forming a capping agent (Soni and Prakash 2011). Several researchers supported nitrate reductase for extracellular synthesis of metallic NPs (Vigneshwaran et al. 2006; Wang et al. 2009; Deepa and Panda 2014; Siddiqi and Husen 2016; Boroumand Moghaddam et al. 2017).

Cadmium sulfide nanoparticle synthesis by yeast involves sequestration of Cd^{2+} by glutathione-related peptides followed by reduction within the cell. Ahmad et al. (2002) reported that cadmium sulfide nanoparticle synthesis by *Fusarium oxysporum* was based on a sulfate reductase (enzyme) process. The nanoparticle formation proceeds by release of sulfate reductase enzymes by *F. oxysporum*, conversion of sulfate ions to sulfide ions that subsequently react with aqueous Cd^{2+} ions to yield highly stable CdS nanoparticles. While the reduction of sulfate to sulfite is known in sulfate-reducing bacteria (which are strictly anaerobic), this is the first report on the secretion of sulfate-reducing enzymes by a fungus. The extracellular synthesis of AgNP by *P. chrysosporium* is attributed to laccase, while intracellular gold nanoparticle synthesis was attributed to ligninase (Sanghi et al. 2011).

Fungi have several advantages over bacteria for NP biosynthesis. They secrete larger amounts of extracellular proteins with diverse functions. The so-called secretome in fungi include all the secreted proteins into the extracellular space (Girard et al. 2013). The high concentration of the fungal secretome has been used for industrial production of homologous and heterologous proteins. For instance, the expression of a functionally active class I fungal hydrophobin from the entomopathogenic fungus *Beauveria bassiana* has been reported (Kirkland and Keyhani 2011). The tripeptide glutathione is a well-known reducing agent involved in metal reduction and is known to participate in cadmium sulfide (CdS) biosynthesis in yeasts and fungi (Chen et al. 2009). However, the knowledge of the fungal secretome is still largely underexplored especially for halophilic and halotolerant fungi. The large and relatively unexplored fungal secretome is an advantage because of the role of extracellular proteins and enzymes it generates have in metal reduction and nanoparticle synthesis.

19.4 Potential Applications

Bionanoparticles have found uses in biomedical and environmental fields. In the biomedical field, these nanoparticles have been investigated for antimicrobial applications (Sondi and Salopek-Sondi 2004), biosensing (Yu et al. 2003; Mckindles and Tiquia-Arashiro 2012; Tiquia-Arashiro 2012), imaging (Boisselier and Astruc 2009), and drug delivery (Muller et al. 2013). In the environmental field, nanoparticles have been investigated for applications in bioremediation of diverse contaminants (Srivastava et al. 2012; Tiquia-Arashiro and Rodrigues 2016c), water treatment (Ma et al. 2012; Yu et al. 2013), improving plant resistance (McKnight et al. 2003; Rai et al. 2012), and production of clean energy (Wan et al. 2015; Tiquia-Arashiro and Rodrigues 2016c). Overall, bionanoparticles have attracted the attention of diverse researchers because their synthesis is more environmentally friendly and produces more homogeneously distributed nanoparticles, and some of them can be easily biodegradable. Although there are several studies investigating the application of fungal-based nanoparticles, they are still way less studied than bacterial-based nanoparticles. Researchers are still identifying the microbiological synthetic pathways of these bionanoparticles. It is expected that with the advancement of the understanding of bionanoparticle synthesis pathways, the application of bionanoparticles will expand to many more fields than biomedical and environmental and they will be potentially applied in diverse nanotechnological industries.

19.5 Conclusions and Future Perspectives

The interest for bionanoparticles has increased in the past years because they present very different properties and functions than synthetic nanoparticles and they tend to be more biocompatible than their inorganic nonbiological counterparts. The

"green" method for nanoparticle synthesis, which is rapidly replacing traditional chemical syntheses, is of great interest because of eco-friendliness, economic views, feasibility, and wide range of applications in several areas such as nanomedicine and catalysis medicine. The most obvious disadvantages of biological nanoparticles (BNP) are that they frequently do not withstand high or low temperatures, extreme pH values, high salt concentrations, presence of harsh chemicals and potential environmental conditions that could lead to their hydrolysis (Tiquia-Arashiro and Rodrigues 2016e, f). It is possible, however, that BNPs from extremophiles or extremotolerant microorganisms might overcome these issues. While a variety of prokaryotic and eukaryotic microorganisms have been investigated with respect to their nanoparticle synthetic abilities, the vast biodiversity encountered in the fungal halophilic/halotolerant world has been relatively less explored. Furthermore, most of the studies are related to the synthesis of silver nanoparticles, followed by those of gold and less on cadmium, lead, and zinc. One reason for this could be the relative ease with which the noble metal ions of gold and silver are reduced. Currently, there are no reports on synthesis of nanoparticles of platinum, bismuth, antimony sulfide, and titanium oxide by halotolerant fungi. As summarized in this review, biologically active products from halotolerant fungi represent excellent scaffolds for this purpose. However, there is a need to understand the mechanisms involved in the synthetic process. Another limitation of the studies is that the experiments have been conducted at laboratory scale and there are hardly any efforts for the scale-up of these processes. In the future, these shortcomings need to be addressed in an effective manner to harness the actual nanoparticle synthetic potential of the halotolerant to their full extent.

Chapter 20
Cellulases from Thermophilic Fungi: Recent Insights and Biotechnological Potential

Duo-Chuan Li and Anastassios C. Papageorgiou

20.1 Introduction

Cellulose accounts for 20–50% in dry weight of the plant cell wall material and is the most abundant and renewable nonfossil carbon source on Earth. Enzymatic hydrolysis of cellulose to its constituent monosaccharides has attracted considerable attention in recent years for the production of food and biofuels. Compared to current industrial processes such as heat, mechanical, and acid treatment of cellulose, cellulose degradation by enzymes is considered a more environment-friendly process (Wilson 2009; Plecha et al. 2013). However, cellulose is the most recalcitrant carbohydrate polymer to enzymatic degradation amongst all polysaccharides of the plant cell wall. The enzymatic degradation of cellulose to glucose requires the synergistic action of endocellulases (E.C.3.1.1.4), exocellulases (cellobiohydrolases, CBH, E.C.3.2.1.91), and β-glucosidases (E.C.3.2.1.21). Endoglucanases initiate hydrolysis by cutting internal glycosidic linkages in a random fashion, which results in a rapid decrease of polymer length and a gradual increase in the reducing sugar concentration. Exocellulases act upon either the reducing or the nonreducing ends to release cello-oligosaccharides and cellobiose units. At the end, β-glucosidases cleave cellobiose to release glucose molecules (Vlasenko et al. 2010).

Thermophilic cellulases have become key enzymes for efficient biomass degradation. Their importance stems from the fact that at higher temperatures, cellulose swells and becomes more susceptible to breaking. Thermophilic fungi have received significant attention in the past years as a reservoir of new thermostable enzymes for

use in many biotechnological applications (de Cassia Pereira et al. 2015). Thermophilic fungi grow at a temperature of 50 °C or above, and at a minimum of 20 °C or above (Maheshwari et al. 2000). A number of thermophilic fungi have been isolated in recent years, and the cellulases they produce have been characterized at structural and functional level. Recently, the genomes of *Myceliophthora thermophila* and *Thielavia terrestris* were sequenced and revealed high efficiency of their enzymes to hydrolyze all major polysaccharides found in biomass (Berka et al. 2011). In this review, up-to-date information on molecular, genetic, engineering, and structure-function aspects of thermophilic fungal cellulases is presented for the first time and current research efforts to improve their properties for better use in biotechnological applications are highlighted.

20.2 Cloning, Expression, and Regulation

20.2.1 Regulation of Expression

Production of fungal cellulases is commonly induced only in the presence of cellulose as a substrate (Suto and Tomita 2001). However, owing to its insolubility, cellulose is unable to trigger cellulase induction directly. Thus, constitutive cellulase activity at a basal level is required for cellulase induction. Various disaccharides, such as cellobiose, lactose, and sophorose, have been found to strongly induce cellulase expression (Vaheri et al. 1979). A mechanism of self-synthesized cellobiose from uridine diphosphate glucose cellobiose synthetase was recently reported in the cellulolytic fungus *Rhizopus stolonifer* (Zhang et al. 2017). The synthesized cellobiose was able to promote the transcription of cellulase genes. Recently, xylose was also reported to induce cellulase expression in the thermophilic fungus *Thermoascus aurantiacus* (Schuerg et al. 2017).

The cellulase gene expression in fungi has been proposed to be controlled by a repressor/inducer system (Suto and Tomita 2001). In this system, cellulose or other products of degradation act as inducers, whereas glucose or other easily metabolized carbon sources act as repressors. The repressor/inducer system has also been described in thermophilic fungal cellulases (Maheshwari et al. 2000). In the thermophilic fungus *Talaromyces emersonii*, expression of a cellobiohydrolase gene (*cbh2*) was found to be induced by cellulose and repressed by glucose (Murray et al. 2003). Similar regulation patterns are also exhibited by other cellulase genes from thermophilic fungi, such as *T. emersonii cel7* (Grassick et al. 2004), *Humicola grisea* var. *thermoidea cbh* (Pocas-Fonseca et al. 2000), *T. emersonii bg1* (Collins et al. 2007), and *T. aurantiacus cbh1/cel7a* (Benko et al. 2007).

Glucose repression is a common phenomenon in the regulation of fungal cellulase genes and involves the upstream regulatory sequence (URS) (Furukawa et al. 2009; Ilmen et al. 1997). The protein product of the regulatory gene *cre1* in *Trichoderma reesei* is a negatively acting transcription factor that binds to DNA

consensus sequence SYGGRG (where S = C or G, Y = C or T, R = A or G) in the URS. In the presence of glucose, the activated CRE1 (a Cys_2His_2 zinc finger protein) binds to the consensus motif and represses cellulase gene transcription (Ilmen et al. 1997; Nakari-Setälä et al. 2009). Modification of *cre1* gene expression by RNA interference has been suggested for the improvement of cellulase expression (Yang et al. 2015). Three new transcription factors (ACEI, ACEII, and XYR1) involved in cellulase gene regulation have been identified in the mesophilic fungus *T. reesei* (Silva-Rocha et al. 2014). ACEI represses expression of all major cellulase genes in the presence of cellulose. ACEII binds to GGSTAAA sequences in the promoter regions of *cbh1* and *cbh2* and induces expression of *cbh1* and *cbh2*. XYR1 is a zinc binuclear cluster protein that binds to a GGCTAA motif in the 5′-upstream region of XYR1-regulated genes and is involved in the induction of all major cellulase genes. Unlike the transcription factors of *T. reesei* cellulase genes, transcription factors of cellulase genes in thermophilic fungi have not been identified so far. However, there are potential binding sites in the 5′-upstream region of these genes (Collins et al. 2007; Hong et al. 2003a; Murray et al. 2003, 2004; Takashima et al. 1996), and CREI genes from two thermophilic fungi (*Talaromyces emersonii* and *T. aurantiacus*) have been cloned (GenBank AF440004 and AY604200, respectively). It is, therefore, likely that cellulase regulation in thermophilic fungi is similar to that in *T. reesei*.

20.2.2 Gene Cloning

About 50 genes encoding thermophilic fungal cellulases have been isolated, analyzed, and expressed. A brief summary is given in Table 20.1. Cellulases are classified into glycoside hydrolase (GH) families 1, 3, 5, 6, 7, 8, 9, 12, 26, 44, 45, 48, and 61 (http://www.cazy.org). Thermophilic fungal cellulases are found in families 1, 3, 5, 6, 7, 12, 45, and 61. GH61 family members are now recognized as Cu(II) ion-dependent lytic polysaccharide monooxygenases (LPMOs) and are included in auxiliary activity families of the CAZy database (Busk and Lange 2015).

The entire sequence of genes encoding thermophilic fungal cellulase contains an open reading frame (ORF) usually interrupted by introns with consensus 5′ and 3′ intron splice sites, a 3′ untranslated sequence (UTS), a 5′ UTS, and a URS or upstream regulatory region (URR). In the URS of thermophilic fungal cellulases, CAAT and TATAA boxes are present. In particular, some sequences involved in the regulation of cellulase expression are found in the URS of thermophilic fungal cellulases, including the consensus motifs (SYGGRG) for CREI/CREA binding, a consensus sequence (GCCARG) for the putative pH-response transcription factor PacC (Murray et al. 2003), and one or more copies of cellulase expression regulator (ACEI, ACEII, and XYR1) binding sites AGGCAAA, GGSTAAA, and GGCATT (Collins et al. 2007; Hong et al. 2003a; Takashima et al. 1996). In addition, putative glycosylation sites (Asn-X-Thr/Ser) in most of the deduced amino acid sequences of thermophilic fungal cellulases have been identified (Collins et al. 2007; Li et al. 2009).

NR=not reported

20.2.3 Heterologous Expression

Most cloned cellulase genes of thermophilic fungi are well expressed in heterologous host organisms, such as *E. coli*, yeast, and filamentous fungi (Table 20.1). The majority of the recombinant cellulases expressed in yeast and filamentous fungi are glycosylated (Li et al. 2009; Takashima et al. 1999a). Notably, when a gene encoding a β-glucosidase of *Talaromyces emersonii* was cloned into *T. reesei*, the secreted recombinant enzyme contained 17 potential N-glycosylation sites in its functionally active form (Murray et al. 2004). Glycosylation could further contribute to the thermostability improvement of cellulases as previously suggested (Meldgaard and Svendsen 1994). The mechanism, however, is still unknown. It has been reported that N-glycosylation could increase solubility and reduce aggregation (Ioannou et al. 1998; Kayser et al. 2011). Analysis of protein structures deposited in the Protein Data Bank has also suggested a decrease in protein dynamics upon N-glycosylation without significant global or local structural changes (Lee et al. 2015).

20.3 Purification and Characterization

Purified thermophilic fungal cellulases have been characterized in terms of molecular weight, optimal pH, optimal temperature, thermostability, and glycosylation. Usually, thermophilic fungal cellulases are single polypeptides, although some β-glucosidases are dimeric (Gudmundsson et al. 2016; Mamma et al. 2004). The molecular weight of thermophilic fungal cellulases has a wide range (30–250 kDa) with different carbohydrate contents (2–50%). Optimal pH and temperature are similar for the majority of the purified cellulases from thermophilic fungi. Thermophilic fungal cellulases are active in the pH range 4.0–7.0 and have a high temperature maximum at 50–80 °C for activity (Table 20.1). In addition, they exhibit remarkable thermal stability and are stable at 60 °C with longer half-life at 70 °C, 80 °C, and 90 °C than those from other fungi.

The mechanism of protein thermostability has been studied more extensively in thermophilic bacteria and hyperthermophilic archaea (Pack and Yoo 2004; Trivedi et al. 2006; Tiquia and Mormile 2010). However, a common mechanism has not been established so far and several contributors to protein thermostability have been proposed. A recent analysis suggested that an increase in ion pairs on the protein surface and a stronger hydrophobic interior are the major factors of increased protein thermostability (Taylor and Vaisman 2010). Compared with thermophilic proteins from thermophilic bacteria and hyperthermophilic archaea, the understanding of the nature and mechanism of thermostability of proteins from thermophilic fungi is relatively poor. Hence, further studies are necessary for comprehensive understanding of thermostability in cellulases from thermophilic fungi.

20.4 Structure

20.4.1 Primary Structure

A common characteristic of cellulases is their modular structure. Typically, endocellulases and cellobiohydrolases are composed of four modules (Fig. 20.1): a signal peptide that mediates secretion, a cellulose-binding domain (CBD) for attachment to the substrate, a catalytic domain (CD) responsible for the hydrolysis of the substrate, and a hinge region (linker) rich in Ser, Thr, and Pro residues. The hinge region is usually post-translationally glycosylated. An example of primary structure variations includes *Talaromyces emersonii* CBHII, which is characterized by a modular structure (Murray et al. 2003), whereas *T. emersonii* CBH1 consists solely of a catalytic domain (Grassick et al. 2004). Similarly, in *Chaetomium thermophilum* CBHs (CBH1, CBH2, and CBH3), CBH1 and CBH2 exhibit a typical CBD, a linker, and a CD. In contrast, CBH3 only comprises a catalytic domain and lacks a CBD and a hinge region (Li et al. 2009). Interestingly, *T. aurantiacus* cellulases compared to other fungal cellulases (e.g., *T. reesei*) lack CBDs (Le Costaouëc et al. 2013). However, cellulases without CBDs can still be efficiently used (Pakarinen et al. 2014).

CBDs are composed of less than 40 amino acids and they interact with cellulose through a flat platform-like hydrophobic binding site that is thought to be complementary to the flat surfaces presented by cellulose crystals (Shoseyov et al. 2006). It has been shown that deletion of the CBDs from *T. reesei* Cel7A and Cel6A and *Humicola grisea* CBH1 greatly reduces enzymatic activity toward crystalline cellulose (Takashima et al. 1998), suggesting that the tight binding to cellulose through the CBDs is necessary for the efficient hydrolysis of crystalline cellulose. Further studies have shown that three aromatic residues in CBD affect its cellulose-binding ability and enzymatic activities. Indeed, substitution of the three aromatic residues of *Humicola grisea* CBH1 CBD with other amino acids has demonstrated their importance in the interplay of high activity of *Humicola grisea* CBH1 on crystalline

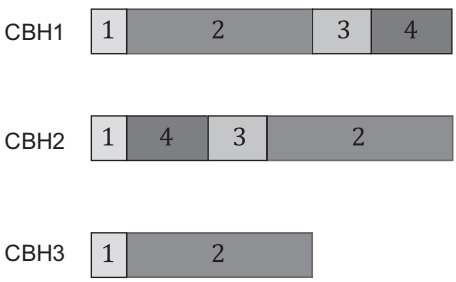

Fig. 20.1 Domain organization of cellobiohydrolases CBH1 (AY861347), CBH2 (AY861348), and CBH3 of *C. thermophilum* (Li et al. 2009). (1) Signal peptide, (2) catalytic domain (CD), (3) ST-rich region, (4) cellulose-binding domain (CBD)

cellulose and high cellulose-binding ability (Takashima et al. 2007). It has been further shown that CBDs promote the enzyme's action on insoluble substrates but are not needed when the enzyme attacks soluble substrates. It has therefore been suggested that CBHs without CBD might play an important role in the hydrolysis of soluble substrates (Li et al. 2009).

20.4.2 Three-Dimensional (3-D) Structure

The 3-D structures of thermophilic fungal cellulases from families 1, 5, 6, 7, 12, and 45 have been reported (Table 20.2) and are described below along with structural information of LPMOs (formerly GH61).

20.4.2.1 Family 1

The crystal structure of a *Humicola insolens* GH1 β-glucosidase has been reported at 2.6 Å resolution (de Giuseppe et al. 2014). In contrast to most β-glucosidases that are inhibited by glucose, this particular GH1 β-glucosidase exhibits tolerance toward glucose. The active site is located in a deep and narrow cavity (Fig. 20.2).

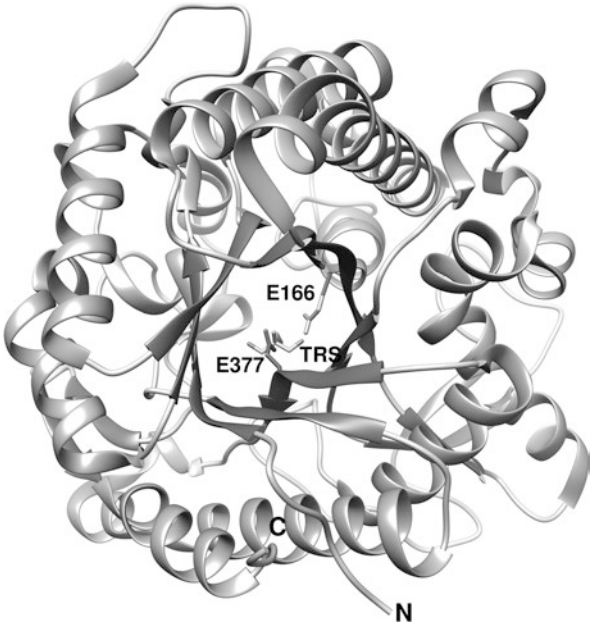

Fig. 20.2 Ribbon diagram of GH1 β-glucosidase from *Humicola insolens* (PDB id 4mdo; TRS, Tris buffer). Catalytic residues, bound ligands, and disulfide bridges are depicted in stick representation. All figures of the structures were created with CHIMERA (Pettersen et al. 2004)

The glucose tolerance was attributed to residues Trp168 and Leu173, which are conserved in glucose-tolerant GH1 enzymes and limit the access of glucose to the −1 subsite by imposing constraints at the +2 subsite.

20.4.2.2 Family 3

The crystal structure of a GH3 β-glucosidase (Cel3A) from *R. emersonii* (*Re*Cel3A) has been determined at 2.2 Å resolution (Gudmundsson et al. 2016). *Re*Cel3A was heterologously expressed in a *H. jecorina* strain and found highly glycosylated with a total of 181 glycosylation residues distributed in 16 glycosylation sites. *Re*Cel3A structure (Fig. 20.3) consists of three domains similar to other GH3 β-glucosidases: an N-terminal triose phosphate isomerase (TIM)-barrel-like domain, a middle $(\alpha/\beta)_6$-sandwich domain, and a C-terminal domain with a fibronectin type III-like fold.

20.4.2.3 Family 5

Family 5 cellulases belong to the endoglucanase type. The overall fold is a common $(\beta/\alpha)_8$-barrel. The structure of *Thermoascus aurantiacus* Cel5A is known (Lo Leggio and Larsen 2002; Van Petegem et al. 2002) and consists solely of a catalytic domain (Fig. 20.4). A substrate-binding cleft rich in Trp residues is visible at the C-terminal end of the barrel. The size and shape of the cleft suggest the binding of

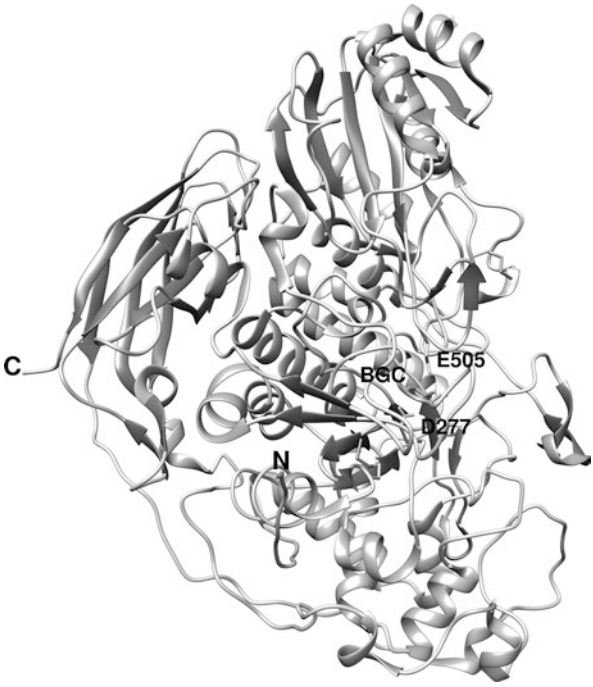

Fig. 20.3 Ribbon diagram of *Re*Cel3A (PDB id 5ju6)

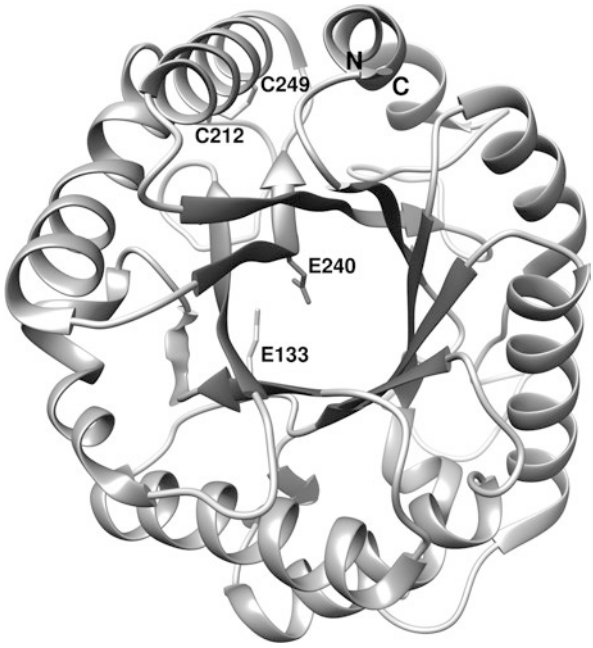

Fig. 20.4 *Thermoascus aurantiacus* GH5 endoglucanase (PDB id 1gzj)

at least seven glucose residues (−4 to +3). Contrary to other GH5 cellulase structures, Cel5A has only a few extra-barrel features, including a short two-stranded β-sheet in β/α-loop 3 and three one-turn helices. The enzyme contains two conserved cysteine residues (Cys212 and Cys249) that form a disulfide bridge.

20.4.2.4 Family 6

Family 6 comprises both endoglucanases and cellobiohydrolases. 3-D structures have been reported for the endoglucanase Cel6B and the cellobiohydrolase Cel6A from *Humicola insolens* (Davies et al. 2000; Varrot et al. 2003). Their structure exhibits a distorted β/α-barrel with the central β-barrel made up of seven instead of eight parallel β-strands (Fig. 20.5). A substrate-binding crevice is formed between strands I and VII. The crevice of the Cel6A contains at least four substrate-binding sites, −2 to +2, whereas that of the Cel6B has six substrate-binding sites, −2 to +4. A significant difference between the endoglucanase Cel6B and the cellobiohydrolase Cel6A is the presence of two extended surface loops that enclose the active site of Cel6A. The absence of these loops in Cel6B results in an open substrate cleft in Cel6B. Owing to this structural difference, endoglucanase can hydrolyze bonds internally in cellulose chains while cellobiohydrolase acts on chain ends.

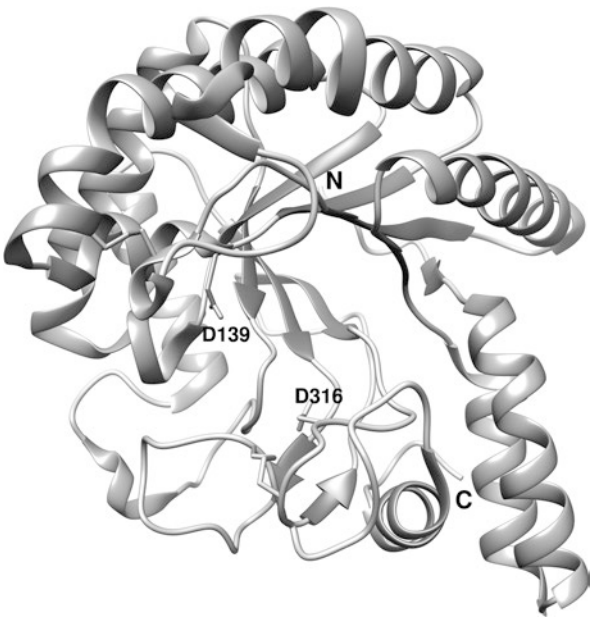

Fig. 20.5 Ribbon diagram of *Humicola insolens* Cel6B endoglucanase (PDB id 1dys)

20.4.2.5 Family 7

Similar to GH6, GH7 contains endoglucanases and cellobiohydrolases. 3-D structures of various family members have been reported. However, only a few structures from thermophilic fungi are currently known, including *Talaromyces emersonii* CBHIB (Grassick et al. 2004), *Humicola insolens* EGI (Davies et al. 1997; MacKenzie et al. 1998), *Melanocarpus albomyces* Cel7B (Parkkinen et al. 2008), and *Humicola grisea* Cel7A (Momeni et al. 2014). The overall 3-D architecture of this family exhibits a double β-sandwich. The structure of *M. albomyces* Cel7B (Fig. 20.6), similarly to *Talaromyces emersonii* CBHIB, is a representative of GH7 cellobiohydrolases (Grassick et al. 2004). It consists of two antiparallel β-sheets packed face to face to form a β-sandwich. Owing to their strong curvature, these two β-sheets form the concave and convex surfaces of the sandwich. A main characteristic of Cel7B is an enclosed substrate-binding tunnel formed by extended loops stabilized by nine disulfide bonds. The tunnel is about 50 Å long and contains the substrate-binding sites, −7 to +2 (Parkkinen et al. 2008). *Humicola grisea* Cel7A (PDB id 4csi) has 56% sequence identity with *M. albomyces* Cel7B and exhibits various loop deviations (Momeni et al. 2014) that may contribute to its increased thermostability.

Humicola insolens EGI has a β-sandwich structure with two large antiparallel β-sheets (Davies et al. 1997; MacKenzie et al. 1998) similar to *M. albomyces* Cel7B

Fig. 20.6 *Melanocarpus albomyces* GH7 cellobiohydrolase in complex with cellotetraose (PDB id 2rg0; CTT=cellotetraose)

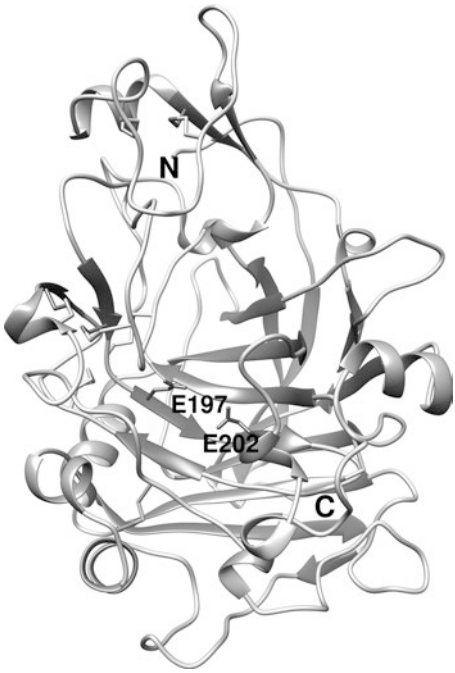

Fig. 20.7 *Humicola insolens* GH7 endoglucanase EGI (PDB id 2a39)

(Fig. 20.7). However, EGI has an open long active site cleft in the center of a canyon formed by the curvature of the β-strands of the β-sandwich while Cel7B has an enclosed substrate-binding tunnel (Davies et al. 1997; Parkkinen et al. 2008), which is similar to GH6 endoglucanases and cellobiohydrolases. *C. thermophilum* CBH3 is a thermostable and single-module cellobiohydrolase with no 3-D structure available (Li et al. 2009). This cellobiohydrolase shares high sequence identity (80%) with *M. albomyces* Cel7B (Parkkinen et al. 2008). Homology modelling has shown that all the key residues in the catalytic site and substrate-binding site as well as the disulfide bonds of *M. albomyces* Cel7B are also present in *C. thermophilum* CBH3.

20.4.2.6 Family 12

The crystal structure of a GH12 fungal cellulase from *Humicola grisea* has been reported (Sandgren et al. 2003). It comprises two antiparallel β-sheets, which pack on top of each other to form a compact curved β-sandwich (Fig. 20.8). The concave face creates an approximately 35 Å-long and unblocked substrate-binding site able to bind at least six glycan residues. Details of the non-covalent interactions between the enzyme and the glucosyl chain in subsites −4 to +2 have been revealed by crystal structures of four enzyme-ligand complexes (Sandgren et al. 2004).

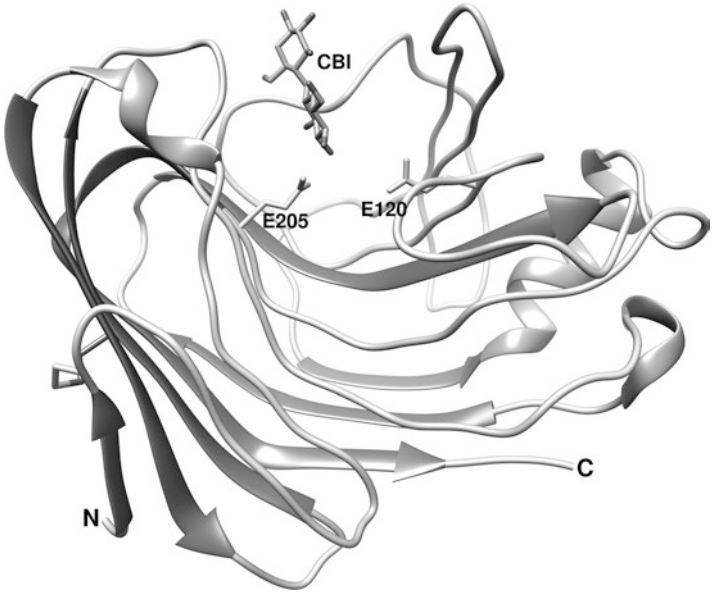

Fig. 20.8 Catalytic domain of *Humicola grisea* GH12 Cel12A in complex with cellobiose (PDB id 1uu4; CBI=cellobiose)

20.4.2.7 Family 45

The structures of three GH45 endoglucanases have been solved: *Humicola insolens* Cel45A (EGV) (Davies et al. 1993), *Melanocarpus albomyces* 20 kDa endoglucanase (Hirvonen and Papageorgiou 2003; Valjakka and Rouvinen 2003), and *Theilavia terrestris* Cel45 (Gao et al. 2017). These three endoglucanases have similar overall fold, which consists of a six-stranded β-barrel with interconnecting loops (Fig. 20.9). The β-strands are connected with long disulfide-bonded loop structures (seven disulfide bridges) while the rest of the structure is completed by three α-helices. A substrate-binding groove is formed between the β-barrel and the loop structures. This groove, approximately 40 Å long, 10 Å deep, and 12 Å wide, is subdivided into six substrate-binding sites, from −4 to +2 (Hirvonen and Papageorgiou 2003).

20.4.2.8 Lytic Polysaccharide Monooxygenases

LPMOs use a cellulose degradation mechanism different from that of cellulases. The reaction proceeds through an oxidative step that involves hydroxylation of crystalline cellulose at the C1 or C4 carbon, leading to subsequent cleavage of the glycosidic bond. The 3-D structure of LPMOs exhibits a predominantly β-sandwich fold with two twisted antiparallel β-sheets connected through loops of various

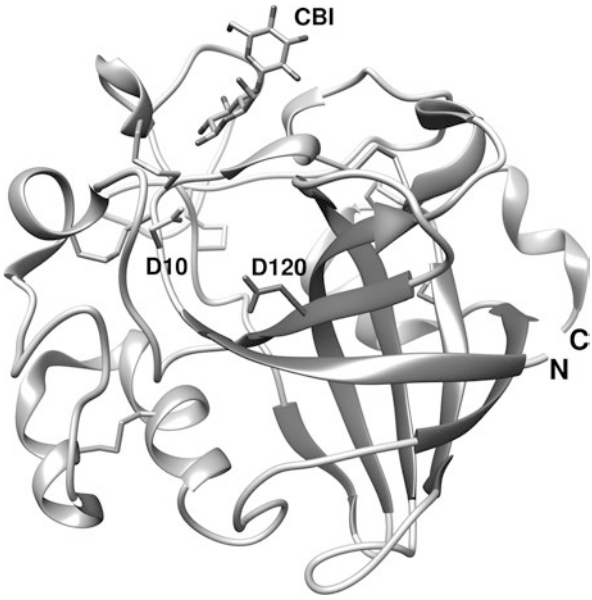

Fig. 20.9 *Melanocarpus albomyces* GH45 endoglucanase in complex with cellobiose (PDB id 1oa7)

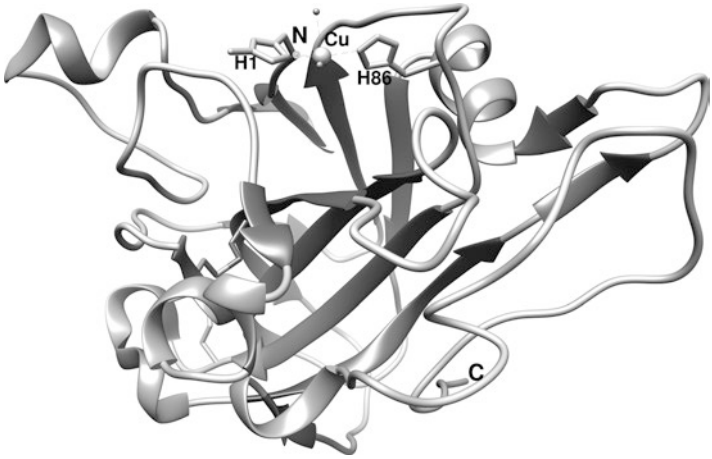

Fig. 20.10 *T. aurantiacus* GH61 (PDB id 2yet). Cu(II) ion and water molecules are shown as spheres

lengths and conformation (Fig. 20.10). The active site is located on a flat solvent-exposed region of the molecule in contrast to traditional cellulases that possess a substrate-binding cleft or tunnel. A tightly bound Cu(II) ion involved in the reaction has been found in the active site. His1, one of the Cu(II) coordinating residues, is methylated in some LPMO structures, including that of *T. aurantiacus* GH61, but not in all (Quinlan et al. 2011). The reason for the methylation is still unknown.

20.5 Improvement of Thermophilic Fungal Cellulases

Cellulose degradation in an efficient and cheap way is a major challenge in biomass conversion by cellulases. Consequently, cellulases need to acquire higher catalytic efficiency on cellulose, higher stability at elevated temperature and at non-physiological pH, and higher tolerance to end-product inhibition (Percival Zhang et al. 2006). Currently, there are two main research approaches of cellulase improvement: structure-based rational site-directed mutagenesis and random mutagenesis through directed evolution. The site-directed mutagenesis requires detailed knowledge of the 3-D protein structure. Conversely, the directed evolution approach is not limited by the lack of the protein 3-D structure but requires an efficient method for high-throughput screening (Labrou 2010).

20.5.1 Thermostability Improvement

Although cellulases from thermophilic fungi are thermostable, further increase of their thermostability is desirable for industrial applications. Improvement of *Melanocarpus albomyces* Cel7B has been pursued by error-prone PCR and 49 positive mutant clones were screened from 14,600 random clones by a robotic high-throughput thermostability screening method (Voutilainen et al. 2007). Two positive thermostable mutants, Ala30Thr and Ser290Thr, showed improved unfolding temperature (T_m) by 1.5 and 3.5 °C, respectively. In addition, the optimum temperature on a soluble substrate for the Ala30Thr mutant was improved by 5 °C. The amino acid alterations are located in the β-strands away from the Cel7B active-site tunnel, which could improve protein packing. In another approach, introduction of additional disulfide bridges to the catalytic module of *Talaromyces emersonii* Cel7A resulted in three mutants with improved thermostability, as shown by Avicel hydrolysis efficiency at 75 °C (Voutilainen et al. 2010).

Structural analysis of thermostable *Humicola grisea* Cel12A has revealed three unusual free cysteines in the enzyme: Cys175, Cys206, and Cys216. Consequently, three Cel12A mutants were constructed by site-directed mutagenesis: Cys175Gly, Cys206Pro, and Cys216Val. It was found that the three free cysteines play a significant role in modulating the stability of the enzyme (Sandgren et al. 2005). More specifically, Cys206Pro and Cys216Val mutations caused a reduction in the T_m of 9.1 °C and 5.5 °C, respectively, compared to the wild-type enzyme. Moreover, when Cys175 was mutated to Gly, the T_m of the enzyme was increased by 1.3 °C. Recent reports of fold-specific thermostability through variations in amino acid compositions of endoglucanases (Yennamalli et al. 2011) have provided additional strategies for thermostability improvement.

Random mutagenesis and recombination of beneficial mutations were employed for the construction of a chimeric Cel6A cellobiohydrolase (Wu and Arnold 2013). Increased hydrophobic interactions and reduced loop flexibility by introduction of Pro residues were found to improve thermostability.

A computational approach, SCHEMA, which uses protein structure data to generate new sequences for special purposes that minimize structure disruption when they are introduced in chimeric proteins, has been employed to create thermostable fungal cellulases (Heinzelman et al. 2009). The high-resolution structure of *Humicola insolens* CBHII (Varrot et al. 2003) used as a template for SCHEMA yielded a collection of highly thermostable CBHII chimeras. Using the computer-generated sequences, a total of 31 new cellulase genes were synthesized and expressed in *S. cerevisiae*. Each purified enzyme was found to be more stable than the most stable parent cellulase from *Humicola insolens*, as measured either by half-life inactivation at 63 °C or by $T_{1/2}$. These findings demonstrated the value of structure-guided recombination for efficient generation of highly stable cellulases.

Improvement of cellulase stability in detergent solutions has also been pursued (Otzen et al. 1999). *H. insolens* Cel45 endoglucanase is inactivated by the anionic surfactant C12-LAS, owing to the surface positive charges of the enzyme (Otzen et al. 1999). Based on the Cel45 crystal structure, surface residues were mutated by site-directed mutagenesis. Introduction of positive charges or removal of negative charges was found to greatly increase detergent sensitivity. The R158E/R196E double mutant, in particular, exhibited synergistic stabilization, presumably by preventing C12-LAS from binding to the protein.

20.5.2 Activity Improvement

Improvement of cellulase activity using site-directed mutagenesis and directed evolution has been pursued in recent years. However, owing to the lack of general rules for site-directed mutagenesis and the limitation of screening methods, there are only a few successful examples of cellulase mutants with significantly higher activity (Percival Zhang et al. 2006). As mentioned earlier, the S290 T mutant of *Melanocarpus albomyces* Cel7B exhibits not only improved thermostability but also a two-fold increase in the rate of Avicel hydrolysis at 70 °C (Voutilainen et al. 2009). Similar results have been obtained for *T. emersonii* Cel7A with site-directed mutagenesis (Voutilainen et al. 2010). Directed evolution of *Chaetomium thermophilum* CBHII produced mutants able to retain >50% of their activity at 80 °C for 1 h while the wild type lost all its activity under the same conditions (Wang et al. 2012).

Recent studies have shown the potential of adding or replacing a CBD to alter the enzyme characteristics and to improve hydrolytic activity (Limon et al. 2001; Shoseyov et al. 2006). *Humicola grisea*, for example, contains two endoglucanases: EGL3 with a CBD and EGL4 without a CBD. The fusion protein, EGL4CBD, which consists of the EGL4 catalytic domain and the EGL3 CBD, shows relatively high activity to carboxymethyl cellulose (Takashima et al. 1999a). *Melanocarpus albomyces* Cel7A, Cel7B, and Cel45A lack a consensus CBD and the associated linker (Haakana et al. 2004). The efficiency of these three cellulases to hydrolyze crystalline cellulose was improved after they were genetically modified to carry the CBD of *T. reesei* CBHI (Szijarto et al. 2008).

20.5.3 Conversion to Glycosynthases

An important development in cellulase engineering is the conversion of cellulases to glycosynthases by site-directed mutagenesis (Shaikh and Withers 2008). Glycosynthases are retaining GH mutants in which the catalytic nucleophile has been replaced by a non-nucleophilic residue. The first glycosynthase from thermophilic fungus was derived from *Humicola insolens* Cel7B following mutation of E197 to Ala. The resultant Cel7B E197A glycosynthase was able to catalyze regio- and stereoselective glycosylation in high yield (Fort et al. 2000). Three mutants of the *H. insolens* Cel7B E197A glycosynthase, E197A/H209A, and E197A/H209G double mutants, and Cel7B E197A/H209A/A211T triple mutant, were subsequently prepared and characterized (Blanchard et al. 2007). These second-generation glycosynthase mutants were rationally redesigned at the +1 subsite to broad the substrate specificity of the glycosynthase. The results showed that E197A/H209A and E197A/H209G preferentially catalyze the formation of a β-(1,4) linkage between two disaccharides. In contrast, the E197A and E197A/H209A/A211T mutants produce predominantly a β-(1,3)-linked tetrasaccharide. This work indicated that the regioselectivity of the glycosylation reaction catalyzed by *Humicola insolens* Cel7B E197A glycosynthase could be modulated by appropriate active site mutations. Use of β-glucosidases for the synthesis of a variety of glycoconjugates, such as alkyl glucosides and aminoglycosides, has gathered momentum in recent years. A GH3 β-glucosidase from the thermophilic fungus *Myceliophthora thermophila* has been studied and found to act as an efficient biocatalyst in alkyl glycoside synthesis (Karnaouri et al. 2013).

20.6 Conclusions and Future Perspectives

Thermophilic fungal cellulases are promising alternatives in biotechnological applications. However, from about 40–50 species of known thermophilic fungi, only a minority of thermophilic fungal cellulases has been characterized so far in detail. A systematic characterization of cellulases is necessary to understand better their thermostability, enzyme mechanism, synergism of the cellulase system, and evolutionary relationships. Site-directed mutagenesis and directed evolution are currently the most preferable approaches for obtaining novel cellulase variants. In addition, the emergence of LPMOs as a complementary cellulose-degrading system offers new opportunities for the future. Further improvement of thermophilic fungal cellulases will assist in developing better and more versatile enzymes for their use alone or in mixtures for biotechnological applications.

Chapter 21
β-Galactosidases from an Acidophilic Fungus, *Teratosphaeria acidotherma* AIU BGA-1

Kimiyasu Isobe and Miwa Yamada

21.1 Introduction

Compared with bacteria, fungi generally grow well at a slightly lower pH range with a lower optimal growth temperature of 25–30 °C. Because of these biological characteristics, fungi have been used to discover some acidophilic enzymes, but the isolated enzymes are not always stable at an extremely low pH range. In our previous investigation of screening for enzymes with high activity and stability at an extremely low pH range, we isolated >100 fungal strains by culturing at pH 1.0 or 2.5 and 42–45 °C, and we obtained the following results (Isobe et al. 2006). Of these isolated strains, four strains that were identified as *Aspergillus niger* produced a catalase (EC 1.11.1.6) with high activity at pH 3.0 and stability at pH 2.0. This result indicated that enzymes with high activity and stability at an extremely low pH range can be obtained from fungal strains capable of growing at extremely acidic and rather high-temperature environments. We next applied the cultivation conditions we used to the screening of extremely acidophilic β-D-galactosidases (β-D-galactoside galactohydrolase, EC 3.2.1.23).

β-D-Galactosidase, which is commonly known as lactase, catalyzes the hydrolysis of lactose into glucose and galactose. This enzyme is naturally present in the human intestine, and it contributes to the hydrolysis of lactose in milk or dairy products. Lactose-intolerant individuals, who have only low levels of this enzyme, cannot efficiently digest lactose. Microbial β-D-galactosidases are thus used to produce milk and other dairy products with low-lactose contents. Enzymes are also applied to increase the lactose solubility or sweetness of foods, because lactose is the main carbohydrate with relatively low sweetness in milk and whey.

Many microbial β-D-galactosidases with different properties have been demonstrated to use lactose in milk or whey. For example, enzymes with a neutral optimum pH have been used to hydrolyze lactose in milk (Biermann and Glantz 1968; Cavaille and Combes 1955; Kim et al. 2003; Laderoa et al. 2002). Enzymes with an optimum pH in the acidic range have been developed for use in the processing of acidic whey and its permeate (El-Gindy 2003; Gonzalez and Monsan 1991; Hatzinikolaou et al. 2005; Nagy et al. 2001; Nakkharat and Haltrich 2006; Shaikh et al. 1999; Takenishi et al. 1983). Some acidophilic enzymes have also been used as a digestive supplement for lactose-intolerant individuals (O'Connell and Walsh 2008; Wang et al. 2009). Several β-D-galactosidases with transgalactosylation activity have been studied for the production of prebiotic galacto-oligosaccharides or structural and functional modifications of food materials (Chakraborti et al. 2000; Gupta et al. 2012; Lu et al. 2009; Wang et al. 2014). Thus, β-D-galactosidase is one of the most important enzymes in the food, dairy, baking, and pharmaceutical industries, and microorganisms have been assessed as potential sources of different types of β-D-galactosidase.

We demonstrated that the acidophilic fungus *Teratosphaeria acidotherma* AIU BGA-1, which was isolated from an acidic and high-temperature hot spring in Japan, produced not only one acidophilic β-D-galactosidase, but also two extremely acidophilic enzymes and one alkalophilic enzyme in the mycelia (Isobe et al. 2013a). This chapter describes our screening for a new fungal producer of β-D-galactosidases and its optimal cultivation conditions for the production of β-D-galactosidases. The specific characteristics of two extremely acidophilic enzymes and one alkalophilic enzyme are also summarized and compared with those of other microbial β-D-galactosidases.

21.2 Materials and Methods

21.2.1 Isolation of a Fungal Producer of Extremely Acidophilic β-D-Galactosidase

Fungal strains growing at an extremely low pH range were isolated from different acidic sites (Isobe et al. 2013a). Each suspension of soil collected from the acidic and/or high-temperature sites was spread on an agar plate of glucose medium consisting of 2.0% glucose, 0.2% corn steep liquor, 0.2% NH_4NO_3, 0.1% KH_2PO_4, 0.1% Na_2HPO_4, 0.05% $MgSO_4 \cdot 7H_2O$, 0.15% $Ca(NO_3)_2 \cdot 4H_2O$, and 0.1% $FeCl_3 \cdot 6H_2O$, pH 1.0 or pH 2.5, and incubated at 35–45 °C for 7 days. The fungal strains that grew on the agar plates were isolated and inoculated into 10 mL of a lactose medium that had the same components as the glucose medium except that glucose was replaced by lactose and the pH was 4.0. The cultivation was performed at 30 °C for 2 days with shaking.

Aspergillus niger strains from the Japan Collection of Microorganisms (JCM) were also incubated with the lactose medium under the same conditions. The selected strains were then inoculated into 150 mL of the lactose medium in a 500-mL culture flask and incubated at 30 °C for 2 days with shaking.

The mycelia of each strain were collected by filtration and suspended with 10 mM potassium phosphate buffer (KPB), pH 7.0, and disrupted using a Multi-Beads Shocker (Yasui Kikai, Osaka, Japan) below 5 °C for 8 min. The supernatant solution was collected by centrifugation at 10,000 × *g* for 10 min and then used for the assay of β-D-galactosidase activity at pH 1.5, 4.5, and 7.0. The strain that exhibited the highest relative activity of β-D-galactosidase at pH 1.5 to that at pH 4.5 was selected as a producer of extremely acidophilic β-D-galactosidases (Isobe et al. 2013a).

21.2.2 Taxonomic Studies of the Selected Strain

The identification of the selected strain was performed at TechnoSuruga Laboratory (Shizuoka, Japan) (Isobe et al. 2013a). In brief, the strain was incubated on a potato-dextrose agar plate (Nihon Seiyaku, Tokyo, Japan) and an oatmeal agar plate (Becton Dickinson, Lincoln Park, NJ) at 25 °C in the dark, and the morphological characteristics were observed with both a compound microscope and a stereomicroscope. The sequences of 28S rDNA-D1/D2 and ITS-5.8S rDNA were analyzed using a PrimeSTAR HS DNA polymerase (Takara Bio, Otsu, Japan), an ABI BigDye Terminator v3.1 Kit (Applied Biosystems, Foster City, CA), and an ABI PRISM 3130x1 Genetic Analyzer System (Applied Biosystems). The sequence alignment and calculation of the homology levels were carried out using the GenBank, DDBJ, and EMBL databases.

21.2.3 Cultivation of the Selected Strain

The selected strain was incubated with the lactose medium, pH 4.0, at 30 °C for 4 days to obtain the acidophilic enzymes or with the lactose medium, pH 5.0, for 2 days to obtain the alkalophilic enzyme (Chiba et al. 2015; Isobe et al. 2013b; Yamada et al. 2017).

21.2.4 Enzyme Activity Assay

The β-D-galactosidase activity was assayed using 2-nitrophenyl-β-D-galactopyranoside (2-NPGA) dissolved with 0.1 M CH_3COONa-HCl, pH 1.5, 0.1 M CH_3COOH-NaOH, pH 4.5, 0.1 M KPB, pH 7.0, or 0.1 M NH_4Cl-NH_3, pH

8.5. Ten millimolar of 2-NPGA was incubated with the enzyme at 37 °C for 15 or 60 min at pH 1.5, 4.5, 7.0, or 8.5. The reaction was terminated by adding 10% Na_2CO_3 (final concentration, 5%), and the 2-nitrophenol released was quantified by measuring the absorbance at 420 nm. One unit of enzyme activity was defined as the amount of enzyme catalyzing the release of one micromole of 2-nitrophenol per minute under the above conditions. The molar absorptivity for the dye formed under the above conditions was 4.6×10^3 M^{-1} cm^{-1} (Isobe et al. 2013b; Chiba et al. 2015; Yamada et al. 2017).

The lactose hydrolyzing activity was spectrophotometrically assayed by measuring the glucose formation velocity from lactose at 555 nm by coupling with glucose oxidase and peroxidase (Isobe et al. 2013b).

21.2.5 Isolation and Purification of β-D-Galactosidases

As described further in the Results section below, the β-D-galactosidase activity was separated into three peaks by ion-exchange column chromatography (Fig. 21.2a), and one of these peaks was further separated into two peaks by hydrophobic column chromatography (Fig. 21.2b) (Isobe et al. 2013a). Of these four enzymes, two enzymes were extremely acidophilic and one enzyme was alkalophilic. Therefore, these three enzymes were purified to a homogeneous state.

21.2.5.1 Enzyme 1: Alkalophilic Enzyme with Optimal pH 8.0

The mycelia harvested at 2 days of cultivation with the lactose medium at pH 5.0 were disrupted with glass beads in 10 mM KPB, pH 7.0, by a Multi-Beads Shocker, and the supernatant collected by centrifugation was used as a crude enzyme solution. The enzyme solution was then applied onto a DEAE-Toyopearl column equilibrated with 20 mM KPB, pH 6.7. The adsorbed enzyme was eluted by a linear gradient of 20 mM KPB, pH 6.7, and the same buffer containing 0.1 M NaCl, and the active fractions with high activity at pH 7.0 were collected (the first peak in Fig. 21.2a). The eluate was applied to a Phenyl-Toyopearl column, and the adsorbed enzyme was eluted by a linear gradient of 10 mM KPB, pH 7.5, containing 1.2 M and 0.4 M ammonium sulfate. The eluate was applied to a hydroxyapatite column equilibrated with 20 mM KPB, pH 7.5, and the adsorbed enzyme was eluted by a linear gradient of 20 and 90 mM KPB, pH 7.5 (Yamada et al. 2017).

21.2.5.2 Enzyme 2a: Acidophilic Enzyme with Optimal pH 1.0

The buffer used was KPB, pH 6.5, containing 0.5 mM phenylmethanesulfonyl fluoride (PMSF). Mycelia harvested at 4 days of cultivation with the lactate medium, pH 4.0, were disrupted with glass beads in 10 mM buffer, and the supernatant

collected by centrifugation was used as a crude enzyme solution. The enzyme proteins precipitated between 45% and 80% saturated ammonium sulfate were then collected from the crude enzyme solution. The precipitate was dissolved with 40 mM buffer and dialyzed against the same buffer solution. The dialyzed enzyme solution was applied to a DEAE-Toyopearl column, and the adsorbed enzymes were eluted by a linear gradient of 40 mM buffer and the same buffer containing 0.1 M NaCl (active fractions with high activity at pH 1.5 were collected; the second peak in Fig. 21.2a). This partial purification from mycelia was carried out two times, and both eluates were mixed.

To the mixed enzyme solution, 1.2 M solid ammonium sulfate was added, and the enzyme solution was applied to a Phenyl-Toyopearl column equilibrated with 20 mM buffer containing 1.2 M ammonium sulfate. The adsorbed enzyme was eluted by a linear gradient of the same equilibrium buffer and 20 mM buffer. The active fractions with high activity at pH 1.5 were collected (the first peak in Fig. 21.2b) and dialyzed against 10 mM buffer. The dialyzed enzyme solution was applied to a GigaCapQ-Toyopearl column, and the adsorbed enzyme was eluted by a linear gradient with 70 mM buffer and the same buffer containing 0.2 NaCl.

The active fractions were applied again to a Phenyl-Toyopearl column, and the adsorbed enzyme was eluted by a linear gradient of 20 mM buffer containing 1.2 and 0.5 M ammonium sulfate. The eluate was dialyzed and applied again to a GigaCapQ-Toyopearl column equilibrated with 40 mM buffer. The enzyme was eluted by a linear gradient of 40 mM buffer, pH 6.5 and 3.0, and active fractions were concentrated by ultrafiltration. The concentrated enzyme solution was applied to a Toyopearl HW-55 column equilibrated with 50 mM buffer without PMSF (Chiba et al. 2015).

21.2.5.3 Enzyme 3: Acidophilic Enzyme with Optimal pH 3.5

The purification steps from ammonium sulfate fractionation to Phenyl-Toyopearl column chromatography were performed under the same conditions as those used for enzyme 2a, and the third peak of the DEAE-Toyopearl column chromatography was collected (Fig. 21.2a). The eluate from the Phenyl-Toyopearl column was applied again to a DEAE-Toyopearl column, and the enzyme was eluted under the same conditions as those used for the first DEAE-Toyopearl column chromatography. Then, the eluate was applied to a 4-aminophenyl-β-D-galactopyranoside-Toyopearl column, and the adsorbed enzyme was eluted by a linear gradient of 10 mM KPB, pH 6.5, and the same buffer containing 0.15 NaCl. The eluate was concentrated and applied to a Toyopearl HW-55 column under the same conditions as those used for enzyme 2a (Isobe et al. 2013b).

21.2.6 Thin-Layer Chromatography (TLC) Analysis of the Reaction Products from Lactose

TLC analysis of the products by lactose hydrolysis was performed using a silica gel plate (Silica Gel 60F 254; Merck, Darmstadt, Germany) and a solvent composed of *n*-butanol:*n*-propanol:ethanol:water (2:3:3:2). The spots were detected by heating for a few minutes on a hot plate after the plate was sprayed with a solution containing 20 mg of diphenylamine, 20 μL of aniline, and 0.1 mL of phosphoric acid in 1.0 mL of acetone (Isobe et al. 2013b).

21.2.7 Buffer for Optimal pH and pH Stability

The effects of enzyme activity and stability were analyzed with CH_3COONa-HCl, pH 1.0–4.5; CH_3COONa-CH_3COOH, pH 4.0–5.5; KPB, pH 5.5–8.0; and NH_4Cl-NH_4OH, pH 8.0–10.0 (Isobe et al. 2013b).

21.3 Results

21.3.1 Isolation of a Fungal Producer of Extremely Acidophilic β-D-Galactosidase

We incubated each of the fungal strains isolated on the glucose medium and the *A. niger* strains from the JCM with the lactose medium, pH 4.0, for 2 days, and assayed the β-D-galactosidase activity at pH 1.5, 4.5, and 7.0 using the crude enzyme solution. Of the strains tested, 14 strains exhibited >5 mU per mL at each of the above three pH values, and we divided the 14 strains into three groups based on the ratios of the enzyme activities at pH 1.5, 4.5, and 7.0 (Table 21.1). One strain exhibited high activity at both pH 1.5 and pH 7.0 compared to that at pH 4.5 (group A). Three strains exhibited similar enzyme activities at both pH 1.5 and 4.5, and the values were much higher than those at pH 7.0 (group B). Ten strains exhibited higher activity at pH 4.5 than that at pH 1.5 and pH 7.0 (group C). The five *A. niger* strains (JCM nos. 1922, 5546, 5548, 5634, and 5697) were classified into group C. These results indicated that strains of groups A and B might produce acidophilic β-D-galactosidase in the mycelia.

We then incubated each crude enzyme solution from the four strains in groups A and B at pH 1.5 and 5.0 for 3 h at 37 °C, and the pH stability of β-D-galactosidase was analyzed. The enzyme from the single group A strain remained >90% and 95% of the original activity at pH 1.5 and 5.0, respectively, whereas the enzymes from the three group B strains were stable at pH 5.0, but not at pH 1.5 (data not shown). These results indicated that the group A strain might produce a β-D-galactosidase

Table 21.1 β-D-Galactosidase activity of isolated fungi and *A. niger* strains (Isobe et al. 2013a)

Group	Strain	β-D-Galactosidase activity (mU/mL)			Relative activity (%)	
		pH 1.5	pH 4.5	pH 7.0	pH 1.5/4.5	pH 7.0/4.5
A	1	12.1	5.50	7.43	220	135
B	1	107	103	21.3	104	21
	2	71.5	78.8	14.2	91	18
	3	59.1	55.8	11.7	106	21
C	1	10.3	40.5	9.78	25	24
	2	10.2	42.0	8.64	24	21
	3	6.76	38.9	7.07	17	18
	4	6.52	30.5	7.43	21	24
	5	6.28	28.1	7.07	22	25
	JCM 5697	8.09	28.0	6.16	29	22
	JCM 5634	23.5	88.1	22.5	27	26
	JCM 5548	9.84	36.8	8.33	27	23
	JCM 5546	6.40	33.6	7.00	19	21
	JCM 1922	15.9	68.8	12.9	23	19

Each strain was incubated with the lactose medium, pH 4.0, at 30 °C for 2 days. The enzyme activities of crude enzyme solution were assayed under standard assay conditions. The enzyme activities are expressed as mU/mL of the crude enzyme solution.

that is stable at an extremely low pH range. We therefore selected the group A strain and used it in our subsequent investigations (Isobe et al. 2013a).

21.3.2 Identification of the Selected Strain

The sequence of 28S rDNA-D1/D2 of the selected strain was 100% identical to that of *T. acidotherma* NBRC106057T, NBRC106058, NBRC106059, and NBRC106060 (AB537898, AB537899, AB537900, and AB537901, respectively) (Yamazaki et al. 2010), whereas the similarity to the other *Teratosphaeria* strains was <95%. The sequence of ITS-5.8S rDNA was also 100% identical to that of the above four strains, but not to that of the other *Teratosphaeria* strains.

When we incubated the selected strain at 25 °C for 9 days, it grew well at pH 2.0 on the agar plate, and the colonies were velvet with a grayish-yellow color on the potato dextrose agar plate and an olive color on the oatmeal agar plate. The vegetative hyphae had septa, and a part of the hyphae formed thick-walled cells and meristematic cells. These biological traits and morphological characteristics supported the genetic results, although the formation of an ascoma was not recognized by cultivation on an agar plate at 25 °C for 6 weeks. We therefore concluded that the selected strain belongs to *T. acidotherma*, and we named it *T. acidotherma* AIU BGA-1 (Isobe et al. 2013a).

21.3.3 Optimal Cultivation Conditions of the Selected Strain for β-D-Galactosidase Production

When we cultivated the BGA-1 strain with the medium containing glucose or lactose, the β-D-galactosidase production in the lactose medium was much higher than that in the glucose medium. Thus, β-D-galactosidase was induced by lactose (Isobe et al. 2013a).

The effect of the pH on the enzyme production was then analyzed by culturing with the lactose medium at an initial pH of 2.0–6.0. The strain grew well at pH 2.0–4.0, and the growth speed slowed down remarkably at pH 5.0 and 6.0. The enzyme production at pH 2.0–4.0 was also higher than that at pH 5.0 and 6.0. The relative values of enzyme activity at pH 1.5 to that at pH 4.5 in the cultures at pH 2.0–4.0 were also higher than those in the cultures at pH 5.0 and pH 6.0. In contrast, the relative enzyme activity at pH 7.0 to pH 4.5 became higher by shifting the initial pH from 3.0 to 6.0 (Table 21.2). These results indicated that more than one β-D-galactosidase including an extremely acidophilic enzyme was produced by the BGA-1 strain, and the product amounts of enzymes were affected by the initial pH of the lactose medium (Isobe et al. 2013a).

We also analyzed the effect of cultivation time on the enzyme production by cultivation with the lactose medium, pH 4.0, for 4 days. The enzyme activity at pH 1.5 was higher than that at pH 4.5 and 7.0 at 2 days of cultivation, and the enzyme activities at pH 1.5 and 4.5 were increased by prolonging the cultivation time, but the activity at pH 7.0 was not increased (Fig. 21.1). These results also indicated that the BGA-1 strain produced multiple β-D-galactosidases including an extremely acidophilic enzyme. We thus cultivated the strain with the lactose medium, pH 4.0, for 2 days and identified the β-D-galactosidases in the mycelia (Isobe et al. 2013a).

Table 21.2 The effect of initial pH on the β-D-galactosidase production by *T. acidotherma* AIU BGA-1 (Isobe et al. 2013a)

Initial pH	Growth (g/100 mL broth)	β-D-Galactosidase activity (U/100 mL broth)			Relative activity (%)	
		pH 1.5	pH 4.5	pH 7.0	pH 1.5/4.5	pH 7.0/4.5
2.0	0.92	1.01	0.87	0.30	116	34
3.0	2.13	2.56	2.27	0.91	113	40
4.0	1.70	2.11	1.64	0.88	135	54
5.0	0.36	0.23	0.29	0.17	77	56
6.0	0.22	0.092	0.094	0.10	98	106

T. acidotherma AIU BGA-1 was incubated with the lactose medium, pH 2.0–6.0, at 30 °C for 4 days, and the β-D-galactosidase activity was assayed at pH 1.5, 4.5, and 7.0. Data are the mean values of three independent cultivations, std. dev. <15%.

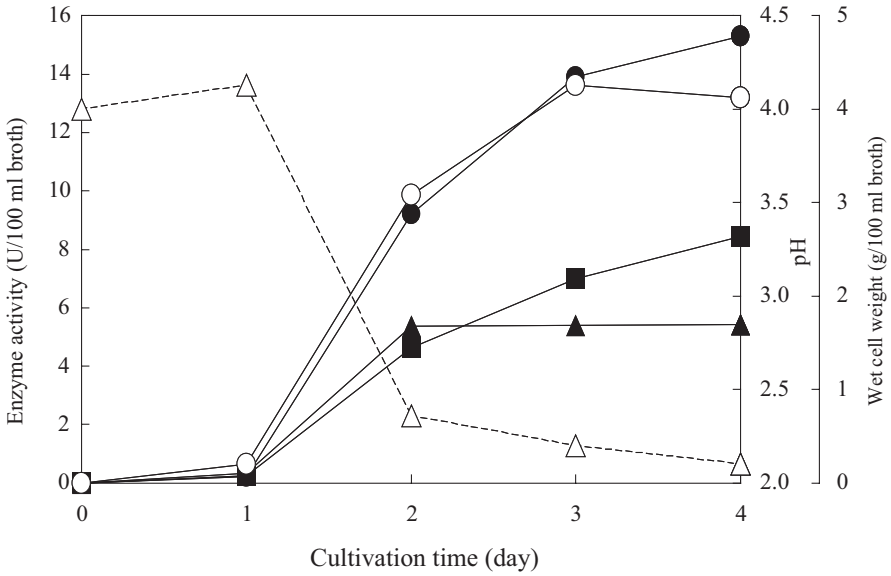

Fig. 21.1 The production of β-D-galactosidase by *T. acidotherma* AIU BGA-1 (Isobe et al. 2013a). The strain was incubated in a 3 L culture flask containing 1 L of the lactose medium at 30 °C for 4 days, and β-D-galactosidase activity was assayed each day. Enzyme activity at pH 1.5, *closed circles*; pH 4.5, *closed squares*; pH 7.0, *closed triangles*. Cell growth, *open circles*; The pH of the culture broth, *dotted line with open triangles*

21.3.4 Identification of Multiple Forms of β-D-Galactosidase

The crude enzyme solution from mycelia harvested after 2 days of cultivation was applied to DEAE-Toyopearl column chromatography, and the β-D-galactosidase activity of each fraction was assayed at pH 1.5, 4.5, and 7.0. The enzyme activity was separated into three peaks (Fig. 21.2a). The first eluate exhibited high activity at pH 7.0 (enzyme 1). The second eluate contained a discernible shoulder, and the main part exhibited high activity at pH 1.5 and low activity at pH 4.5 and 7.0, whereas the shoulder part exhibited similar activity at pH 1.5 and 4.5 (enzymes 2a plus 2b). The third eluate exhibited high activity at pH 1.5 and 4.5 (enzyme 3). The second eluate with a shoulder was further separated into two peaks by Phenyl-Toyopearl column chromatography (Fig. 21.2b), in which the former eluate exhibited high activity at pH 1.5 (enzyme 2a), and the latter eluate exhibited high activity at pH 4.5 (enzyme 2b). It was thus revealed that the BGA-1 strain produced four β-D-galactosidases.

We then analyzed the pH activity profiles of the four β-D-galactosidases between 1.0 and 8.0 by incubating at 30 °C for 60 min using the above partially purified enzymes. Enzymes 1, 2a, 2b, and 3 exhibited the highest activity at pH 8.0, 1.0–1.5, 4.0–5.5, and 2.0–4.0, respectively. Thus, enzymes 2a and 3 are acidophilic β-D-galactosidases with high activity at an extremely low pH range, and enzyme 1 is an alkalophilic β-D-galactosidase (Isobe et al. 2013a). We therefore focused on these three enzymes (1, 2a, and 3) and purified them.

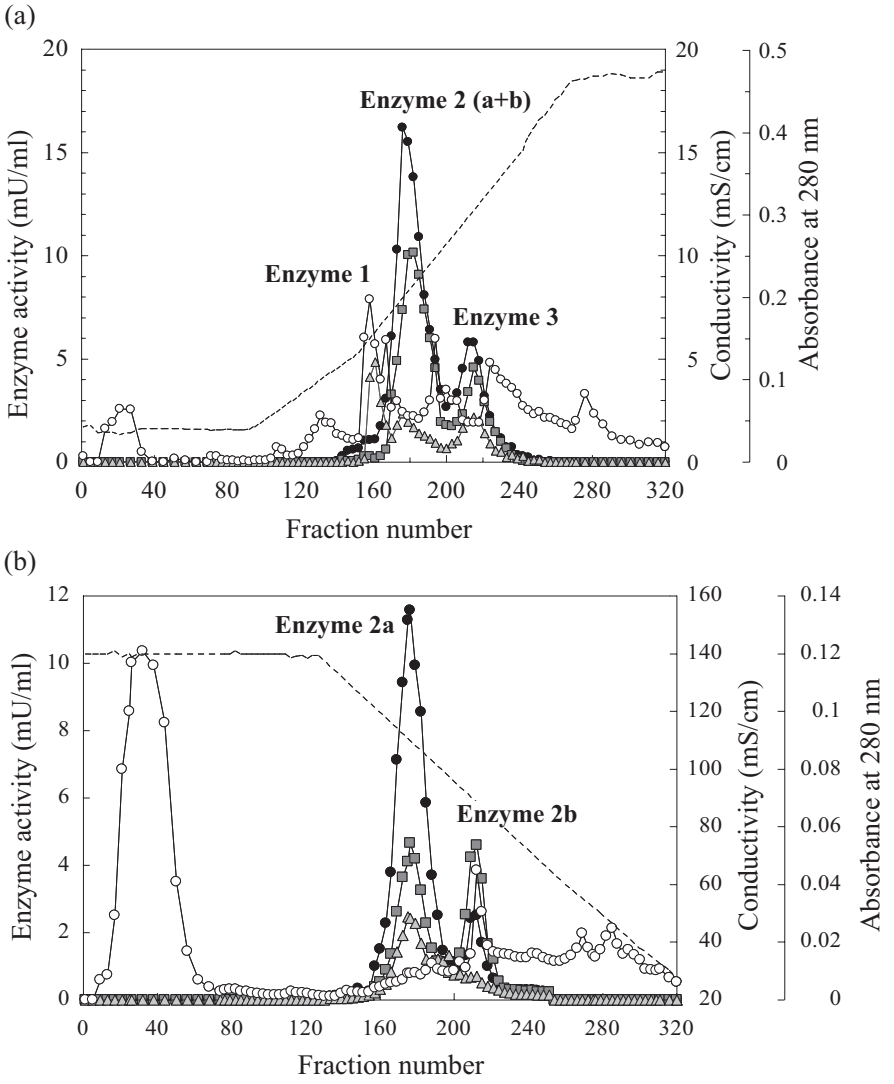

Fig. 21.2 Elution profiles of the β-D-galactosidases by column chromatography with DEAE-Toyopearl (**a**) and Phenyl-Toyopearl (**b**) columns (Isobe et al. 2013a). (**a**) The crude enzyme solution was applied to a DEAE-Toyopearl column equilibrated with 10 mM KPB, pH 6.5, and adsorbed enzymes were eluted by a linear gradient of 10 mM KPB pH 6.5 and 0.16 M NaCl. (**b**) To the second eluate from a DEAE-Toyopearl column, 1.2 M solid ammonium sulfate was added, and the enzyme solution was applied to a Phenyl-Toyopearl column. The adsorbed enzymes were eluted by a linear gradient of 20 mM KPB, pH 6.5, containing 1.2 M ammonium sulfate and 20 mM buffer. Enzyme activity at pH 1.5, *closed circles*; pH 4.5, *gray squares*; pH 7.0, gray *triangles*. The absorbance value at 280 nm, *open circles*; conductivity, *dotted lines*

21.3.5 Purification of the Three Enzymes

Since the pH stability of enzymes is important for enzyme purification, we analyzed the pH stability of the above three enzymes by incubation at pH 1.5, 5.0, and 7.0 for 3 h at 37 °C. Enzymes 2a and 3 retained >95% of the original activity at these three pH values. In contrast, enzyme 1 was stable at pH 7.0, but unstable at pH 1.5 and 5.0 (Isobe et al. 2013a). We thus purified enzymes 1, 2a, and 3 to the homogeneous state using different pH values and methods as described in the Materials and Methods section above. The specific activity of purified enzymes 1, 2a, and 3 was 4.05, 8.03, and 5.48 U/mg of protein at pH 8.5, 1.5, and 4.5, respectively (Yamada et al. 2017; Chiba et al. 2015; Isobe et al. 2013b). These purified enzymes were used for subsequent studies.

21.3.6 Molecular Mass and N-Terminal Amino Acid Sequence

The molecular mass of the native and denatured enzyme 1 was estimated to be 180 kDa by gel filtration and 120 kDa by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), indicating that enzyme 1 has a monomeric structure (Yamada et al. 2017). The molecular mass of enzyme 2a was also estimated to be 180 kDa by gel filtration. The denatured enzyme 2a was separated into two protein bands with the molecular masses of 120 and 66 kDa on SDS-PAGE (Chiba et al. 2015). The native enzyme 3 showed a molecular mass of 140 kDa by gel filtration, and the denatured state was separated into two protein bands with the molecular masses of 86 and 50 kDa on SDS-PAGE (Isobe et al. 2013b). Thus, enzymes 2a and 3 were composed of a heterodimer.

The N-terminal amino acid sequences of the large subunit of enzyme 2a and the small subunit of enzyme 3 were found to be SPNLQDIVTVDGESY and NTRMIIFNDK, respectively; those of the small subunit of enzyme 2a and the large subunit of enzyme 3 were not identified (Chiba et al. 2015; Isobe et al. 2013b). The N-terminal amino acid sequence of enzyme 1 was also not identified (Yamada et al. 2017).

21.3.7 Effect of pH on Enzyme Activity and Stability

The pH activity profiles of three enzymes were analyzed in the pH range of 1.0–10.0 by incubation at 37 °C for 15 min. Enzyme 1 exhibited the highest activity at pH 8.0, and the enzyme activity at pH 6.5 and pH 10.0 was 50% of that at pH 8.0 (Yamada et al. 2017). Enzyme 2a exhibited the highest activity at pH 1.0, and the enzyme activity at pH 3.5–4.0 was 50% of that at pH 1.0 (Chiba et al. 2015). Enzyme 3 exhibited the highest activity at pH 3.0–3.5, and the enzyme activity at pH 1.0, 1.5, and 6.0 was 50%, 85% and 80% of that at pH 3.5, respectively (Isobe et al. 2013b) (Fig. 21.3a).

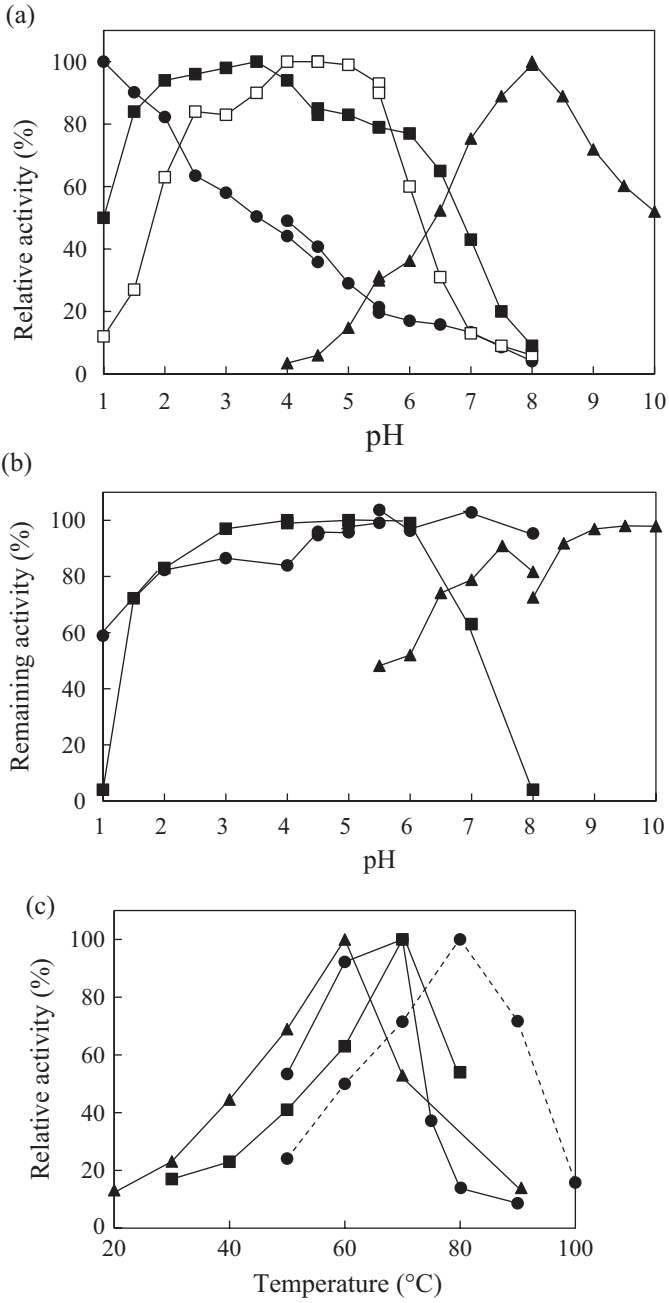

Fig. 21.3 Effects of pH and temperature on the activity and stability of the β-D-galactosidases from *T. acidotherma* AIU BGA-1 (Isobe et al. 2013b; Chiba et al. 2015; Yamada et al. 2017). (**a**) Effects of pH on enzyme activity. The β-D-galactosidase activities of enzymes 1, 2a, and 3 were

These three enzymes also exhibited different pH stability. When alkalophilic enzyme 1 was incubated at 40 °C for 30 min, >80% of the original activity remained in the pH range of 7.5–10.0, but <50% of the original activity remained below pH 6.0 (Yamada et al. 2017). When enzyme 2a was incubated at 50 °C for 30 min, >80% of the original activity remained in the pH range of 2.0–8.0, and 60% of the original activity remained at pH 1.0 (Chiba et al. 2015). Enzyme 3 retained >80% of the original activity in the pH range 2.0–6.0 by incubation at 50 °C for 60 min, and 70% and 60% of the original activity at pH 1.5 and 7.0, respectively (Isobe et al. 2013b) (Fig. 21.3b).

21.3.8 Effect of Temperature on Enzyme Activity

We analyzed the optimal temperature of the three enzymes at the optimal pH of each enzyme. Enzymes 1, 2a, and 3 exhibited the highest activity at 60, 70, and 70 °C at pH 8.5, 1.0, and 4.5, respectively. Since the stability of enzyme 2a at above pH 2.0 was higher than that at pH 1.0, we also analyzed the optimal temperature at pH 4.5, and its highest activity was obtained at 80 °C (Yamada et al. 2017; Chiba et al. 2015; Isobe et al. 2013b) (Fig. 21.3c).

21.3.9 Substrate Specificity and Kinetic Properties

We analyzed the substrate specificity of enzymes 1, 2a, and 3 at the optimal pH of each enzyme using lactose, 2-NPGA, 4-NPGA, 4-nitrophenyl β-D-glucopyranoside (4-NPGL), 4-nitrophenyl β-D-xylopyranoside (4-NPXY), 4-nitrophenyl β-D-fucopyranoside (4-NPFU), 4-nitrophenyl β-D-mannopyranoside (4-NPMA), and 4-nitrophenyl β-L-arabinofuranoside (4-NPAR). Enzyme 1 exhibited the highest activity toward 4-NPGA, and the apparent K_m value was estimated to be 0.49 mM at pH 8.5. Enzyme 1 also exhibited activity toward 2-NPGA, whose K_m value was

Fig. 21.3 (continued) assayed using the purified enzymes under standard conditions using the indicated buffer and pH. The β-D-galactosidase activity of enzyme 2b was assayed using partially purified enzyme 2b (the eluate from Phenyl-Toyopearl column chromatography). The relative activities are shown as a percentage of the highest activity for each enzyme. (**b**) The pH stability. Enzymes 1, 2a, and 3 were incubated at 40 °C for 30 min, 50 °C for 30 min, and 50 °C for 60 min, respectively, without substrate. The enzyme activities before and after heating were assayed under the standard assay conditions of each enzyme. The remaining activities are shown by the percentage to the enzyme activity without heating. (**c**) Effects of temperature on enzyme activity. The β-D-galactosidase activities of enzymes 1, 2a, and 3 were assayed at the optimal pH of each enzyme at the indicated temperatures. The activity of enzyme 2a was also assayed at pH 4.5 (*dotted line with closed circles*). The β-D-galactosidase activity of enzyme 1, *closed triangles*; enzyme 2a, *closed circles*; enzyme 2b, *open squares*; and enzyme 3, *closed squares*

Table 21.3 Substrate specificity and kinetic values of enzymes 1, 2a, and 3 (Yamada et al. 2017; Chiba et al. 2015; Isobe et al. 2013b)

	Enzyme 1		Enzyme 2a				Enzyme 3	
	Relative activity (%) (10 mM)	K_m (mM)	Relative activity (%) (10 mM)		K_m (mM)		Relative activity (%) (20 mM)	K_m (mM)
Substrate	pH 8.5	pH 8.5	pH 1.5	pH 4.5	pH 1.5	pH 4.5	pH 4.5	pH 4.5
2-NPGA	37.8	0.35	59.2	31.8	0.82	0.43	62.5	0.19
4-NPGA	100	0.49	23.8	86.7	0.46	0.41	100	1.2
4-NPFU	<5	n.d.	100	100	n.d.	n.d.	10	n.d.
Lactose		701			618			170

Enzyme activities for 2-NPGA, 4-NPGA, and 4-NPFU were assayed under standard assay conditions at the optimal pH or stable pH of each enzyme. The relative activities are expressed as a percentage of the highest enzyme activity. The lactose-hydrolyzing activity was assayed by the glucose oxidase method. The substrate concentrations for estimating the K_m value for 2-NPGA, 4-NPGA, and lactose are described in references (Yamada et al. 2017; Chiba et al. 2015; Isobe et al. 2013b). n.d., not detectable. *2-NPGA* 2-nitrophenyl-β-D-galactopyranoside, *4-NPGA* 4-nitrophenyl-β-D-galactopyranoside, *4-NPFU* 4-nitrophenyl β-D-fucopyranoside

estimated to be 0.35 mM, but it did not exhibit activity toward the other nitrophenyl pyranosides tested. The K_m value for lactose was estimated as 701 mM by the glucose oxidase method (Yamada et al. 2017).

Enzyme 2a exhibited high activity toward 4-NPFU, 2-NPGA, and 4-NPGA at pH 1.5 and 4.5. Among these substrates, 4-NPFU was the best substrate, but its K_m value was not estimated because the reaction rate for 4-NPFU increased almost linearly up to 40 mM 4-NPFU. The apparent K_m value for 2-NPGA was estimated as 0.82 mM at pH 1.5, and 0.43 mM at pH 4.5, respectively. That for 4-NPGA was 0.46 mM at pH 1.5, and 0.41 mM at pH 4.5. The value for lactose was 618 mM at pH 1.5 (Chiba et al. 2015).

Enzyme 3 exhibited the highest activity for 4-NPGA, and 2-NPGA was also a good substrate at pH 4.5. The apparent K_m values for 2-NPGA, 4-NPGA, and lactose were estimated as 0.19, 1.2, and 170 mM, respectively (Isobe et al. 2013b) (Table 21.3).

21.3.10 Inhibitor Specificity

Enzyme 1 was activated and stabilized by Mn^{2+} but inhibited by chelating reagents (EDTA and *o*-phenanthroline) and metals (Cu^{2+} and Ni^{2+}) (Yamada et al. 2017). Enzymes 2a and 3 were not remarkably affected by carbonyl or the chelating and sulfhydryl reagents or metals tested (Chiba et al. 2015; Isobe et al. 2013b).

21.3.11 Hydrolysis of Lactose, Milk, and Whey

When enzyme 1 was incubated with lactose at 37 °C for 20 h at pH 8.5, galactose and glucose were identified as the products from lactose, and several other spots were detected at a different position from those of the galactose and glucose by TLC analysis (Fig. 21.4a). This result indicated that enzyme 1 would have galacto-oligosaccharide formation activity at the alkaline pH range (Yamada et al. 2017). In the

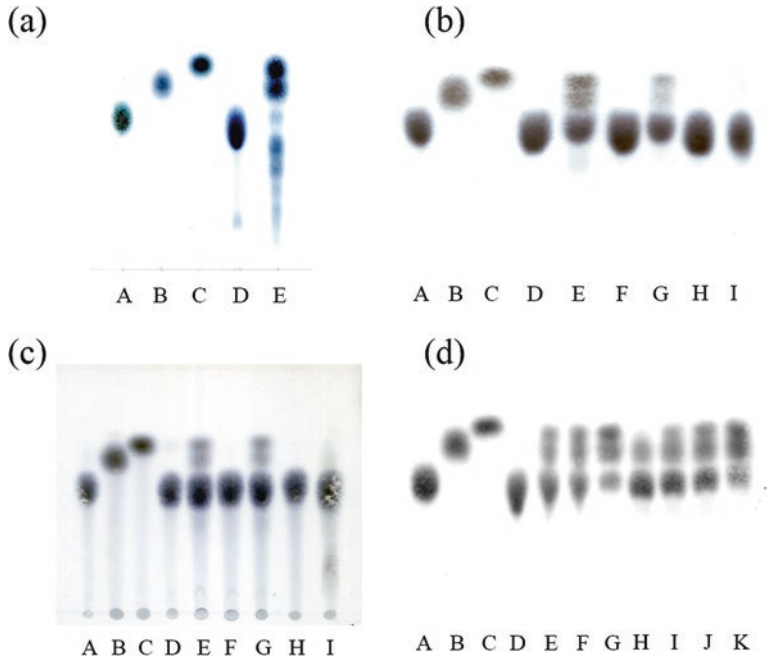

Fig. 21.4 TLC analysis of the reaction products from lactose by hydrolysis with β-D-galactosidases from *T. acidotherma* AIU BGA-1 (Yamada et al. 2017; Chiba et al. 2015; Isobe et al. 2013b). Enzymes 1, 2b, and 3 were each incubated with lactose, and the reaction was terminated by boiling. The reaction products were detected as described in the Materials and Methods section. (**a**) Enzyme 1 (16 mU) was incubated with 0.3 M lactose and 2 mM $MnCl_2$ at 37 °C and pH 8.5 for 20 h. A, lactose; B, galactose; C, glucose; D, lactose without enzyme 1; E, lactose with enzyme 1. (**b**) Enzyme 2a (4.2 mU) was incubated with 0.1 M lactose at 37 °C for 20 h at pH 1.5, 4.5, and 7.0. A, lactose; B, galactose; C, glucose; D, lactose incubated at pH 1.5 without enzyme; E, lactose incubated at pH 1.5 with enzyme 2a; F, lactose incubated at pH 4.5 without enzyme; G, lactose incubated at pH 4.5 with enzyme 2a; H, lactose incubated at pH 7.0 without enzyme; I, lactose incubated at pH 7.0 with enzyme 2a. (**c**) Enzyme 3 (4.2 mU) was incubated with 0.1 M lactose under the same conditions as those used for enzyme 2a. The lines of TLC are also the same as that in panel (**b**). (**d**) Milk or whey from yogurt adjusted to pH 1.5 was incubated with enzyme 2a (50–300 mU) at 50 °C for 20 h. A, lactose; B, galactose; C, glucose; D, milk without enzyme; E, milk with 50 mU of enzyme 2a; F, milk with 100 mU of enzyme 2a; G, milk with 300 mU of enzyme 2a; H, whey without enzyme; I, whey with 50 mU of enzyme 2a; J, whey with 100 mU of enzyme 2a; K, whey with 300 mU of enzyme 2a

cases of enzymes 2a and 3, the formation of galactose and glucose was also identified from lactose by incubation at pH 1.5 and 4.5, but other new spots were not detected. Neither enzyme hydrolyzed lactose by incubation at pH 7.0 (Chiba et al. 2015; Isobe et al. 2013b) (Fig. 21.4b, c). These results agreed with the pH activity profiles of both enzymes. We then incubated enzyme 2a with milk or whey at pH 1.5, and we observed that the enzyme efficiently catalyzed the hydrolysis of lactose in milk and whey into galactose and glucose at an extremely low pH range (Chiba et al. 2015) (Fig. 21.4d).

21.4 Discussion

There is increasing demand for enzymes with high activity and stability at a low pH range in order to expand the application of enzymes into extremely low pH ranges. Since fungi generally grow well in the low pH range, they have attracted attention as producers of such enzymes. However, there have been only a few reports on the isolation of fungal strains that produce extremely acidophilic enzymes. We isolated *T. acidotherma* AIU BGA-1 from an acidic hot spring as a new producer of extremely acidophilic β-D-galactosidases. This strain grew well in the pH range 2.0–4.0, and its growth rate slowed down at pH 5.0 and 6.0. The production of β-D-galactosidases was also highest by incubation at pH 3.0 and decreased by shifting the initial pH to 5.0–6.0. These results are in agreement with our previous finding that when fungal strains capable of growing well under extremely acidic conditions at high temperature were cultivated with a liquid medium with the initial pH of 3.0, the final pH of the culture broth varied widely between 2.5 and 9.0, and enzymes with high activity and stability at the low pH range were obtained in the strains maintained at pH below 6.0 (Isobe et al. 2006). Thus, the isolation of fungal strains that grow well under extremely low pH and high temperature conditions was effective to obtain extremely acidophilic enzymes.

T. acidotherma AIU BGA-1 showed interesting enzyme production characteristics. This strain produced four β-D-galactosidases with different pH activity profiles in the mycelia, two extremely acidophilic enzymes, one acidophilic enzyme, and one alkalophilic enzyme, although the strain grew well in the acidic pH range. Regarding the production of multiple forms of β-D-galactosidase, it was reported that *A. niger* produced three extracellular β-D-galactosidases with different molecular masses (Widmer and Leuba 1979). All of these enzymes exhibited high activity at the pH range 2.0–5.0, and their pI values and amino acid compositions were similar, whereas their carbohydrate contents differed. It was thus presumed that the multiple forms of the *A. niger* β-D-galactosidase are due to the differences of the carbohydrate content.

It was also reported that *Aspergillus carbonalius* produced two extracellular β-D-galactosidases with different pH activity profiles (one is optimal at pH 2.5–3.5 and

the other is optimal at pH 3.0–3.5; both enzymes have no activity at pH 1.5) and different molecular masses (O'Connell and Walsh 2008). Although both enzymes are glycoproteins, their amino acid compositions differ. Thus, multiple forms of the *A. carbonalius* β-D-galactosidase are related to the differences in amino acid and carbohydrate compositions. Multiple forms of β-D-galactosidase were also demonstrated from a commercial enzyme powder produced by *Saccharomyces lactis* (Mbuyi-Kalala et al. 1988). The enzyme powder contained four β-D-galactosidases with different molecular mass and carbohydrate content values. The β-D-galactosidases exhibited high activity at the neutral pH range, and the multiplicity of the *Saccharomyces* β-D-galactosidase was affected by the differences in carbohydrate content in a manner similar to that of the *A. niger* β-D-galactosidases. In contrast to these strains, *T. acidotherma* AIU BGA-1 produced four intracellular β-D-galactosidases with widely different pH activity profiles: two were extremely acidophilic, one was acidophilic, and one was alkalophilic. Thus, *T. acidotherma* AIU BGA-1 is the first fungal producer of multiple forms of intracellular β-D-galactosidase with widely different pH activity profiles.

Among the three acidophilic β-D-galactosidases from *T. acidotherma* AIU BGA-1, enzyme 2a exhibited the highest activity at pH 1.0. Enzyme 3 exhibited the highest activity at pH 3.0–3.5, and the enzyme activity at pH 1.0 was 50% of that at pH 3.0. Enzyme 2b exhibited the highest activity at pH 4.0–5.0, and the enzyme activity at pH 2.0 and pH 1.0 was 63% and 12% of that at pH 4.0, respectively (Fig. 21.3a). Thus, enzymes 2a and 3 are extremely acidophilic.

Many acidophilic β-D-galactosidases with high activity at a low pH range have been identified from different fungal strains (Table 21.4). Most of those acidophilic enzymes exhibit maximal activity in the pH range 2.5–5.5 (Gonzalez and Monsan 1991; Hatzinikolaou et al. 2005; Isobe et al. 2013b; Manzanares et al. 1998; Nagy et al. 2001; O'Connell and Walsh 2008; Shaikh et al. 1999; Takenishi et al. 1983; Widmer and Leuba 1979). An acidophilic β-galactosidase with maximum activity at pH 1.5 was isolated from *Bispora* sp., and its enzyme activity at pH 1.0 was 60–70% of that at pH 1.5 (Wang et al. 2009). Thus, enzyme 2a from *T. acidotherma* AIU BGA-1 exhibited the lowest optimal pH value among the microbial β-D-galactosidases reported to date. Enzyme 2a also exhibited its highest stability and highest optimal temperature at extremely acidic pH values among the known microbial β-D-galactosidases.

With respect to the physicochemical properties of microbial β-D-galactosidases, enzymes 2a and 3 differ from the acidophilic enzymes from *Penicillium chrysogenum* (Nagy et al. 2001) and *Rhizopus* sp. (Shaikh et al. 1999) in terms of molecular mass and subunit compositions. Enzyme 2a has a 180 kDa molecular mass with two heterosubunits of 120 and 66 kDa. Enzyme 3 has a 140 kDa molecular mass composed of two heterosubunits of 86 and 50 kDa (Chiba et al. 2015; Isobe et al. 2013b). In contrast, the enzyme from *P. chrysogenum* and the enzyme from *Rhizopus* sp. have a 270 kDa molecular mass with four identical subunits and a 250 kDa molecular mass with two identical subunits, respectively. Enzymes 2a and 3 from

Table 21.4 Comparison of characteristics of acidophilic β-D-galactosidases from fungal strains

Origin	Mol. mass (kDa)	Subunit (kDa)	K_m value (mM)		Active range (pH)	Opt-pH	pH-Stab	Opt-temp (°C)	Inhibitor	pI	Refs.
			2-NPG	Lactose							
Enzyme 2a	180	66, 120	0.43	618	1.0–4.5	<1.0	1.0–8.0	80	Non	4.6	Chiba et al. (2015)

A. niger				32–89	2.5–6.0	3.0–3.5	3.0–6.0	65			Hatzinikolaou et al. (2005)
A. niger	124–173		2.4	85–125	1.7–5.2	3.5		70		4.6	Widmer and Leuba (1979)
A. niger	93	93	1.3			4.0	3.0–5.0	60–65		4.6	Manzanares et al. (1998)
A. fonsecaeus	126		1.8	61	2.0–6.0	2.6–4.5				4.2	Gonzalez and Monsan (1991)
P. chrysogenum	270	66	1.8		3.5–6.5	4		30		4.6	Nagy et al. (2001)
P. multicolor	126	130	0.6	8.9	2.0–6.0	4.0	3.5–7.5	60	Hg^{2+}, Cu^{2+}		Takenishi et al. (1983)
Rhizopus sp.	250	120	1.3	50		4.5	3.5–7.5	60	Hg^{2+}, Cu^{2+}	4.2	Shaikh et al. (1999)
T. thermophilus	49	50	24	18	4.5–7.0	5.5–6.0	5.5–7.5	50	Cu^{2+}	4.5	Nakkharat and Haltrich (2006)
A. carbonarius	139	110	2.6	83	3.0–6.0	3.0–3.5		55			O'Connell and Walsh (2008)
A. carbonarius	152	120	0.56	309	2.0–5.5	2.5–3.0		65			O'Connell and Walsh (2008)
Bisopra sp.	130	130	5.2	0.31	1.0–3.0	1.5	1.5–6.0	60	SDS, ME		Wang et al. (2009)

Talaromyces acidotherma AIU BGA-1 are also clearly different from acidophilic enzymes from *A. niger* (Manzanares et al. 1998; Widmer and Leuba 1979), *T. thermophilus* (Nakkharat and Haltrich 2006), *Penicillium multicolor* (Takenishi et al. 1983), *Aspergillus fonsecaeus* (Gonzalez and Monsan 1991), *Aspergillus carbonarius* (O'Connell and Walsh 2008), and *Bispora* sp. (Wang et al. 2009), because these seven enzymes each has a monomeric structure.

Although *T. acidotherma* AIU BGA-1 grew well at pH 2.0–4.0, the strain also produced alkalophilic β-D-galactosidase (enzyme 1) with optimal activity at pH 8.0 and high stability at pH 7.0–10.0 (Yamada et al. 2017). To date, many acidophilic and neutrophilic β-D-galactosidases have been isolated from fungal strains, but alkalophilic β-galactosidases with maximal activity at pH 7.5–10.5 have been derived only from bacterial strains such as *Meiothermus ruber* DSM 1279 (Gupta et al. 2012), *Bacillus* sp. MTCC 3088 (Chakraborti et al. 2000), *Enterobacter cloacae* B5 (Lu et al. 2009), *Pseudoalteromonas* sp. (Fernandes et al. 2002), *Arthrobacter* sp. ON14 (Xu et al. 2011), and *Arthrobacter psychrolactophilus* F2 (Nakagawa et al. 2007) (Table 21.5). Thus, *T. acidotherma* AIU BGA-1 is the first fungal producer of alkalophilic β-D-galactosidase.

Among these alkalophilic β-D-galactosidases, the enzymes from *M. ruber* DSM 1279, *Bacillus* sp. MTCC 3088, and *E. cloacae* B5 exhibited not only lactose hydrolysis activity but also transgalactosylation activity to catalyze the formation of galacto-oligosaccharide (Chakraborti et al. 2000; Gupta et al. 2012; Lu et al. 2009; Wang et al. 2014). Since *T. acidotherma* enzyme 1 also produced galacto-oligosaccharides by incubation with lactose, the enzyme would catalyze the same reactions as those by bacterial alkalophilic β-D-galactosidases, whereas the K_m value of enzyme 1 for lactose was higher than that of bacterial enzymes.

Regarding physicochemical properties, *T. acidotherma* enzyme 1 has a monomeric structure with a 180-kDa molecular mass. On the other hand, enzymes from *M. ruber* DSM 1279, *Bacillus* sp. MTCC 3088, and *E. cloacae* B5 have the molecular mass of 190, 484, and 442 kDa, respectively, and are composed of hetero- or identical subunits (Chakraborti et al. 2000; Gupta et al. 2012; Lu et al. 2009). Thus, alkalophilic β-D-galactosidase from *T. acidotherma* AIU BGA-1 catalyzes the same reaction, but the structure is different from the structures of these three bacterial enzymes. The optimal temperature of *T. acidotherma* enzyme 1 is also significantly different from those of the alkalophilic β-D-galactosidases from *E. cloacae* (Lu et al. 2009), *Pseudoalteromonas* sp. (Fernandes et al. 2002), *Arthrobacter* sp. (Xu et al. 2011), and *A. psychrolactophilus* (Nakagawa et al. 2007) (Table 21.5).

Table 21.5 Comparison of characteristics of alkalophilic β-D-galactosidases from microorganisms

Origin	Mol. mass (kDa)	Subunit (kDa)	K_m value (mM)		Opt-pH	Opt-temp (°C)	Inhibitor (metals)	Activator (metals)	Refs.
			2-NPGA	Lactose					
Enzyme 1	180	120	0.35	701	8.0	60	Cu^{2+}, Ni^{2+}	Mn^{2+}	Yamada et al. (2017)
M. ruber	190	46	5.0	333	8.0	65	Cu^{2+}, Cd^{2+}, Fe^{2+}	Mn^{2+}, Zn^{2+}	Gupta et al. (2012)
Bacillus sp.	484	115, 87, 72, 46, 41			8.0	60	Cu^{2+}, Ni^{2+}, Hg^{2+}, Ag^{2+}	Mg^{2+}	Chakraborti et al. (2000)
E. cloacae	442	119	0.01	0.3	7.5–10.5	35			Lu et al. (2009)
Pseudoalteromonas sp.	513	110	0.16		9.0	26	Cu^{2+}, Zn^{2+}, Hg^{2+}	Mg^{2+}, Mn^{2+}	Fernandes et al. (2002)
Arthrobacter sp.		116			8.0	15	Cu^{2+}, Zn^{2+}	Mg^{2+}, Mn^{2+}	Xu et al. (2011)
A. psychrolactophilus		130	2.7	42.1	8.0	10			Nakagawa et al. (2007)

21.5 Conclusions

The strain *T. acidotherma* isolated from an extremely low-pH and high-temperature environment grew well at a low pH range and produced four intracellular β-D-galactosidases by incubation with lactose: two extremely acidophilic enzymes, one acidophilic enzyme, and one alkalophilic enzyme. This strain will be useful to obtain β-D-galactosidases with different pH activity profiles by one cultivation. Among these enzymes, the two extremely acidophilic enzymes and the single alkalophilic enzyme are novel β-D-galactosidases. The extremely acidophilic enzymes are desirable for the efficient hydrolysis of lactose in milk or whey at an extremely low pH range. The alkalophilic enzyme would be applicable to the production of galacto-oligosaccharides. Thus, the β-D-galactosidases from *T. acidotherma* AIU BGA-1 have great advantages for industrial applications.

Chapter 22
Fungi from Extreme Environments: A Potential Source of Laccases Group of Extremozymes

Om Prakash, Kapil Mahabare, Krishna Kumar Yadav, and Rohit Sharma

22.1 Introduction

Laccases are a mixture of synergistic enzymes and include laccase, phenol oxidase, phenol peroxidase, lignin peroxidase, manganese peroxidase, tyrosinase, etc. They are copper-containing blue phenol oxidase and are common among various groups of organisms including bacteria, fungi and plants (Mayer 2006). Various groups of plants, animals and microbes produce phenol oxidases, both intracellular and extracellular, for a variety of purposes. Fungi, the second largest members of eukaryotic kingdom produce variety of phenol oxidases. Among all the fungi, *Ascomycota* and *Basidiomycota* particularly produce intracellular phenol oxidases and use them to synthesize protective compounds like melanin (pigmentation), in spore formation and detoxification of toxic compounds from their environment. Phenol oxidase enzymes are also responsible for fungal pathogenicity due to their plant cell wall lignin degradation potential. These enzymes hydrolyze lignocelluloses present in agro-waste, especially facilitating the degradation of lignin component which is the most complex constituent of plant cell wall. These are non-specific enzymes which can act on variety of phenolic substances. Hence, they are flexible and can be used in a range of industrial processes (Nigam 2013). These enzymes are well known in bioremediation, industrial effluent treatment containing hazardous chemicals like dyes, phenols and other xenobiotic compounds (Robinson et al. 2001a, b; Robinson and Nigam 2008; Dahiya et al. 2001). It is quite popular that the leather industry has adopted eco-friendly methods for tanning process using keratinases instead of chemicals. Similarly pulp and paper industries have adopted treatment of wood pulp by ligninolytic enzymes for lignin degradation. These ligninolytic enzymes are also

being used in the wine, fruit juice and denim industries (Dahiya et al. 1998). Recently, concerns for decontamination of hazardous chemicals and environmental contaminants have been increased, especially in developing countries. India is also taking immense efforts in this direction to treat these hazardous compounds before releasing them in the environment. There are many compounds which are causing toxic effects on health and also damaging environment due to their presence in water bodies. This adversely affects soil and water microbiota, aquatic life, plants and human health. In humans, it is reported to cause cardiac toxicity, liver and kidney damage, neurotoxicity, reproductive and developmental toxicity and reduced blood pressure. Such compounds have long persistence in the environment and also show bioaccumulation and biomagnification in plants and animals. As discussed earlier, these are naturally present in fruits and part of plant components. Many phenolic compounds are also produced by humans through manufacturing of various day-to-day materials. At present, aquatic environments including rivers, pond, lakes, etc. are the most affected habitats in terms of phenolic contamination. These compounds enter the water bodies through natural, industrial, domestic and agricultural practices (Wallace 1996). Decomposition is not a problem for naturally produced phenols of plants and fruits origin because nature has developed the mechanism for their degradation. Wastewater from industries is really a matter of concern as it accumulates phenolic compounds in large quantity, which is difficult to manage. These compounds are also present in effluent of chemical and pharmaceutical industries, including petroleum refineries, petrochemical industries, coal gasification, resin manufacturing industries, dye synthesis units, pharmaceutical industries, pulp and paper mills, etc. In several countries, due to lack of standard norms, these compounds are gradually increasing in water bodies and creating health hazards in rivers. In addition, phenolic compounds also undergo transformation due to presence of other compounds in the aquatic body and microbial activities (Kulkarni and Kaware 2013). Due to their harmful effects, there is an urgent need to remove them from the environment (Huang et al. 2015; Nuhoglu and Yalcin 2005). Phenolic compounds are diverse in nature but in this chapter we will give the emphasis on three main types of compounds, namely phenol, cresol and alkyl phenol.

Many industries like pulp and paper are nowadays focusing on research on fungal and bacterial based bioremediation strategies due to their ability to synthesize polyphenol oxidase. It can be used for degradation of lignocelluloses and residual polyaromatic hydrocarbons for production of pulp, transformation of fuels and bioremediation of soils contaminated with toxic products (Duran et al. 2002; Claus 2003, 2004; Rabinovich et al. 2004; Masai et al. 2007) (Table 22.1). Fungi are the most potent producers of enzymes involved in lignin degradation. They require these enzymes for penetration into the plants cell wall, degradation of wood and litter biomass, etc. Pathogenic fungi and wood-rotting fungi have been studied in detail for the production of laccases (Robinson et al. 2001a, b; Robinson and Nigam 2008). These enzymes have been produced economically using several agricultural wastes as substrates on a large scale (Nigam and Pandey 2009).

Among fungi, they are mainly produced by members of *Basidiomycota* and *Ascomycota* while *Zygomycota*, *Chytridiomycota* and *Glomeromycota* are not reported to produce them. Several members of *Ascomycota* and *Basidiomycota* produce these enzymes, *viz., Podospora anserine, Sclerotinia sclerotium, Pleurotus ostreatus, P. sapidus, Agaricus bisporus, Lentinus edodes, Schizophyllum commune, Trichoderma versicolor* and many other wood-rotting fungi (Bodke et al. 2012). There is only one report of slime moulds, *Physarum polycephalum* (Daniel et al. 1963), for this activity.

Fungi from extreme environment have also been studied to obtain suitable enzymes which can work in the harsh conditions of fermentation and in the conditions of paper-pulp delignification and waste treatment. Pulp and paper industries usually use thermophilic enzymes. Five thermophilic laccase enzyme isoforms were isolated, purified and characterized from xerophytic plants *Cereus pterogonus* and *Opuntia vulgaris* (Gali and Kotteazeth 2012, 2013; Kumar and Srikumar 2011, 2012). Different forms of laccases with extraordinary properties have been obtained from fungi like *Steccherinum ochraceum* and *Polyporus versicolor* (Chernykh et al. 2008; Nigam 2013). Several fungi, *viz., Curvularia lonarensis, Penicillium* sp., and *Trametes* sp., have been reported from various extreme environments (thermophiles, alkaliphiles, psychrophiles, marine fungi, etc.) which have been studied for the laccase enzyme production potentials (Sharma et al. 2016; Dhakar et al. 2014; Dhakar and Pandey 2013) which we discuss below in detail.

Fungal based biotechnology is still in the developmental stage since past few decades and has improved significantly. Fungi from terrestrial origin have diverse properties and are used in the production of antibiotics, extracellular enzymes, organic acids, etc. (Pointing and Hyde 2001) (Fig. 22.1a). In the past couple of decades, fungi have also been used as 'cell factories' due to the advancement in molecular and genetic tools (Punt et al. 2002). Only few studies are available on fungal laccases from extremophilic fungi as compared to terrestrial and mesophilic

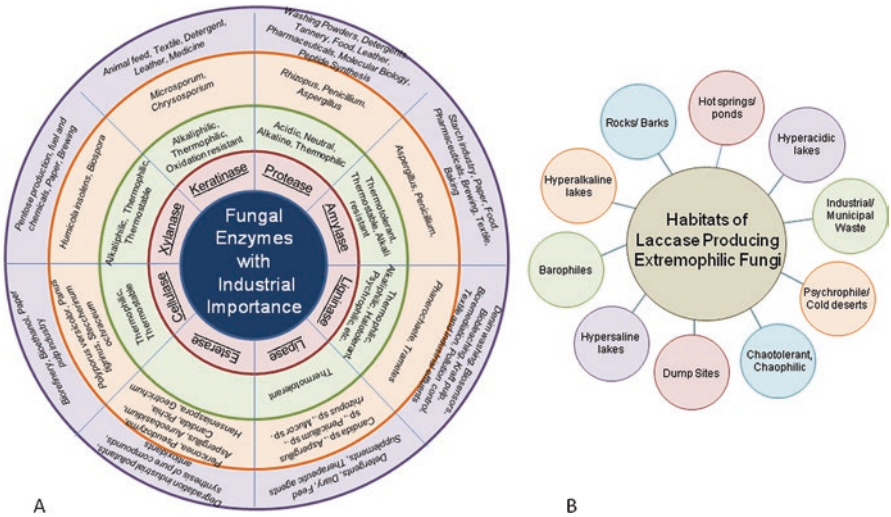

Fig. 22.1 (**a**) Scope of industrial applications of various enzymes produced by fungi in industries, viz., textile, paper pulp, food and feed, and pharmaceutical industries. (**b**) Habitats of laccase-producing fungi from extreme environments

counterparts. What prospects do the extremophilic fungi have in such situation? Why and how these fungi have become more important target group of organisms for pharmaceutical and environmental perspectives? This chapter discussed importance of extremophilic fungi in production of laccases in association with description of fungal diversity from extremophilic environments as it helps to understand the distribution of laccases producing fungi. The emphasis is on (a) molecular biology and genetics of fungal laccases, (b) factors affecting production of laccases from extremophilic fungi and (c) recent advances on fungal laccases and potential of fungal laccases from extreme habitats.

22.2 Laccases Producing Fungi from Extreme Habitats

Fungi living in extreme environment such as high or low temperatures (thermophiles and psychrophiles), high salinity (halophiles), acidic or alkaline pH values (acidophiles and alkaliphiles, respectively), anoxygenic conditions (anaerobic fungi), high pressures (barophiles), etc. (Poli et al. 2017; Dalmaso et al. 2015; Magan 2007) are known as extremophilic fungi (Fig. 22.1b). Many reports are available on extracellular phenol oxidase by fungi from different habitats (Crognale et al. 2012) but only a few studies on laccase-producing fungi from extreme environment like marine, hot springs and soda lakes are available.

22.2.1 Laccase from Alkaliphilic Fungi

The hyperalkaline habitat has both ecological and industrial significance as in high alkaline condition very few fungi can grow. It has been reported that most of the municipal wastewater treatment plants and effluents from industries have high alkalinity, and high concentration of metal ions. Hence fungi surviving in such conditions and with laccase-producing capacity can work as excellent bioinoculant for bioaugmentation-based bioremediation. Functional metagenomic studies of Soda Lake have showed that many uncultured fungi have laccases-like Cu-oxidase encoded with potential in degradation of phenolic compounds (Vavourakis et al. 2016; Ausec et al. 2011). Crognale et al. (2012) had also reported phenol oxidase-producing halotolerant fungi from olive brine wastewater. Sharma et al. (2016) isolated 104 fungal strains from Lonar lake (Fig. 22.2), a hyperalkaline habitat, and 14 were positive for enzyme production in primary screening using 2,2′-azino-bis-(3-ethylbenzthiazoline-6-sulfonic acid (ABTS) as substrate. It included *Fusarium equiseti*, *Curvularia lonarensis*, *Cladosporium funiculosum*, *Cladosporium oxysporum*, *Cladosporium halotolerans*, *Aspergillus niger*, a probable novel *Cladorrhinum* species and an unidentified fungus. Among these *Fusarium* sp. MEF008, *Curvularia lonarensis* MEF018 (Fig. 22.2), *Cladorrhinum* sp. MEF109 and *Cladosporium* sp. MEF135

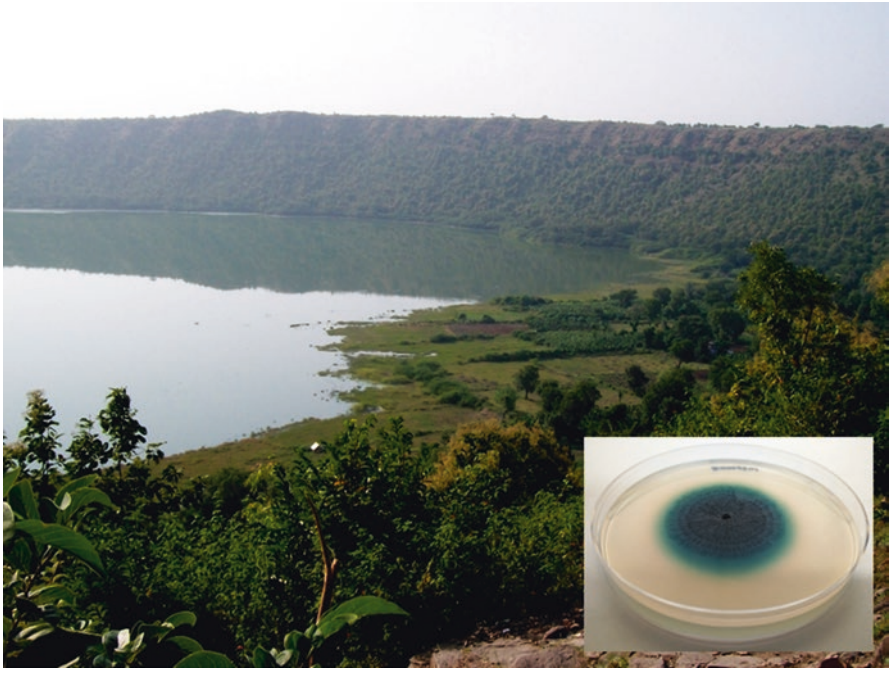

Fig. 22.2 View of Lonar Lake, an alkaliphilic lake located at Buldhana district of Maharashtra state, India; (inset) plate showing culture (MEF018) positive for phenol oxidase production containing ABTS as substrate

Table 22.2 List of phenol oxidase-producing fungi isolated from Lonar Lake

Serial No.	Strain Id's	Identification	Isolated from	Phenol oxidase
1	MEF008	*Fusarium equiseti*	Lonar Lake	+++
2	MEF018	*Curvularia lonarensis*	Lonar Lake	++++
3	MEF040	*Cladosporium funiculosum*	Lonar Lake	+
4	MEF041	*Cladosporium oxysporum*	Lonar Lake	+
5	MEF135	*Cladosporium oxysporum*	Lonar Lake	+++
6	MEF062	Unidentified	Lonar Lake	+
7	MEF073	*Cladosporium halotolerans*	Lonar Lake	+
8	MEF095	*Aspergillus niger*	Lonar Lake	+
9	MEF104	*Cladorrhinum* sp. nov.	Lonar Lake	+
10	MEF121	*Cladorrhinum* sp. nov.	Lonar Lake	+
11	MEF127	*Cladorrhinum* sp. nov.	Lonar Lake	+
12	MEF109	*Cladorrhinum* sp.	Lonar Lake	+++
13	MEF133	*Cladorrhinum* sp.	Lonar Lake	+
14	MEF134	*Cladorrhinum* sp.	Lonar Lake	+

were higher phenol oxidase producer (Table 22.2). *Curvularia lonarensis* MEF018, an alkaliphilic fungus with potential to be exploited industrially, produced laccases at 40 °C, pH 12–14, and at salinity of 3%. While working on Lonar Lake, we observed that the fungi which were collected from the banks of the lake with wooden debris had showed phenol oxidase activity. The lake which is reported to be formed by meteor impact is surrounded by trees of *Acacia* sp. The wooden debris of trees falls on the lake water, leaching phenol in the lake water with time. In due course of time, fungi colonizing the wooden debris have developed the ability to produce laccase enzymes, thus playing an important role in the lake ecosystem. Such ecological adaptations of fungal strains have helped them to develop capacity to produce metabolites and enzymes which act at high temperature, pH, or salt concentrations.

22.2.2 Laccase from Marine Fungi

The applications of laccases in degradation of xenobiotics by aquatic, obligate marine (and marine-derived) fungi have been observed (Martin et al. 2009; Junghanns et al. 2009; Pointing and Hyde 2000; Li et al. 2002). These marine fungi produce unique secondary metabolites and enzymes not reported from fungi residing in terrestrial habitats (Jensen and Fenical 2002). D'Souza-Ticlo et al. (2009a, b) reported that a marine isolate of *Cerrena unicolor* MTCC 5159 produces halotolerant laccase and also degrades raw textile mill effluents (Verma et al. 2010). Generally, marine fungi are able to grow on decaying lignocelluloses substrates like branches, leaves, and woods of mangroves which include mostly the members of *Ascomycota* and with few exceptions of species of *Basidiomycota* (Hyde and Jones 1988). Marine fungi play an important role in the degradation of mangrove leaves, wood pieces and other wooden

debris on the shores, thus forming detritus. These fungi play a significant role in the mineralization in the tropical marine ecosystem. However, the information related to marine laccase is still sparse and needs more work on the characterization of the type of lignin-modifying enzymes present in marine ecosystems. Raghukumar et al. (1994) isolated 17 fungi from marine habitats, out of which 12 were laccase positive which included *Gliocladium* sp., *Sordaria fimicola*, *Gongronella* sp., *Aigialus grandis*, *Halosarpheia ratnagiriensis*, *Verruculina enalia*, *Cirrenalia pygmea*, *Zalerion varium* and *Hypoxylon oceanicum.* Jaouani et al. (2014) have explored the fungal diversity of Sebkha El Melah, a Saharan salt flat located in southern Tunisia and isolated 21 moderately halotolerant fungi. It included 15 taxa belonging to 6 genera of *Ascomycota*, *viz., Cladosporium* spp., *Alternaria* spp., *Aspergillus* spp., *Penicillium* spp., *Ulocladium* sp. and *Engyodontium* sp. Three species out of 15 showed laccase activities at 10% NaCl, viz., *Cladosporium halotolerans*, *Cladosporium sphaerospermum* and *Penicillium canescens*. Laccase production at 10% salt by these strains is of biotechnological interest, especially in bioremediation of organic pollutants in high salt-contaminated environments.

22.2.3 Laccase from Thermophilic Fungi

Now we know that life can exist in extreme environments and molecular studies related to their survival mechanisms in extreme condition shed new insight about their survival strategies in extreme habitats. The stabilization of processes due to thermal stress is because of multiple reasons and involves DNA, RNA, proteins, ribosomes and enzymes (Poli et al. 2017). Thermophilic fungi received immense attention due to their ability to produce enzymes suitable for industrial purposes. Species belonging to genus *Corynascus* (*Myceliopthora*) have been of interest to mycologist as it produces thermostable enzymes. For example, *Corynascus thermophilus* (basionym: *Thielavia thermophila*) produced thermostable laccases with high activity and ability to express in various hosts (Berka et al. 1997; Bulter et al. 2003; Babot et al. 2011). Laccases produced by *C. thermophilus* ATCC 42464 are completely characterized, patented and genome sequenced (Bhat and Maheshwari 1987; Roy et al. 1990; Sadhukhan et al. 1992; Badhan et al. 2007; Beeson et al. 2011). However, there is no other report of any thermophilic fungi which is so extensively studied for laccase production. It shows the scarcity of thermophilic laccase-producing strains available so far.

22.2.4 Laccase from Deep-Sea Sponge Fungi

Studies on fungal diversity of marine sponges have been reported (Baker et al. 2009; Wang et al. 2008; Richards et al. 2012; He et al. 2014). Members of *Eurotiales*, *Capnoidales*, *Pleosporales* and *Hypocreales* have been identified and found to be

associated with various sponges (Suryanarayanan 2012). Aspergillus and Penicillium genera are ubiquitous with marine sponges whereas other genera which are associated with sponges but not that frequent include Alternaria, Acremonium, Beauveria, Cladosporium, Curvularia, Eurotium, Fusarium, Gymnascella, Paecilomyces, Petriella, Pichia, Spicellum and Trichoderma (Suryanarayanan 2012). Many marine fungi isolated from sponges have been screened for their lignocelluloytic activities (Bucher et al. 2004; Bianchi 2011; Richards et al. 2012). Fungi with lignocellulolytic activity from sea and other marine habitats like mangrove forests and sponges have been reported (Baker et al. 2009; Bonugli-Santos et al. 2010a, b). Batista-García et al. (2017) isolated fungi from sponges, *Stelletta normani* (*Demospongiae*, *Astrophorida*, *Ancorinidae*), from a depth of 751 m from Irish waters in the North Atlantic Ocean. Three halotolerant strains were isolated and identified which displayed laccase production along with other enzymes (CMCase and xylanase), viz., *Cadophora* sp. TS2, *Emericellopsis* sp. TS11 and *Pseudogymnoascus* sp. TS 12. These strains also showed psychrotolerance with optimal growth at 20 °C. Such strains are of immense importance both ecologically and industrially as they play significant role in maintenance of ecosystem and in development of industrial biotechnology.

22.2.5 Laccase from Lichen

Lichen is a symbiotic association between a fungus and cyanobacterium. These are the microbes which preliminarily colonize on rocky substrates which is also considered an extreme environment due to lack of nutritional substrate. They are involved in the weathering of rocks and conversion and accumulation of organic matter forming the primitive soil (Nash 1996; Chen et al. 2000). Zavarzina and Zavarzin (2006) while studying the formation of primitive soil under vegetation observed that many lichens have the ability to produce and release phenol oxidases in environment.

Little information is available on the laccase isoforms from lichens. Extracellular laccase activity is considered to be due to combination of multi-copper oxidases, phenol peroxides and tyrosinases (Laufer et al. 2006a). Studies on lichen *Peltigera malacea* (a member of order *Peltigerales*) showed that the active form is a tetramer with a high molecular mass of 340 kD (Laufer et al. 2009). Work on lichens *Solorina crocea* and *Peltigera apthosa* shows that both contained a dimeric laccase (ca. 170 kD) and a monomeric form (ca.85 kD) (Lisov et al. 2007). Recently, Laufer et al. (2006b) and Zavarzina and Zavarzin (2006) reported that many lichens within the suborder Peltigerineae show high rates of extracellular laccase activity. In other groups of fungi laccases have been reported from a mass range of 60–70 kD, but laccases from lichen are heavier in the range of 200–350 kD (Baldrian 2006; Laufer et al. 2009). It has been found that almost all members of *Peltigerineae* family of lichens show some degree of laccase activity. Beckett et al. (2012, 2013) also reported strong peroxidase activity in various genera of *Peltigerales* order like

Lobaria, *Pseudocyphellaria* and *Sticta* and non-Peltigeralean lichens. They also showed that high laccase activity was present in the cell walls of thalli. However, their role in biology of lichens still needs more work as most of them grow on oligotrophic conditions, viz., rocks, bark, etc.

22.2.6 Laccase from Psychrophilic Fungi

Several fungi are capable of producing extremozymes at varying temperature, pH and salt range. It is known that they play an important role in biodegradation in low-temperature habitats. Dhakar and Pandey (2013) and Dhakar et al. (2014) studied the production of laccases by thermotolerant *Trametes hirsuta* (MTCC 11397) and *Penicillium pinophilum* (MCC 1049) isolated from a glacial site in Indian Himalayan Region (IHR). Such features make the strains efficient for the degradation in extreme conditions. However, as per literature survey very few studies have been done on psychrophilic fungal laccases.

22.2.7 Laccase from Fungi Inhabiting Dumping Sites

Ndahebwa Muhonja et al. (2018) studied the molecular and biochemical aspect of characterization of low-density polyethene (LDPE)-degrading fungi from Dandora dumpsite, Nairobi. They isolated ten fungal isolates and screened for their ability to produce extracellular laccase. *Aspergillus fumigatus* B2, 2 exhibited the highest presence of laccase which is reported to play a role in degradation of polyethene. In another study, Sumathi et al. (2016) studied the degradation of polyvinyl chloride (PVC) by laccase using a fungus *Cochliobolus* sp., isolated from plastic dumped soils near plastic industry in Renigunta near to Tirupati, Chittoor district of Andhra Pradesh, India. Plastic waste has become one of the worst man-made problems accounting for 20–30% of municipal solid waste in landfill sites. These are extreme man-made habitats wherein there is large concentration of metal toxicity, gases, etc. These studies demonstrate that fungi isolated from such habitats have potential application for bioremediation as there was significant difference in the Fourier-transform infrared spectroscopy (FTIR), Gas chromatography–mass spectrometry (GC-MS), Scanning Electron Microscope (SEM) results of control and *Cochliobolus* species-treated low-molecular-weight PVC. There is a need to conduct more studies in such extreme environments to isolate potential strains with desirable properties of bioremediations like PVC degradation and develop environment-friendly technology.

There is an immense hidden potential present in diverse group of fungi found in extreme environments (Tiquia and Mormile 2010). They are still not exploited for laccase to their complete potential due to difficulty in the culturing of such fungi in laboratory. In recent times, metagenomics has been regarded as a powerful omics tool,

by which we can conduct diversity analysis of any microbe including fungi by direct DNA extraction and sequencing from different matrix (Barone et al. 2014; Handelsman 2004). Studies on functional aspect mainly focused on enzyme encoding gene(s) and discovery of novel biocatalysts, secondary metabolites and bioactive compounds (Wong 2010). Metagenomic approach can be used to study the gene encoding novel laccase enzymes for industrial production. At present, such studies are mainly focussed on extreme habitats from which it seems too difficult to cultivate the fungal population. It has been extremely effective in the discovery of novel extremophilic enzymes discovered from marine habitats, cold-adapted enzymes, thermophilic homologs, etc. Metagenomic tools are more commonly used with bacteria as compared with fungi. Fang et al. (2012) discovered a novel laccase with alkaline activity from bacterium. Miyazaki (2005) detected copper-inducible laccase activity in *Thermus thermophilus* HB27. It became possible by searching the genome databases of aerobic thermophilic bacteria for laccases and an open reading frame (OPR) annotated TTC1370 in *T. thermophilus* HB27 (Henne et al. 2004). Suryanarayanan et al. (2012) and Kunamneni et al. (2008) have also reported laccases from fungal endophytes of plants, which may not be an extreme habitat but surely a unique one. However most of the fungal diversity of extreme environments is still unexplored because of the imitating of the extreme conditions. Moreover, it is estimated that very less fungi of extreme environments are known; hence, a lot of fungal diversity still remains to be explored and exploited for laccase production. Use of metagenomics in fungi will provide an opportunity of culture-independent study of fungal diversity of extreme environments and its biotechnological application enzymes such as laccase (Fig. 22.3a).

22.3 Biological and Ecological Role of Laccase in Extreme Habitats

Extreme environments pose severe physicochemical conditions to the microbes accompanied by low molecular diffusion, macromolecular interactions and low metabolic rate. Hence, to survive in extreme climatic and environmental conditions, microbes including fungi need physiological adaptations. These adaptations facilitate in cellular functions and metabolic reactions. In such habitats fungi and other microbes possess proteins and enzymes which are robust in nature and help them to survive in harsh conditions. Fungi follow absorptive mode of nutrition and enzymes play an important role in breaking down the complex food material into simpler ones for absorption purpose. In addition, it also helps in invasion of plants during pathogenesis (fungal virulence factors) by plant-wounding response and pathogen defence (Beckett et al. 2005). The role of laccase has been studied in detail in white-rot fungi, where they participate in reactions that produce reactive oxygen species (ROS) such as the superoxide (O_2^-) and hydroxyl radicals (–OH). These molecules are involved in lignin degradation (Hammel et al. 2002; Leonowicz et al. 2001).

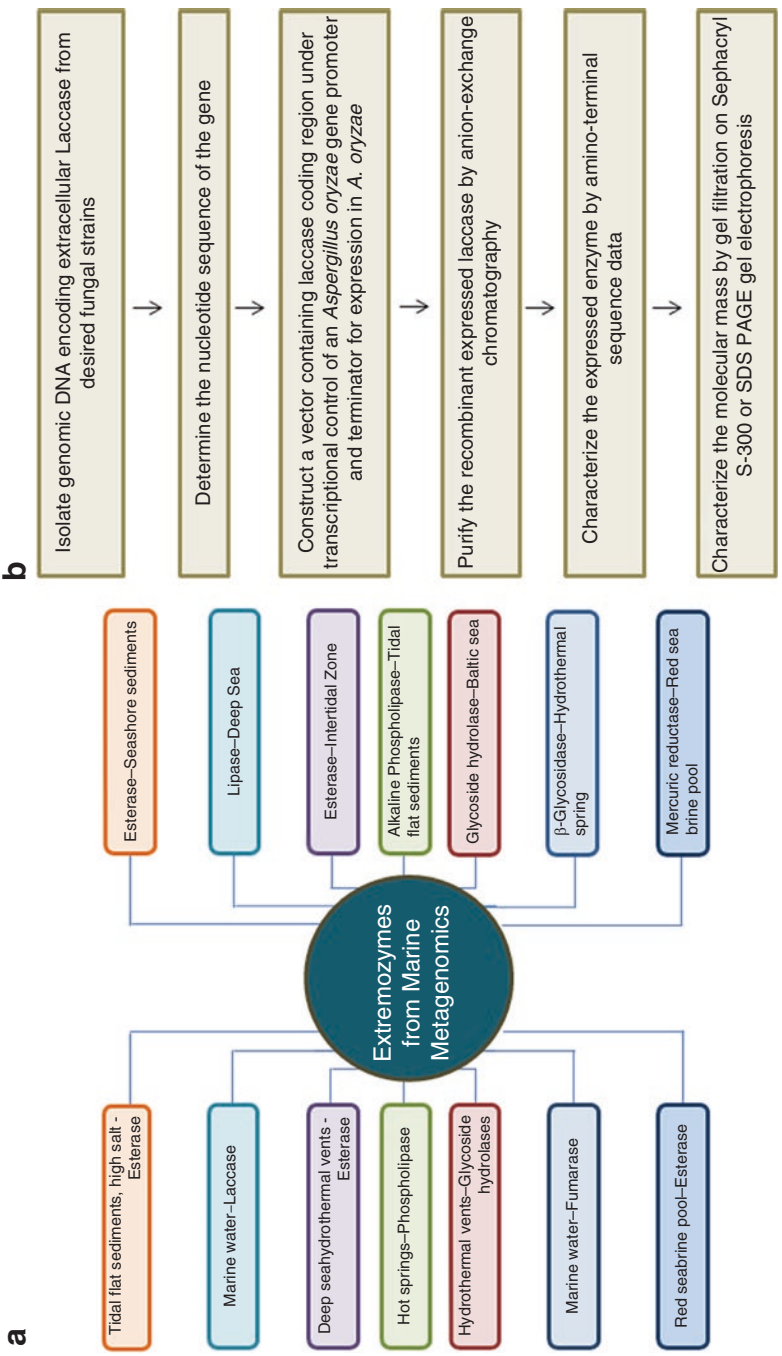

Fig. 22.3 (**a**) Metagenomics have helped in the discovery of several extremozymes from obligate marine or associated environment; (**b**) flowchart of methodology used for characterization of gene encoding laccase enzyme

Fungal laccases are reported to be involved in development stages of fungi like morphogenesis and melanin production which is also related to the pathogen factor (Baldrian 2006). Laccases have also been reported to have other physiological roles like development of fruiting bodies, sporulation, fungal spore pigmentation and cell wall reconstitution (Alcalde 2007). In extreme environments, laccases are involved in polymerization and depolymerization of humic acids in sediments of marine habitats (Zavarzina et al. 2004). The dothideaceous black yeasts synthesize DHN-melanin. In the last step of the DHN-melanin pathway where 1,8-DHN molecules conjoin to form melanin polymer and enzymes such as phenol oxidases (tyrosinase and laccases), peroxidases are responsible for the same (Yurlova et al. 2008).

Lignin is a complex plant cell wall component consisting of phenylpropanoid units linked by C–C and C–O bonds. Since very less organisms secrete laccases extracellularly fungi with laccase production potential play an important role in lignin depolymerization. Although enzymes are substrate specific, an important aspect of laccases enzyme is that it has a broad range of substrates. This is because it consists of a group of enzymes which includes lignin peroxidase, manganese peroxidases, laccases, tyrosinases, phenol oxidase, etc. Authors observed that fungi of Lonar Lake were playing an important role by contributing in the carbon cycle by degrading the phenolic compounds released from the woods, thus playing a significant role in the alkaliphilic ecosystem. In man-made extreme environments such as plastic-dumping sites and landfills fungi are involved in polymer degradation through depolymerization and polymer is broken into smaller subunits. Some fungi growing in such habitats utilize the plastic materials as a source of carbon. *Pestalotiopsis microspora*, *Fusarium solani*, *Alternaria solani*, *Spicaria* spp., *Penicillium oxalicum*, *P. chrysogenum*, *Aspergillus fumigatus*, *A. terreus* and *A. flavus* isolates were found to grow on polyester polyurethane (PUR) as the sole carbon (Russell et al. 2011; Kale et al. 2015; Ojha et al. 2017; Ibrahim et al. 2011). The discovery of new laccases and Thurston's (1994) study have extensively reviewed the role of laccase in the biology of the fungi, but further studies on laccases using advance method will further extend our knowledge about their role in fungal biology.

22.4 Potential of Laccase Enzymes

The pulp consists of cellulosic fibres of wood, crops and waste paper. It is made from mechanical and chemical processes that separate cellulose fibres from rest of the wood. It includes application of harsh conditions like high temperatures (~80 °C), alkaline pH and use of chemicals. Developed countries are pushing for use of eco-friendly methods as an alternative of chemical methods, and enzymatic bio-pulping is being considered a viable option. It is eco-friendly, safer and a profitable solution for the paper and pulp industry using stable hyperthermophilic/alkaline enzymes. Sarmiento et al. (2015) have listed selected examples of in-development and commercially available hot and cold-adapted extremozymes (Table 22.3). The paper and pulp industries are using laccases for bio-bleaching and degradation

Table 22.3 Examples of commercially available cold-active and thermostable enzymes (adopted and modified from Sarmiento et al. 2015)

Market	Enzyme	Commercially available	Uses
Cold-active enzymes			
Molecular biology	Alkaline phosphatases	Antarctic phosphatase (New England Biolabs Inc.)	Dephosphorylation of 5′ end of a linearized fragment of DNA
	Uracil-DNA N-glycosylases (UNGs)	Uracil-DNA N-glycosylase (UNG) (ArcticZymes), Antarctic Thermolabile UDG (New England Biolabs Inc.) and	Release of free uracil from uracil-containing DNA
	Nucleases	Cryonase (Takara-Clontech)	Digestion of all types of DNA and RNA
Detergent	Lipases	Lipoclean®, Lipex®, Lipolase® Ultra, Kannase, Liquanase®, Polarzyme®, (Novozymes)	Breaking down of lipid stains
	Proteases	Purafect® Prima, Properase®, Excellase (Genencor)	Breaking down of protein stains
	Amylases	Stainzyme® Plus (Novozymes), Preferenz™ S100 (DuPont), Purafect® OxAm (Genencor)	Breakdown starch-based stains
	Cellulases	Rocksoft™ Antarctic, Antarctic LTC (Dyadic), UTA-88 and UTA-90 (Hunan Youtell Biochemical), Retrocell Recop and Retrocell ZircoN (EpyGen Biotech), Celluzyme®, Celluclean® (Novozymes)	Wash of cotton fabrics
	Mannanases	Mannaway® (Novozymes), Effectenz™ (DuPont)	Degradation of mannan or gum
	Pectate lyases	XPect® (Novozymes)	Pectin-stain removal activity
Textile	Amylases	Optisize® COOL and Optisize NEXT (Genencor/DuPont)	Desizing of woven fabrics
	Cellulases	Primafast® GOLD HSL IndiAge® NeutraFlex, PrimaGreen® EcoLight 1 and PrimaGreen® EcoFade LT100 (Genencor/DuPont)	Bio-finishing combined with dyeing of cellulosic fabrics
Food and beverages	Pectinases	Novoshape® (Novozymes), Pectinase 62L (Biocatalysts), Lallzyme® (Lallemand)	Fermentation of beer and wine, breadmaking, and fruit juice processing

(continued)

Table 22.3 (continued)

Market	Enzyme	Commercially available	Uses
Other	Catalase	Catalase (CAT), (Swissaustral)	Textile, cosmetic applications
Thermostable enzymes			
Food and beverages	Amylases	Avantec®, Termamyl® SC, Liquozyme®, Novamyl®, Fungamyl® (Novozymes), Fuelzyme®	Enzymatic starch hydrolysis to form syrups. Applied in processes, such as baking, brewing, preparation of digestive aids, production of cakes and fruit juices
	Glucoamylases	Spirizyme® (Novozymes)	Used on liquefied starch-containing substrates
	Glucose (xylose) isomerases	Sweetzyme® (Novozymes)	Isomerization equilibrium of glucose into fructose
	Proteases	Protease PLUS	Applied in brewing to hydrolyze most proteins
	Amyloglucosidases	GlucoStar PLUS (Dyadic)	Used in processing aids
	Xylanases, cellulases, pectinases, mannanases, β-xylosidases, α-l-arabinofuranosidases, amylases, protease, other	CeluStar XL, BrewZyme LP, Dyadic Beta Glucanase BP CONC, Dyadic xylanase PLUS, Xylanase 2XP CONC, AlphaStar CONC and Protease AP CONC. (Dyadic), Panzea BG, Panzea 10× BG, Panzea Dual (Novozymes), Cellulase 13P (Biocatalysts)	Hydrolysis of hemicellulose and cellulose to lower molecular weight polymers in brewing
	Lipases and xylanases	Lipopan® and Pentopan® (Novozymes)	Stronger dough in bakery
	Glucose oxidases	Gluzym® (Novozymes)	Stronger gluten in bakery
Pulp and paper	Xylanases	Luminase® PB-100 and PB-200 (Verenium), Xylacid® (Varuna Biocell), Xyn 10A (Megazyme)	Bio-bleaching
	Laccases	Laccase (Novozyme)	Bio-bleaching
	Lipases and esterases	Lipase B Lipozyme® CALB L, Lipase A NovoCor®AD L, Resinase™ HT and Resinase A2X (Novozymes), Optimyze® (Buckman Laboratories)	Pitch control
	Cellulases/hemicellulases preparations	FibreZyme® G5000, FibreZyme® LBL CONC, FibreZyme™ LDI and FibreZyme™ G4 (Dyadic)	Modify cellulose and hemicellulose components of virgin and recycled pulps
	Amylase	Dexamyl-HTP (Varuna Biocell)	Modified starch of coated paper

of lignin (which renders dark colour to pulp), thus improving the colour of the product. According to Virk et al. (2012), laccases also help in removal of tacky materials containing resins from the wood. Fungal laccases have been more popular for use in bio-bleaching as compared to laccases of bacterial origin (Baldrian 2004, 2006). Fungi from extreme environment are considered as an important source of commercial enzymes such as amylase, lipases, protease and cellulase. Novozymes are such thermostable laccases produced from thermophilic fungus *Corynascus thermophilus*. AB Vista (Wiltshire, UK) has the patent for thermostable laccase enzyme effective between 30 °C and 80 °C (Paloheimo et al. 2006; Sarmiento et al. 2015). For commercial production, the laccase gene from *M. thermophila* is cloned in *Aspergillus oryzae* and the enzyme is active up to 70 °C (Xu et al. 1996; Berka et al. 1997) (Fig. 22.3b). Novozyme commercially produces laccase enzyme (EC number 1.10.32) Novozym® 51003, from fungus *Aspergillus oryzae.* It is produced in liquid form and oxidizes various phenols, anilines, benzenethiols, metal ion complexes and other compounds into quinones or other oxidized compounds, with concomitant reduction of dioxygen to water. Another product Novozymes DeniLite® is being used for enzymatic bleaching solutions altering the indigo colour through oxidation. It has made denim bleaching safer, eco-friendly and more sustainable. The rapid action of enzymes coupled with low working temperature of peroxidase enzyme helps in the production of more durable denims.

22.5 Current Challenges and Conclusions

Today, with increasing awareness of climate change and sustainable development, there is an inadvertent pressure on biotechnology to deliver eco-friendly solutions to processes presently employing chemical methods. Biotechnological industries are utilizing a variety of enzymes as solutions to various industrial processes. Many of these are synthesized commercially using fungal strains selected after large-scale screening. Research on extreme environments has helped in the selection of particular fungal strain with desired property. These have also been optimized for the production of high-quality laccase on a large scale for industrial applications. There is a huge requirement of laccases for the industries working in the field of waste management, whether it is biomedical, agriculture, or municipal waste and paper pulp industries (Fig. 22.4). However, there is a need to study various extreme environments with the aim of isolating fungi having potential of laccase production and capable of acting in conditions of high pH, temperature and still maintain high activity. Recent studies in molecular biology and genetics have helped in inserting and expressing the active factor or gene of the desired fungi into bacteria or yeast for rapid and easy production. This has helped in production of laccase of desired property like thermostability, tolerance to acidic or alkaline environments and metal toxicity.

As discussed above, at present most of the studies have been focussed on the laccase produced by white-rot fungi-like species of *Fomes*, *Panus* and *Phanerochaete* (Papinutti et al. 2008; Quaratino et al. 2007; Dahiya et al. 2001) which are mostly

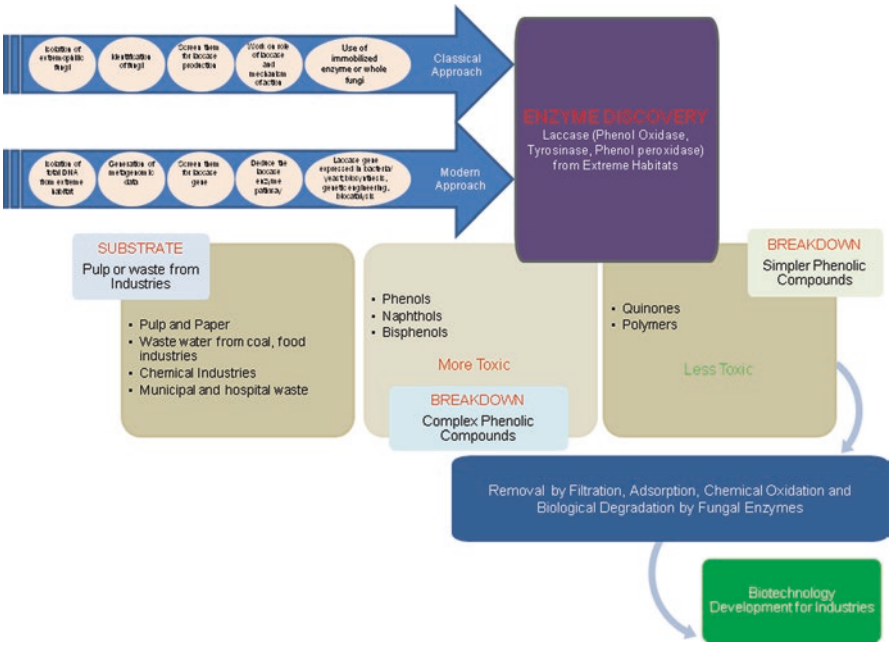

Fig. 22.4 Extremophilic fungi have immense potentials for development of sustainable environmental technologies including biodegradation of phenolic pollutants and provide waste management solutions to various industries. This is well supported by advances in microbial techniques enabling the cloning of gene or gene clusters involved in the biosynthesis of laccases group of enzymes

mesophilic. Hence, there is a need to focus studies on fungi from extreme environments like soda lakes, hot springs, marine habitats, etc. for their isolation and screening for active laccase production. There are more studies on extremophilic bacteria as compared to extremophilic fungi. It may be due to optimized isolation strategies being used and incubation methods being practised and refined in case of bacteria but less practised in case of fungi. Recent techniques of metagenomics can also be employed to know the fungal population of such habitats and then design isolation strategies accordingly (Fig. 22.4). Many researchers have employed strategies to directly understand the functional aspect of an ecosystem using BIOLOG and API strips (Oest et al. 2018; Patel et al. 2019; Tiquia 2010, 2011). Similar strategy can be used in extreme environments that will help to know the laccase activity of the habitat, thus giving an idea of the laccase-producing abilities of the fungal strains inhabiting such habitats. Amplification of laccase gene using specific primers is another strategy for evaluating the capacity of fungal strains for laccase production. Such strategies may yield fungal strains producing laccases with unusual properties useful in industrial applications. There is a growing demand for novel and robust laccases for biotechnology in industrial applications, i.e. biofuel production, pulp and paper industries and eco-friendly municipal waste treatment. Hence, researchers should give attention and make efforts to discover the novel fungi with the capacity to produce laccases from extreme environments.

Chapter 23
Lignocellulose-Degrading Thermophilic Fungi and Their Prospects in Natural Rubber Extraction from Plants

Shomaila Sikandar, Imran Afzal, Naeem Ali, and Katrina Cornish

23.1 Introduction

Fungi are pervasive in nature and are established across a wide range of biological/environmental habitats. To establish they must produce the essential extracellular enzymes in their immediate environment to enable the primary resource capture required for their growth and development. Temperature, salt concentration, pH, gas balance, and water availability are the fundamental abiotic aspects generally affecting their biological role and success (Magan and Aldred 2008). The prospects of isolating new extremophilic fungal species increase when samples are collected from extreme temperatures or pressures, high-radiation environments, or environments with limited nutrients or high salinity. In extreme environments, they develop different survival strategies for reproduction and growth (Timling and Taylor 2012; Gunde-Cimerman and Zalar 2014). Moreover, because fungi have the capability to grow

over a wide range of temperature conditions, they are categorized as psychrophiles (−15–10 °C), mesophiles (20–45 °C), and thermophiles (above 45 °C). A heterogeneous group of genera, including Ascomycetes, Phycomycetes, Mycelia, Sterilia, and Fungi Imperfecti, contain numerous thermotolerant and thermophilic forms (Cooney and Emerson 1964; Mouchacca 1997).

In addition, thermophilic fungi are often found as members of microbial communities colonizing a wide range of diverse substrates, particularly damp organic substrates such as straw-based composts, hay, and tropical soils. Therefore, they form important components during succession on, and colonization of, a wide variety of substrata (Allen and Emerson 1949; Miehe 1907). *Mucor pusillus,* the first identified thermophilic fungi, was isolated from bread (Lindt 1886). *Thermomyces lanuginosus,* previously known as *Humicola lanuginose*, first isolated in 1899 is broadly disseminated and normally isolated from self-heating masses of organic debris (Cooney and Emerson 1964; Emerson 1968; Krause et al. 2003; Tiquia 2005; Sikandar et al. 2017). Different species of thermophilic fungi were isolated from self-heating hay (Miehe 1907), namely, *Thermoascus aurantiacus*, *Thermomyces lanuginosus*, *Thermoidium sulfureum*, and *Mucor pusillus*, and these have also been isolated from several other natural substrates (Noack 1920; Miehe 1930).

In many biotechnological applications, thermophilic fungi have gained substantial attention for new sources of thermostable enzymes (thermozymes) particularly for lignocellulosic biomass degradation (Xie et al. 2014; Tiquia-Arashiro and Mormile 2013). Plant cell walls consist of up to 70% of cellulose, hemicellulose, and pectin (Jørgensen et al. 2007; Plecha et al. 2013). Lignocellulosic biomass consists of agro-industrial, agricultural, forestry, and food wastes that are plentiful, renewable, and low-cost energy sources. These lignocellulosic wastes accumulate in large quantities and can cause environmental problems (Chaudhary et al. 2012). Lignocellulose-degrading fungi are ubiquitous and gain nutrition by the degradation of plant biomass by producing degrading enzymes such as xylanases, cellulases, amylases, mannanase, pectinases, chitinases, proteases, lipases, ligninase, esterases, and phytases (van den Brink and de Vries 2011). In addition, thermophilic fungi produce enzymes which are more thermostable than those of mesophilic fungi, because they are more resistant to proteolysis and chemical denaturation (Table 23.1). Fungal thermozymes have been characterized by their ability to resist proteolysis and tolerate extreme conditions in the presence of denaturing agents, organic solvents, and high salinity (Sunna and Bergquist 2003; Raddadi et al. 2015). Proposed mechanisms of their protein thermostability include tighter packing or compactness (Russell et al. 1994), greater rigidity (Bogin et al. 1998), increased hydrogen bonding (Vogt et al. 1997), and deleted or shortened peptide loops (Russell and Sternberg 1997). A complete analysis of physiology, epigenetics, and metagenomics of fungal consortia showed the underlying production mechanisms of cell wall-degrading enzymes (Guerriero et al. 2015). Genomic taxonomic studies of thermophilic fungi led to their improved classification and deposition in culture collections and their sequences in online nucleotide public databases (de Oliveira et al. 2015).

Table 23.1 Comparison of the growth parameters of some mesophilic and thermophilic fungi

Fungus	Type of fungus	Growth temperature (°C)	References
Neurospora crassa	Mesophile	30	Alberghina (1973)

Humicola lanuginosa strain Y-38	Thermophile	60	Liu et al. (1973)
Penicillium duponti	Mesophile	25	Malcolm and Shepherd (1972)
Pencillium chrysogenum	Mesophile	30	Renosto et al. (1985)

Lignocellulose-degrading thermophilic fungi and their thermozymes have been widely studied for the bioconversion of the lignocellulosic material into value-added products (Xie et al. 2014; Znameroski and Glass 2013). Moreover, they have proven to be an important and efficient source of thermozymes from lignocellulosic biomass that can be useful in many processes, including extraction of natural rubber from rubber-bearing plants (Sikandar et al. 2017). Natural rubber is a biopolymer consisting of 320 to >35,000 isoprene molecules. *Taraxacum kok-saghyz* (TK) also recognized as the rubber dandelion or "Buckeye Gold" is used as an alternative source of rubber plant by multiple commercial groups (van Beilen and Poirier 2007). TK roots comprise 2 to >36% of rubber, along with 25–40% inulin (polysaccharide of fructose), on a dry-weight basis (Buranov and Elmuradov 2009; van Beilen and Poirier 2007). Thus, the potential of lignocellulose-degrading thermophilic fungi to utilize plant biomass to produce cellulases, pectinases, and hemicellulases towards natural rubber extraction needs further investigation. The reduction in cost of enzyme production may lead to an innovation in the commercialization of natural rubber extraction from rubber-bearing plants. For the first time, this review assembles information on the efficiency of lignocellulose-degrading thermophilic fungi and their thermozymes towards an intractable problem associated with previous methods for rubber extraction from rubber-producing dandelions.

23.2 Lignocellulose-Degrading Fungal Thermozymes

Lignocellulose is a tightly, covalently, and non-covalently interconnected material mainly composed of cellulose, pectin, hemicelluloses, and lignin. Wood, grass, municipal solid wastes, agricultural residues, and paper industry wastes are primary sources (Howard et al. 2003; Mussatto and Teixeira 2010). Approximately 70% of lignocellulosic biomass is used in pulp and paper, food, feed, and biofuel, the four largest industrial sector biomass applications (Jørgensen et al. 2007). Accumulation of industrial waste and agricultural residues causes serious pollution but they could be (1) used as substrates for enzyme production or (2) fermented into alcohol or glucose for chemical syntheses or fuels (Kumakura et al. 1988; Nguyen et al. 2013; Tiquia-Arashiro 2014; Pomaranski and Tiquia-Arashiro 2016). Enzymes from lignocellulose-degrading thermophilic fungi frequently have been considered to evaluate their utility in industrial bioprocesses and to characterize and compare physicochemical properties of enzymes from mesophilic fungi. Enzymes secreted into growth media and prepared as culture filtrates have been more often studied than intracellular enzymes. The ability of thermophilic fungi to degrade lignocellulosic biomass at higher temperatures than mesophiles has several advantages: high temperature fermentation using thermophiles decreases substrate viscosity in fermenters, shortens the reaction time, and limits contamination (Blumer-Schuette et al. 2014). Thermostable enzymes require shorter reaction times for maximum plant biomass degradation compared to mesophillic conditions as in *Aspergillus* and *Trichoderma*. Extracellular cell wall-degrading enzymes from thermophilic fungi are comprised of a two-enzyme system (Maheshwari et al. 2000), hydrolases which degrade polysaccharides (Fig. 23.1) and oxidative and extracellular ligninolytic enzymes which open phenyl rings and degrade lignin.

23.2.1 Cellulases

In fungi, three hydrolytic enzymes are responsible for degrading cellulose: (1) endo-(1,4)-*β*-D-glucanase (carboxymethyl cellulase, endocellulase, endoglucanase, [EC 3.2.1.4]) which randomly cuts β-linkages, normally in cellulose amorphous parts; (2) *β*-glucosidase (cellobiase [EC 3.2.1.21]) which releases glucose from cellobiose and short-chain cello-oligosaccharides; and (3) exo-(1,4)-*β*-D-glucanase (exocellulase, avicelase, cellobiohydrolase, microcrystalline cellulase, [EC 3.2.1.91]) which releases cellobiose either from the reducing or the nonreducing end of crystalline cellulose (Bhat and Bhat 1997).

The levels of extracellular cellulases determine the extent of cellulose solubilization, and this led to attempts to develop practical processes to convert cellulose to glucose by isolating and screening cellulase-producing fungi (Mandels 1975; Mandels and Sternberg 1976). Although cellulose was rapidly degraded by some species of thermophilic fungi, the cellulase activity of their culture filtrates was generally low (Mandels 1975). In contrast, the activity of cellulases produced by the thermophilic

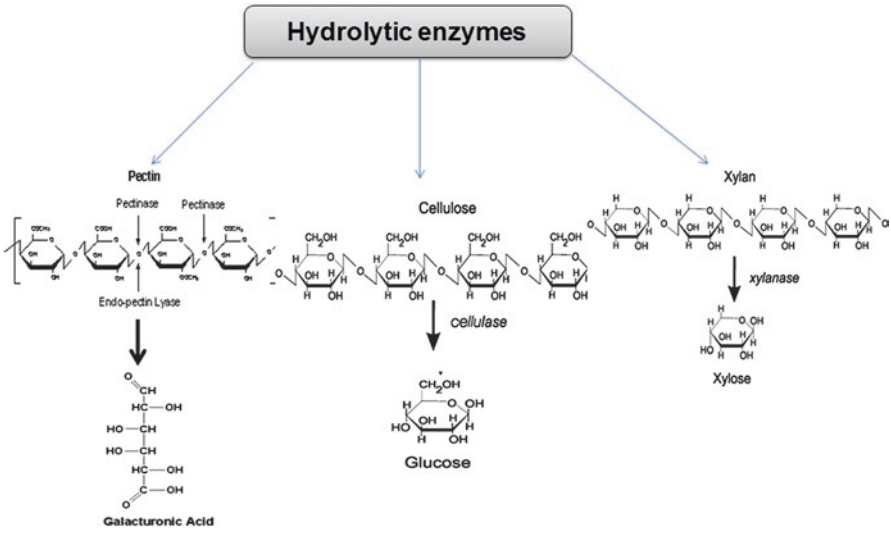

Fig. 23.1 Generalized view of polymeric substances and their products derived from hydrolytic enzymes

fungi *Talaromyces emersonii* (Folan and Coughlan 1978) and *Sporotrichum thermophile* (Coutts and Smith 1976) was closely similar to that produced by *Trichoderma reesei,* the maximum cellulase-producing fungal strain. However, apparent cellulase production is clearly affected by assay method (Oberson et al. 1992). Bhat and Maheshwari (1987) explained that the culture filtrates of endoglucanase and exoglucanase activities of *S. thermophile* strain were lower than that of *T. reesei*. However, in spite of these lower activities, *S. thermophile* grew at five times faster and degraded cellulose more rapidly than *T. reesei*. The vigorous growth of *S. thermophile* was similar on glucose and insoluble cellulose. Based on these observations, the rate or extent of cellulolysis depends on the secreted levels of cellulase activities. As is the case with mesophilic fungi, multiple cellulase enzymes are produced by thermophilic fungi and, in most, crystalline cellulose is the preferred substrate over impure or amorphous forms (Romanelli et al. 1975; McHale and Coughlan 1981; Ganju et al. 1989). However, high cellulase and xylanase activities were secreted by *Thermoascus aurantiacus* (Khandke et al. 1989b; Kawamori et al. 1987), *Humicola insolens* (Hayashida and Yoshioka 1980), and *Thermomyces lanuginosus* (Sikandar et al. 2017), even on lignocellulosic and hemicellulosic substrates.

23.2.2 Xylanases

Xylan, a major component of hemicellulose, is the most plentiful polysaccharide in nature, and a variety of hydrolytic enzymes are mandatory for its complete degradation. These include endoxylanases (EC 3.2.1.8), which hydrolyze β-1,4-linked xylose

(the xylan backbone) and β-xylosidases (EC 3.2.1.37), which cleave xylo-oligomers (Biely 1985). Thermophilic fungi, producing xylanases, have attracted considerable attention in numerous biotechnological applications, particularly lignocellulosic biomass degradation by enzymatic degradation of xylan from lignin carbohydrates and for bio-bleaching of pulp in the paper industry. Xylanase production can be achieved on a wide range of carbon sources including pure xylan (Gomes et al. 1993b), and natural substrates rich in xylan such as wheat bran (Yoshioka et al. 1981; Sikandar et al. 2017), corn cobs (Bennett et al. 1998), and sugarcane bagasse (Prabhu and Maheshwari 1999). Paper waste was a unique carbon source which induced high levels of xylanases in the thermophilic fungi *Humicola lanuginosa* (Anand et al. 1990) and *Thermoascus aurantiacus* (Khandke et al. 1989a). *T. lanuginosus* also is a good producer of xylanases and pectinases (Puchart et al. 1999; Singh et al. 2003; Sikandar et al. 2017). In addition, some xylanase-producing *Thermoascus aurantiacus* and *Thermomyces lanuginosus* fungal strains are active above at 70 °C. The majority of fungal xylanases are endoxylanases, and optimal temperature for most thermophilic xylanases ranges from 55 °C to 65 °C (Table 23.2). The thermostability of xylanases from *T. lanuginosus* was known due to the presence of an extra disulfide bridge which was not present in mesophilic xylanases (Eswaramoorthy et al. 1994).

23.2.3 Pectinases

Pectin is an essential component of plant cell wall and can be hydrolyzed by pectinases by the cleavage of α-1,4 linkages of polygalacturonic acid. Thermophilic fungi producing pectinases are found in decaying fruits and vegetable matter, and very few of them have been isolated and characterized (Adams and Deploey 1978; Sikandar et al. 2017). However, when 40 thermophilic fungal species (previously reported to produce pectinases) belonging to seven genera were cultured on pectin as a carbon source in a medium, no activity was detected in most of the cultures (Inamdar 1987). *T. aurantiacus* produces most stable polygalacturonases, active above 65 °C. Temperature stability remains a significant limitation to commercial utility.

23.3 Natural Rubber

Natural rubber is the important biological materials used in different nonfood applications. It is a polymer containing isoprene units which are linked together in a 1,4-*cis* configuration. Although rubber is produced in over 2500 plant species, commercial production of rubber is almost still exclusively from *Hevea brasiliensis*, the Para rubber tree (Cataldo 2000). The rubber-bearing dandelion *Taraxacum kok-saghyz* holds significant quantities of rubber in its roots (up to 36% on a dry-weight basis (Buranov et al. 2005) although most genotypes contain much less rubber than this (Cornish et al. 2016; Martinez et al. 2015; Ramirez-Cadavid et al. 2017).

In rubber-bearing plants, rubber is formed in rubber particles in the cytosol of ordinary parenchyma cells, or more commonly as free-flowing latex formed in latex vessels (laticifers) in the same anatomical zone as the phloem (Martinez et al. 2015). In TK roots, carbohydrate components of plant biomass such as cellulose, hemicellulose, and pectin are present (Ramirez-Cadavid et al. 2017). Rubber dandelion roots also contain a major amount of inulin and sugars (up to 40%) that can be converted into ethanol or other chemicals (Ramirez-Cadavid et al. 2017; Ramirez-Cadavid et al. 2018; Ujor et al. 2015). The utilization of biopolymers (celluloses, hemicelluloses, and lignin) and bio-products (phenolic compounds) from the remaining biomass signifies an opportunity for increased commercialization activities. Solid rubber can be extracted from dried tissue by several methods including simultaneous or sequential organic solvent extraction (Eagle 1981; Black et al. 1983; Hamerstrand and Montgomery 1984; Schloman et al. 1988), water extraction without (Eskew and Edwards 1946) or with hydrolytic enzymes (Sikandar et al. 2017), or dry milling (Buranov 2009). A new aqueous method was recently reported (Sikandar et al. 2017) using lignocellulose-degrading hydrolytic enzymes from *T. lanuginosus* STm, which were used to enhance the extracted yield and purity of rubber from rubber dandelion (Fig. 23.2).

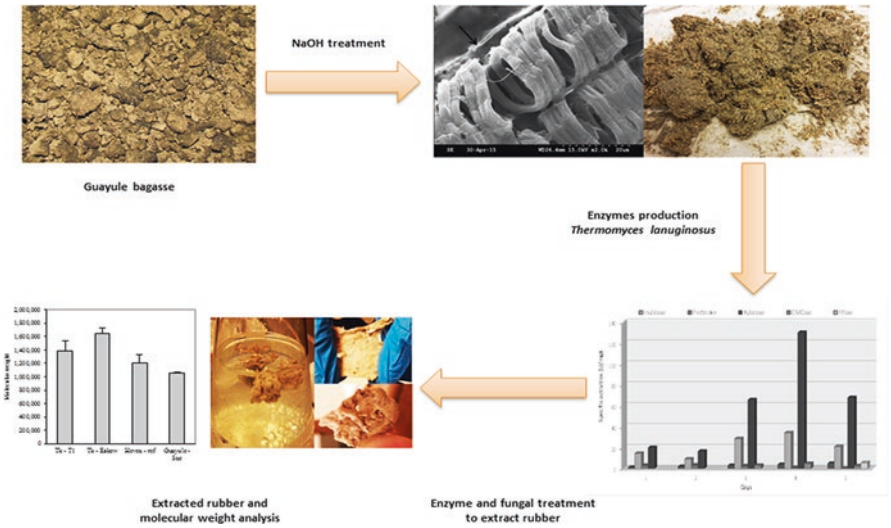

Fig. 23.2 Application of alkali-treated plant biomass for extraction of natural rubber using fungal hydrolytic enzymes

23.4 Natural Rubber Extraction by Fungal Thermozymes

Enzymes from lignocellulose-degrading thermophilic fungi provide diverse biotechnological opportunities for biotransformations and biocatalysis due to their stability across a broad range of temperature, ionic strength, pH, and salinity, and their capability to function in organic solvents, which denature most enzymes from other sources (Adrio and Demain 2014; Karmakar and Ray 2011). These enzymes are used in different industrial and commercial products (Adrio and Demain 2014) due to their reproducibility, high performance, and economic viability (Gurung et al. 2013). Enzyme production using lignocellulosic biomass provides both economic and environmental advantages. According to many previous studies, *T. lanuginosus* produced high levels of xylanases (Gomes et al. 1993a; Jensen et al. 1987; Li et al. 1997). Puchart et al. (1999) also reported maximum xylanase activity (1.0 U/mL) by *T. lanuginosus* using corncob as a carbon source. Previous studies reported that lignocellulosic biomass is a superior substrate for producing lignocellulose-degrading enzymes (Damaso et al. 2000). Newly isolated *T. lanuginosus* STm using lignocellulosic biomass produced high levels of xylanases (67.4 U/mg) and cellulases (16.7 U/mg) (Sikandar et al. 2017). *T. lanuginosus* STm efficiently grows and degrades different lignocellulosic biomass at high temperature, which suggests its efficacy to degrade other types of plant biomass containing rubber.

Conventional methods previously used for rubber extraction included both solvent and water-based methods. In sequential and simultaneous organic solvent extraction methods, acetone is used to extract low-molecular-weight organic com-

pounds, such as terpene resins, whereas rubber extraction requires nonpolar solvents such as cyclohexane, hexane, pentan, or chloroform (Black et al. 1983; Schloman et al. 1988; Eagle 1981; Hamerstrand and Montgomery 1984). However, green dry-milling (Buranov 2009) and benign water-milling (Eskew and Edwards 1946) processes can also be used to extract solid natural rubber. To reduce cost and environment-associated problems with chemical methods of rubber extraction, use of lignocellulose-degrading fungal thermozymes is encouraged. In-house production of fungal thermozymes makes the overall process of natural rubber extraction cost effective. Enzymatic hydrolysis of TK roots is an effective biotechnological process, also used for the production of value-added products. The effectiveness of *T. lanuginosus* STm and its enzymes towards rubber extraction from TK roots is due to physical and biochemical combination (Sikandar et al. 2017), and fungal unique enzymatic fingerprint, wherein the combination of excreted enzymes is capable of disrupting the tight linkages (likely covalent) between the biomass and the rubber.

23.5 Conclusions and Future Perspectives

Thermophilic fungi have been previously isolated and used as sources of novel industrial enzymes owing to their ability to thrive in extreme conditions. In particular, lignocellulose-degrading thermophilic fungi have found applications in the degradation of complex lignocellulosic biomass due to their high resistance under extreme temperature, chemicals, organic solvents, and pH. They have the ability to degrade recalcitrant plant biomass by producing cellulases, pectinases, and xylanases, respectively. The expansion of novel industrial processes built on fungal thermozymes, and the growing demand by industries for novel enzymes, incentivizes new discovery of useful thermophilic fungi. *Thermomyces lanuginosus* STm is a sustainable hydrolytic enzyme source that was used to the extraction of natural rubber from plants containing rubber by increasing its overall yield compared to other conventional processes previously used. Moreover, this bioprocess is more prospective towards cost-effective and environmentally friendly approach. In future, a multifaceted approach including characterization of lignocellulosic biomass for enzyme production, environmental metagenomics, fungal proteomics, and synergistic analysis of natural and genetically optimized thermozymes is required to efficiently and cost-effectively exploit lignocellulose-degrading thermophilic fungi.

Chapter 24
Thermophilic Fungi and Their Enzymes for Biorefineries

Abha Sharma, Anamika Sharma, Surender Singh, Ramesh Chander Kuhad, and Lata Nain

24.1 Introduction

Increasing prices of crude oil, depletion of nonrenewable energy reserves, as well as environmental concerns related to air pollution and global warming have focused on the development of alternative renewable energy resources. However, the issue of food versus fuel makes first-generation biofuels indefensible, thereby generating an overwhelming research interest towards exploitation of abundant lignocellulosic biomass for the production of biofuel as well as other commodity chemicals in a biorefinery approach (Hasunuma and Kondo 2012; Kumar et al. 2008). Biorefinery can also be defined as a facility that integrates biomass conversion processes and equipment to produce fuels, power, heat, and value-added chemicals from biomass with the aid of microorganisms and their enzymes (Fernando et al. 2006; Kamm and Kamm 2004; Nguyen et al. 2013; Pomaranski and Tiquia-Arashiro 2016).

Lignocellulosic biomass is the most abundant and inexhaustible biomass on earth, which holds enormous potential for sustainable production of chemicals and fuels in an eco-friendly manner (Somerville et al. 2010; Taarning et al. 2011; Tiquia-Arashiro and Mormile 2013). The various types of lignocellulosic raw materials include wheat straw, rice straw, palm, corncobs, corn stems and husk, etc. having varying amount of lignocellulosic components. The lignocellulosic biomass has higher amount of oxygen, and lower fractions of hydrogen and carbon with respect

to petroleum resources and as a result more classes of products can be obtained from degradation of lignocellulosic based biorefineries than petroleum-based ones (Plecha et al. 2013; Isikgor and Becer 2016; Tiquia-Arashiro 2014a).

Among microorganisms, fungi with the help of their extracellular enzymes can carry out efficient degradation of plant biomass as it is also their principal carbon source in natural habitat. Consequently, fungi and their enzymes are very attractive with respect to the concept of biorefinery, wherein they are used for the degradation of lignocellulosic biomass with an aim of generating biofuels and other platform chemicals (Kuhad et al. 2010). A large number of enzymes that carry out lignocellulose degradation, viz. cellulases, xylanases, and ligninases, have been purified and characterized from fungi, mainly ascomycetes and basidiomycetes, and in many cases the corresponding enzymes have been cloned (de Vries and Visser 2001). Cellulases act on cellulosic chains of the lignocellulose-releasing monomeric glucose, while xylanases hydrolyze hemicelluloses of the substrate to xylose. The released monomeric sugars are fermented with microorganisms to produce biofuels and commodity chemicals in a biorefinery concept. However, the cellulose microfibrils in the plant cell wall are interrupted by hemicellulose and are surrounded by a lignin matrix (Penjumras et al. 2014). The resistance of lignin to degradation makes enzymatic access to cellulose a major obstacle in the saccharification, thereby attracting considerable interest in the methods employed for breakdown of lignin (Bugg et al. 2011). Pertaining to this, pretreatment methods that remove lignin and hemicellulose from plant material can be divided into the following categories: physical (milling and grinding), physicochemical (steam pretreatment or autohydrolysis, hydrothermolysis, and wet oxidation), chemical (alkali, dilute acid, oxidizing agents, and organic solvents), biological, or a combination of these (Gupta et al. 2011). Among these, biological pretreatment methods indeed provide an eco-friendly alternative to chemical and physical pretreatments, improving biorefinery economics by reducing pretreatment costs and alleviating inhibitor formation (Deswal et al. 2014). Biological pretreatment of lignocellulosic biomass mainly employs white-rot fungi, which degrade lignin and hemicelluloses selectively but very little of cellulose with the aid of their extracellular hemicellulases and ligninases (Sanchez and Demain 2011). Furthermore, due to the complexity of lignin chemical structure and its enzymatic modifications, a variable number of low molecular weight compounds can be released from its microbial degradation, which would be potentially a rich source of renewable aromatic chemicals to be used in food and flavor industry, and for fine chemicals as well as material synthesis (Fisher and Fong 2014).

On the other hand, despite the urgency for developing biorefineries intended to produce fuel and chemicals from renewable resources, low-cost processing technologies which efficiently convert lignocellulosic biomass energy into liquid fuels do not yet exist (Madadi et al. 2017). The high cost of exogenous enzymes used in the process is one of the major limiting factors that make the process expensive and unattainable. Erstwhile, the use of thermophilic enzymes for deconstruction of lignocelluloses provides a possible solution to the above problem, as these enzymes typically have a higher specific activity as well as higher stability

in conditions of elevated temperature prevalent in industrial environments. As a result, they allow extended hydrolysis times and thus decrease the amount of enzyme needed for saccharification (Yeoman et al. 2010), making the process efficient as well as economical. Additionally, these enzymes promote better penetration and cell wall disorganization of the substrate (Turner et al. 2007). Moreover, microbial contamination risks are significantly reduced at elevated temperatures, and finally these enzymes can typically be kept at room temperature without loss of activity, reducing refrigeration cost during transport as well as storage. These advantages attributed to thermostable enzymes are noteworthy as almost one-third of the projected process costs in biomass conversions are associated with enzyme production (Haki and Rakshit 2003; Tiquia-Arashiro 2014b). Therefore, prospecting of novel thermophilic fungi which produce thermostable lignocellulolytic enzymes will be highly advantageous for the successful implementation of biorefineries (Kumar et al. 2008). Thermophilic microbes growing at temperature of 50–80 °C in extreme habitats are source of highly active and thermostable enzymes (Zeldes et al. 2015; Tiquia-Arashiro and Rodrigues 2016). Similarly, engineering existing mesophilic lignocellulolytic microbial enzymes to function efficiently at raised temperatures in order to boost reaction rates and exploit several other advantages of a high-temperature process is another potential alternative (Trudeau et al. 2014).

Keeping all of the above in mind, it can be concluded that thermophilic fungi and their enzymes might be used for the construction of multiproduct modern day biorefineries from lignocellulosics. This chapter discusses the potential and possibilities of thermostable lignocellulolytic enzymes, developed or isolated from thermophilic fungi for bioconversion of lignocellulosic raw materials into biofuel and other commodity chemicals with a biorefining perspective.

24.2 Lignocellulosic Biomass Components and Fungal Enzymes for Their Deconstruction

Lignocellulose is a complex of lignin, cellulose, and hemicellulose present in the plant cell walls (Gupta et al. 2011). Lignin is a highly heterogeneous aromatic polymer that is built from three phenylpropanoid precursors, *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol (Higuchi 1993). On the other hand, cellulose is a linear polysaccharide consisting of β-1,4-linked D-glucose residues (Carpita and Gibeaut 1993), while hemicellulose consists of a backbone of β-1,4-linked D-xylose residues with a number of side groups (Scheller and Ulvskov 2010). Covalent and non-covalent linkages between the polysaccharides and lignin create the intricate structure that provides strength to the plant cell wall and also acts as a defense against microbial attack. However, this strong network can be broken down with the help of fungal enzymes into monomeric sugars, which serve as carbon sources for the fungi to produce hydrolytic enzymes (Gupta et al. 2011).

Lignin degradation in plant material involve three enzymes, namely, lignin peroxidase (LiP), manganese peroxidase (MnP), and versatile peroxidase (VP). LiP (E.C. 1.11.1.14) is a H_2O_2-dependent oxidative enzyme with a wide substrate range of both phenolic and non-phenolic aromatic compounds that includes the propyl side chains of lignin and the aromatic rings of lignin model compounds (Falade et al. 2016). On the other hand, MnP (E.C. 1.11.1.13) relies upon the generation of Mn^{3+} as a diffusible charge-transfer mediator and can reduce amines, dyes, and phenolic lignin model compounds (Fisher and Fong 2014). VPs are skilled of both LiP and MnP (manganese-independent and -dependent) catalytic activities, cleaving high-redox-potential non-phenolics, as well as lower potential aromatics and amines (Pérez-Boada et al. 2005). However, despite their ability to mineralize lignin, peroxidases are generally not used for degradation of plant biomass as the enzymes have a preference towards coupling of phenoxy radicals, leading to polymerization rather than depolymerization of lignin samples under in vitro conditions (Conesa et al. 2002). On the other hand, fungal laccases in presence of synthetic mediators like 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) and hydroxybenzotriazole (HBT) mimic their in vivo lignin-delignifying role and catalyze oxidative degradation of lignin in plant biomass also under in vitro conditions (Jeon and Chang 2013). Laccases (EC 1.10.3.2) are multi-copper oxidases produced by fungi, bacteria, plants, and even insects that catalyze the one-electron oxidation of four equivalents of reducing substrate, with the corresponding four-electron reduction of atmospheric oxygen to water (Yang et al. 2017). Fungal laccases have higher redox potentials than laccases from other species (plants, bacteria, and insects) and thus are of great implication for in vitro oxidative depolymerization reactions (Pogni et al. 2015). A large number of laccases have been isolated from many basidiomycetes fungi for delignification of plant biomass leaving behind white cellulose, which is hydrolyzed further by the action of cellulases and hemicellulases for the release of monomeric sugars for bioconversion to fuels or commodity chemicals (Hatakka and Hammel 2011).

Efficient cellulose hydrolysis of plant biomass requires the concerted action of three different classes of enzymes, namely endoglucanases (E.C. 3.2.1.4), exoglucanases (E.C. 3.2.1.91), and β-glucosidases (E.C. 3.2.1.21), collectively called as cellulases. Endoglucanases randomly hydrolyze internal glycosidic linkages, resulting in rapid decrease in polymer length while exoglucanases or cellobiohydrolases (CBHs) hydrolyze cellulose chains by removing mostly cellobiose (repeating structural unit that makes up the cellulose chain comprising two β-1,4-linked glucose molecules) from either reducing or nonreducing ends, resulting in rapid release of reducing ends. The endo- and exoglucanases degrade cellulose to cellobiose, after which β-glucosidases hydrolyze cellobiose to free glucose molecules (Yeoman et al. 2010). The cellulose-decomposing fungi include members of the Ascomycota, Basidiomycota, Deuteromycota, as well as some chytrids that occur in the rumen of some animals.

Hemicellulose is the second most abundant renewable polysaccharide after cellulose, having a linear backbone of β-1, 4-linked xyloses (Walia et al. 2017). It is a heteropolysaccharide containing O-acetyl, arabinosyl, and 4-O-methyl-D-glucuronic acid

substituent. The complete and efficient enzymatic hydrolysis of this complex polymer requires an array of enzymes with diverse specificity and modes of action. Endo-1,4-β D-xylanase (E.C. 3.2.1.8) randomly cleaves the xylan backbone; β-D-xylosidases (E.C. 3.2.1.37) cleaves xylobiose, whereas the removal of the side groups is catalyzed by α-L-arabinofuranosidases (E.C. 3.2.1.55), D-glucouronidases (E.C. 3.2.1.139), and acetylxylan esterases (E.C. 3.1.1.72). The existence of such a multifunctional xylanolytic enzyme system is relatively common in fungi and a large number of xylanases have been purified and characterized from many ascomycetes (Driss et al. 2012).

24.3 Thermophilic Fungi Involved in Lignocellulosic Degradation

Microorganisms, based on their optimal growth temperatures, can be divided into three main groups: psychrophiles (below 20 °C), mesophiles (moderate temperatures), and thermophiles (high temperatures, above 55 °C) (Turner et al. 2007). Thermostable enzymes are derived from thermophilic microbes as cellular components (enzymes, proteins, and nucleic acids) of thermophilic organisms are also thermostable. In biorefining, renewable resources such as lignocellulosic biomass are utilized for extraction of intermediates or for direct bioconversion into chemicals, commodities, and fuels by the aid of lignocellulolytic enzymes (Fernando et al. 2006). Enzymes that are more thermostable use shorter reaction times for the complete saccharification of plant polysaccharides compared to the mesophilic ones (van den Brink et al. 2013). In this regard, three thermophilic fungi (*Aspergillus nidulans*, *Scytalidium thermophilum*, and *Humicola* sp.) isolated from wheat straw, farm yard manure, and soil showed high cellobiase, CMCase, xylanase, and FPase activities (Kumar et al. 2008). Further, these three fungi were used to compost a mixture (1:1) of paddy straw and lignin-rich soybean trash for 3 months and it was observed that the fungal consortium was effective in converting paddy straw into good-quality compost (Kumar et al. 2008). In another study, thermophillic bacterial-fungal communities were developed to deconstruct switchgrass for biofuel production, and it was observed that *Aspergillus* and *Penicillium* are the dominant fungi present in thermophilic consortia (Jain et al. 2017a). In yet another study, compost inoculated with a psychrotrophic-thermophilic complex microbial agent comprising of a psychrotrophic bacterium consortium (PBC) and a thermophilic cellulolytic fungi consortium (TCFC) in cold-climate conditions showed greater decrease in total organic carbon and C:N ratios, as well as significant increase in total nitrogen, degradation of cellulose and lignin than in only PBC-inoculated compost (Gou et al. 2017).

24.4 Thermostable Cellulases

Fungi are a rich source of thermostable cellulases, and several cellulases have been characterized from a number of fungal species (Table 24.1). Interestingly, a collection of highly thermostable cellobiohydrolases chimeras were obtained by structure-guided recombination of three fungal class II cellulases from thermophilic fungus *Humicola insolens* which were expressed heterologously in *Saccharomyces cerevisiae*. It was observed that five of these chimeras had better half-lives of thermal inactivation at 63 °C, which was even greater than the most stable parent, CBH II enzyme from the thermophilic fungus *Humicola insolens*, suggesting that the chimera collection contain hundreds of highly stable cellulases (Heinzelman et al. 2009).

Couturier and co-workers (2011) identified the gene encoding a thermostable typical multi-modular glycoside hydrolase family 45 endoglucanase in *Pichia pastoris* GS115 genome. The study revealed the first characterized endo-β-1,4 glucanase from yeast, whose thermostability is promising for biotechnological applications related to the saccharification of lignocellulosic biomass (Couturier et al. 2011). In yet another interesting report, the cellulolytic potential of 16 thermophilic fungi from three ascomycete orders *Sordariales*, *Eurotiales*, and *Onygenales* and from the zygomycete order *Mucorales* was investigated, thereby covering all fungal orders that include thermophiles (Busk and Lange 2013).

Trudeau and co-workers (2014) created a stable endoglucanase derived from *Hypocrea jecorina* (anamorph *Trichoderma reesei*) Cel5A by a combination of stabilizing mutations, which were identified using consensus design, chimera studies, and structure-based computational methods. The designed endoglucanase had a 17 °C higher optimal temperature than the wild-type enzyme and hydrolyzed 1.5 times as much cellulose over a period of 60 h at its optimal temperature compared to the wild type at its optimal temperature. Furthermore, the thermostable mixture produced three times as much total sugar as the best mixture of the wild-type enzymes operating at their optimum temperature of 60 °C, clearly demonstrating the advantage of higher temperature cellulose hydrolysis (Trudeau et al. 2014). On the other hand, thermophilic cellulase (0.28 FPU/mL) produced from *Myceliophthora thermophila* under submerged cultivation conditions was used for saccharification of household food waste followed by fermentation with yeast resulting in 19.27 g/L of ethanol (Matsakas and Christakopoulos 2015). Production of thermostable cellulase from *Thermoascus auranticus* RCKK was improved by optimizing process conditions under simultaneous saccharification and fermentation (SSF) using central composite design of response surface methodology, and the crude enzyme was found to very efficiently hydrolyze office waste paper, algal pulp, and biologically treated wheat straw at 60 °C with sugar release of about 830 mg/g, 285 mg/g, and 260 mg/g of the substrate, respectively (Jain et al. 2017b). Similarly, a thermostable β-glucosidase isolated from *Thermotoga napthophila* RUK-10 possess catalytic activity for cellobiose hydrolysis with high potential in biomass conversion (Zhang et al. 2017). However, 19 thermophilic cellulolytic isolates from Algerian soil were found to hold great potential in the recycling of cellulosic biomass for bioenergy production when tested for the degradation of cellulosic biomass (printable paper, filter paper, and cotton) for 14 days of incubation at 60 °C (Khelil and Cheba 2014). Furthermore, a novel thermophilic β-glucosidase was reported from *Thermotoga napthophila* RKU-10 and used for the synthesis of prebiotic galactotrisaccharides at 75 °C, pH 6.5 (Yang et al. 2018). Thermophilic cellulolytic cocktails produced from white-rot fungus, *Inonotus obliquus*, under SSF conditions demonstrated activities of CMCase, Fpase, and β-glucosidase as 27.15 IU/g, 3.16 IU/g, and 2.53 IU/g, respectively, with high catalytic activity at 40–60 °C, releasing 130.24 mg/g of reducing sugars from raw wheat straw (Xu et al. 2018).

24.5 Thermostable Xylanases

Fungi are important sources of hemicellulases as they produce higher titers as compared to yeasts and bacteria. Thermostable β-D-xylosidases have been characterized from many fungal species with optimum temperature ranging from 60 °C to 75 °C (Table 24.2). Interestingly, gene for xylanase (MpXyn10A) was overexpressed from thermophilic fungus *Malbranchea pulchella* in *Aspergillus nidulans* followed by characterization of the expressed protein by Ribeiro and co-workers (2014). The

authors observed optimum activity of the enzyme at pH 5.8 and 80 °C with promising results in degradation of sugarcane bagasse (Ribeiro et al. 2014). However, the thermostability of a fungal GH11 xylanase was improved via site-directed mutagenesis guided by sequence and structural analysis. The recombinant xylanase, XynMUT, was constructed by substituting three residues (N207S, G208S, A210S) with serine at the C-terminus of XynCDBFV and it was concluded that the single-point mutations gave rise to improved thermostability (Han et al. 2017).

24.6 Thermostable Laccases

Among the fungi, certain species express laccases with exceptionally high thermal stability (Table 24.3). Additionally, due to the presence of numerous laccase isoforms owing to multigene family of the enzyme within the same as well as different fungal species, isozymes with different thermal stabilities have been isolated from the same fungus. For instance, three laccase isozymes of *Pleurotus ostreatus* were found to differ significantly in their thermal stabilities with $T_{1/2}$ at 60 °C for 200 min for POXA1, while 30 min for POXC, and only 10 min for POXA2 laccase (Palmieri et al. 1997). In another study, wood-decaying basidiomycete *Steccherinum ochraceum* isolate 1833 was reported to produce three highly thermostable laccase isoforms (I, II, III) with maximum activities in the range of 75–80 °C (Chernykh et al. 2008). On the other hand, a thermostable laccase isoform Pplcc2 from brown-rot fungus *Postia placenta* Mad-698-R was heterologously expressed in *Pichia pastoris* GS115 followed by its purification and characterization (An et al. 2015). However, a thermophilic lignin-degrading microbiota was developed and characterized using enrichment technique on Douglas fir at

55 °C. The results identified genera *Talaromyces, Aspergillus*, and *Byssochlamys* as the dominant fungi associated with lignin degradation under thermophilic conditions (Ceballos et al. 2017).

24.7 Application of Thermophilic Lignocellulolytic Enzymes in Biorefineries

Higher thermostability of the above-discussed lignocellulolytic enzymes allows saccharification of biomass polysaccharides at elevated temperatures. Consequently, the reaction times are shortened, mass transfer as well as substrate viscosity are increased, and as a result efficiency and overall economics of lignocellulose-based biorefineries have improved (Berka et al. 2011). The use of thermophilic enzymes for the production of biofuel and platform chemicals in a biorefinery approach is discussed below:

24.7.1 Biofuel

Biofuel production from lignocellulosic biomass (Fig. 24.1) can be done in three ways: (1) separate hydrolysis and fermentation (SHF), (2) simultaneous saccharification and fermentation (SSF), and (3) consolidated bioprocessing (CBP).

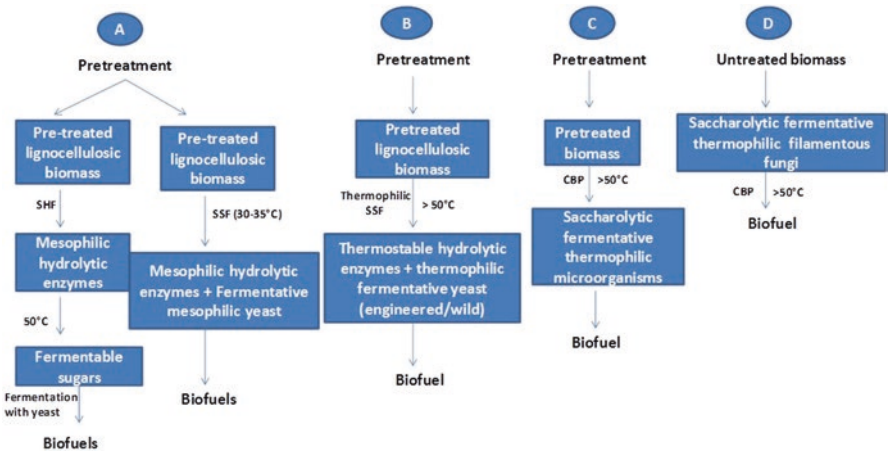

Fig. 24.1 Biofuel production from lignocellulosic biomass (**a**) SHF, wherein hydrolysis of pretreated substrate is carried out by mesophilic enzymes at 50 °C followed by fermentation with yeast at 30 °C and SSF, wherein enzymatic hydrolysis as well as fermentation of pretreated substrate are carried out simultaneously at 30–35 °C; (**b**) thermophilic SSF, wherein the pretreated substrate is simultaneously hydrolyzed as well as fermented at elevated temperatures using thermostable hydrolytic enzymes and thermotolerant yeast strains; (**c**) CBP of pretreated substrate by saccharolytic fermentative thermophilic microbes (bacteria/yeast) at 50 °C; (**d**) CBP of untreated substrate by saccharolytic fermentative thermophilic filamentous fungi at 50 °C

24.7.1.1 Separate Hydrolysis and Fermentation (SHF) Process

Production of biofuel via SHF process involves three main steps: (1) pretreatment of the biomass; (2) enzymatic hydrolysis of pretreated substrate by cellulases and hemicellulases to release monomeric sugars followed by (3) fermentation with yeast to produce alcohol.

The first step of the process, i.e., pretreatment of lignocellulose, can be performed by different methods, viz. physical, chemical, and biological. High temperature and acid have been employed initially in pretreatment of lignocellulosic residues at industrial scales. However, this approach is expensive, slow, and inefficient (Rubin 2008). In addition, the overall yield of the fermentation process will be decreased because the pretreatment releases fermentation inhibitors such as weak acids, furan, and phenolic compounds (Palmqvist and Hahn-Hägerdal 2000). On the other hand, employing biological pretreatment strategy for lignin deconstruction of plant biomass using microorganism, the problem of inhibitors can be overcome with added economic and environmental benefits (Dashtban et al. 2009). In the biological pretreatment process, white-rot fungi are mostly used to degrade lignin and hemicelluloses present in the plant biomass. Recently, three white-rot fungi—*P. florida*, *C. caperata* RCK2011, and *Ganoderma* sp. rckk-02—were used for the degradation of lignin in sugarcane bagasse and it was observed that the biologically pretreated substrate when hydrolyzed with crude cellulase from brown-rot fungus *Fomitopsis* sp.RCK 2011 released 2.4-fold higher sugars than the untreated substrate

(Deswal et al. 2014). Besides, application of thermophilic fungal species in lignocellulose pretreatment at industrial scales will result in further energy savings as the costly cooling after steam pretreatment is avoided. For example, thermophilic fungal species such as *Sporotrichum thermophile* (Bhat and Maheshwari 1987) and *Thermoascus aurantiacus* (Gomes et al. 2000) have been proposed as good candidates for pretreatment as well as bioconversion of lignocellulosic residues to sugars at industrial scales.

In the second step, i.e., hydrolysis step of the process, capabilities of enzymes (cellulases and xylanases) from various filamentous fungi, including members of the genera *Aspergillus, Rhizopus, Monilia, Neurospora*, *Fusarium, Trichoderma*, and *Mucor*, have been explored for the successful production of ethanol from biomass (Madadi et al. 2017). However, these enzymes are generally obtained from the fermentation of mesophilic fungal sources and thus do not work efficiently at higher temperatures >50 °C (Yennamalli et al. 2013). Therefore, to increase process economics as well as process efficiency, there is an intense interest in exploiting the potential of thermostable bioprocessing enzymes. In this regard, two enzyme mixtures, a mesophilic and a thermostable, were exposed to typical process conditions of ethanol production (temperatures from 55 °C to 65 °C and up to 5% ethanol) and then analyzed by enzyme activity assay as well as SDS-PAGE and it was observed that the thermostable and mesophilic mixture remained active at up to 65 °C and 55 °C, respectively (Skovgaard and Jørgensen 2013). In another study by Long and co-workers (2018), hydrolysis of biomass (corn stover, poplar, and kraft pulp) was studied at high temperatures (85 °C) by thermostable xylanase (Xyn10A) from *Thermotoga thermarum* DSM 5069 followed with saccharification step by commercial cellulase. The authors observed that high-temperature xylanase treatment considerably increased cellulose accessibility/hydrolyzability towards cellulases, with smoothed fiber surface morphology, compared with commercial xylanase treatment at 50 °C. The authors concluded that the increased temperature during thermostable xylanase treatment facilitated viscosity reduction of biomass slurry, which exhibited more benefits during hydrolysis of various steam-pretreated substrates at increased solid content (Long et al. 2018).

In the final step of biofuel production, hydrolytic products including monomeric hexoses (glucose, mannose, and galactose) and pentoses (xylose and arabinose) are fermented to ethanol using yeast strains. Among these hydrolytic products, glucose is normally the most abundant, followed by xylose or mannose and other sugars at lower concentration. *Saccharomyces cerevisiae* is the most frequently and traditionally used microorganism for fermenting ethanol from starch-based residues at industrial scales (Hahn-Hägerdal et al. 2007). However, *S. cerevisiae* is unable to efficiently utilize xylose as the sole carbon source or ferment it to ethanol (Chu and Lee 2007). To make industrial lignocellulosic bioconversion more economically feasible, it is necessary to choose microorganisms capable of fermenting both glucose and xylose. This can be achieved by metabolic engineering of *S. cerevisiae* with genes from other xylose-fermenting yeasts like *Pichia stipitis* (Hahn-Hägerdal et al. 2007) as well with the help of nonrecombinant (e.g., adaptation) techniques (Dashtban et al. 2009).

24.7.1.2 Simultaneous Saccharification and Fermentation (SSF) Process

The last two steps of bioconversion of pretreated lignocellulolytic residues to ethanol (hydrolysis and fermentation) can be performed separately (SHF) or simultaneously (SSF). In the separate hydrolysis and fermentation (SHF), the hydrolysate products will be fermented to ethanol in a separate process. The advantage of this method is that both processes can be optimized individually (45–50 °C for hydrolysis, whereas it is 30 °C for fermentation), while drawbacks include costly addition of β-glucosidase to overcome end product inhibition caused by accumulation of enzyme-inhibiting end products (cellobiose and glucose) during the hydrolysis. Alternatively, in simultaneous saccharification and fermentation (SSF), the end products after the pretreatment step are directly converted into ethanol. Therefore, addition of high amounts of β-glucosidase is not necessary and this reduces the process cost (Stenberg et al. 2000). Nevertheless, the main downside of SSF is the need to compromise processing conditions such as temperature and pH at suboptimal levels for each individual step (saccharification and fermentation). Therefore, finding thermotolerant yeasts which can work efficiently at higher temperatures required for optimum enzymatic hydrolysis is necessary for the development of an efficient SSF process (Choudhary et al. 2016). Alternatively, development of recombinant yeast strains with improved thermotolerance will also enhance the performance of SSF substantially.

Hari Krishna and co-workers (2001) compared thermotolerant yeast *Kluyveromyces fragilis* NCIM 3358 with *Saccharomyces cerevisiae* NRRL-Y-132 and found that *K. fragilis* perform better in the SSF process at 42 °C resulting in high yields of ethanol (2.5–3.5% w/v) compared to *S. cerevisiae* (2.0–2.5% w/v) (Hari Krishna et al. 2001). In another study, steam-pretreated lignocellullosic material (eucalyptus, poplar, bagasse, sweet sorghum, mustard, and wheat straw) was used for ethanol production via SSF process using thermotolerant *K. marxianus* at *42 °C* (Ballesteros et al. 2004). Huang and D'Andrea (2006) produced 40 g/L ethanol from 161 g/L of paper sludge organic material containing 66% (w/w) glucan in an SSF process at 42 °C using *S. cerevisiae* TJ14 strain in conjunction with cellulase produced by filamentous fungus *Acremonium cellulolyticus* (Huang and D'Andrea 2006). Interestingly, a respiratory-deficient mutant of *Candida glabrata* produced 17.0 g/L ethanol from 50.0 g/L Avicel microcrystalline cellulose at 42 °C under aerobic conditions (Watanabe et al. 2009). At the same time, a transformation system was constructed to express an *Aspergillus aculeatus* β-glucoside (BGL) gene in a thermotolerant strain of *P. kudriavzevi*, which was also acid and ethanol tolerant. The transformant was found to produce 29 g/L ethanol from 100 g/L Avicel microcrystalline cellulose in simultaneous saccharification and fermentation at 40 °C without addition of BGL (Kitagawa et al. 2010). On the other hand, a newly isolated thermotolerant ethanologenic yeast strain, *Pichia kudriavzevii* IPE100, produced ethanol with a theoretical yield of 85% with glucose at 42 °C (Kwon et al. 2011). In yet another study, mutation screening for thermotolerance was performed in *S. cerevisiae* strains using a proofreading-deficient DNA polymerase or ultraviolet (UV) irradiation, which resulted in *S. cerevisiae* mutants that grow at temperatures

up to 40–42 °C (Abe et al. 2009). However, thermotolerance as well as ethanol tolerance of *S. cerevisiae* were improved using genome shuffling approach by a combination of protoplast fusion and UV irradiation (Shi et al. 2009).

SSF of three delignified lignocellulosic biomass, viz. rice straw, wheat straw, and sugarcane bagasse, was performed at 42 °C using a newly isolated themotolerant yeast, *Kluyveromyces* sp., in conjunction with in-house cellulases from *Aspergillus terreus* (Narra et al. 2015). Further, ten thermophilic yeast strains (capable of growth at 40 °C) were isolated from diverse sources, belonging to various genera like *Saccharomyces*, *Candida*, *Pichia*, and *Wickerhamomyces*. The authors observed that *Saccharomyces cerevisiae* JRC6, isolated from distillery waste, produced ethanol with 88.3% and 89.1% theoretical efficiency at 40 °C and 42 °C, respectively, from glucose (Choudhary et al. 2017). Likewise, 5 thermotolerant yeasts, designated *Saccharomyces cerevisiae* KKU-VN8, KKU-VN20, and KKU-VN27, *Pichia kudriavzevii* KKU-TH33, and *P. kudriavzevii* KKU-TH43 out of 234 yeast isolates from Greater Mekong Sub region (GMS) countries, i.e., Thailand, The Lao People's Democratic Republic (Lao PDR), and Vietnam, were selected for ethanol production at 45 °C (Techaparin et al. 2017).

24.7.1.3 Consolidated Bioprocessing (CBP) Process

Consolidated bioprocessing (CBP) aims to minimize all bioconversion steps of biofuel production into one step in a single reactor using one or more microorganisms. CBP operation featuring cellulase production, cellulose/hemicellulose hydrolysis, and fermentation of 5- and 6-carbon sugars in one step has shown the potential to provide the lowest cost for biological conversion of cellulosic biomass to fuels (Singh et al. 2017). In CBP, the whole process is carried out at a single elevated temperature rather than in three steps (pretreatment, hydrolysis, and fermentation) involving different temperatures. This high-temperature-based biomass processing seems challenging but could be the most rewarding approach for bioethanol production in near future and thermophilic microbes and their enzymes can play an important role in its successful implementation (Acharya and Chaudhary 2012). In past, two approaches have been used for CBP: (1) engineering a cellulase producer to be ethanologenic or (2) engineering an ethanologen, such as *S. cerevisiae* or *Zymomonas mobilis*, to be cellulolytic. But there are various difficulties and challenges in the conversion of a candidate microorganism using gene transfer technology due to the adverse effects of the co-expression of multiple heterologous genes on cell performance, the modulation of simultaneous co-expression of multiple genes at the transcription level and improper folding of some secretory proteins (Xu et al. 2009). On the other hand, search for a native CBP microorganism displaying high levels of alcohol/sugar tolerance, thermotolerance, as well as the ability to utilize multiple sugars is still going on.

CBP of lignocellulosic biomass to ethanol using thermophilic bacteria, *Clostridium thermocellum*, providing a promising solution for efficient lignocellulose conversion without addition of exogenous enzymes was performed (Svetlitchnyi

et al. 2013). However, despite the potential of a number of bacteria to ferment hexose and pentose sugars to ethanol, it is difficult in practice to maintain anaerobic conditions in large-scale fermentation restricting the use of thermophilic anaerobes. Alternatively, use of filamentous fungi in the CBP process will go a long way as even the pretreatment step (Fig. 24.2) can be eliminated due to their delignification ability. In this regard Ali and co-workers reviewed various fungi with the potential of being used in CBP for biofuel production. These included *Trichoderma reesei*, *Fusarium oxysporum, Mucor indicus*, *Monilia sp*., *Rhizopus oryzae*, *Paecilomyces* sp., *Aspergillus oryzae*, *Neocallimastix patriciarum*, and *Neurospora crassa*. All these filamentous fungi possessed the ability to assimilate and metabolize numerous sugars, both hexose and pentose types. Furthermore, these fungi have a greater degree of thermotolerance than many bacteria and can grow at closer to the optimal temperature of enzymatic hydrolysis, i.e., 40–50 °C (Ali et al. 2016).

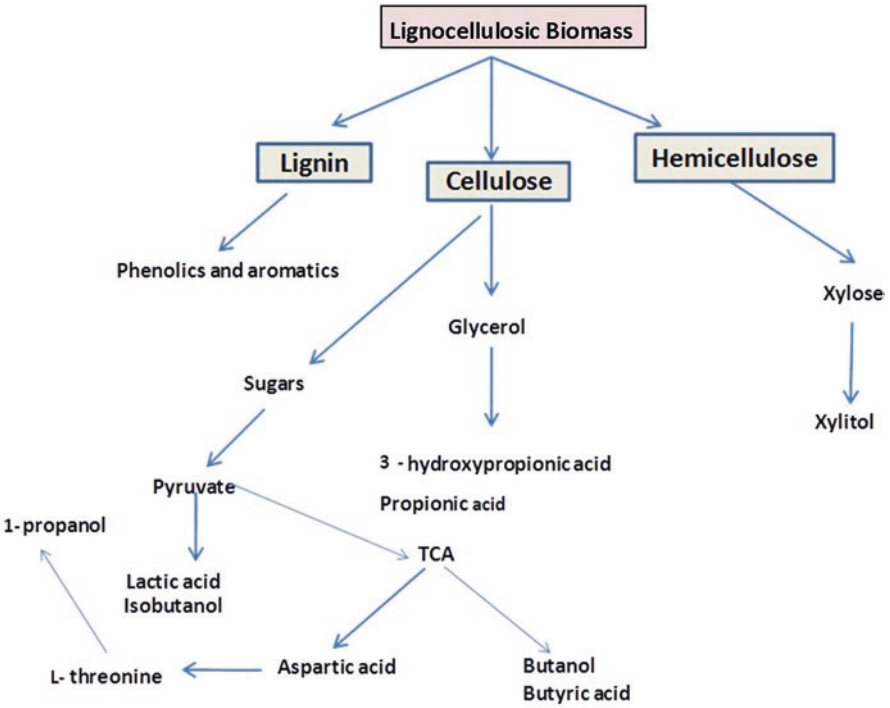

Fig. 24.2 Platform chemical production from lignocellulosic biomass

24.7.2 Platform Chemicals

Increased dependency on the depleting and highly priced petroleum-based products as well as the issue of greenhouse gas emission have raised extensive interest in microbial fermentation processes to produce platform chemicals from renewable resources (Roa Engel et al. 2008). A platform chemical is an intermediate molecule, with a structure able to generate a number of derivatives (Bomtempo et al. 2017) as shown in Fig. 24.2. These biochemicals can be produced from biomass (a) by separate hydrolysis and fermentation of the biomass via intermediate sugars or (b) by simultaneous hydrolysis and fermentation of biomass using thermophilic microbes and their enzymes. Various thermophilic fungi per se have been used for biochemical production from biomass (Table 24.4). A range of platform chemicals being synthesized from biomass are also discussed below:

24.7.2.1 3-Hydroxypropionic Acid

3-Hydroxypropionic acid (3-HP) is an attractive platform chemical, which can be used to produce a variety of commodity chemicals, such as acrylic acid and acrylamide. In a study, 3-HP was isolated from the extracts obtained from submerged cultures of several endophytic fungi, namely *Phomopsis phaseoli*, *Melanconium betulinum*, *Betula pendula*, and *B. pubescens* (Schwarz et al. 2004). However, engineered *Saccharomyces cerevisiae* was also used for the production of 3-HP (Chen et al. 2014; Kildegaard et al. 2015).

24.7.2.2 Itaconic, Fumaric, Ferulic and Malic Acid

Fumaric acid (31%) was produced along with chitin (0.21 g chitin/g biomass) from dairy manure using pelletized filamentous fungus, *Rhizopus oryzae* ATCC 20344 (Liao et al. 2008), while itaconic acid (25 g/L) was produced by fermentation with *Ustilago maydis* on pretreated cellulose and hemicellulosic fractions (Klement et al. 2012). L-Malic acid (titers of 106 g/L and productivity of 0.88 g/L/h) was produced from *Aspergillus* sp. N1-14′ grown in medium containing glucose (Zhou et al.

Table 24.4 Biochemical production from biomass using thermophilic fungi

Biochemical	Thermophilic fungi	Yield	References
3-Hydroxy propionic acid	*Saccharomyces cerevisiae*	463 mg/L	Chen et al. (2014)
(5S)-hydroxyhexane-2-one	*Thermus thermophilus*	3.9 g/L/h	Diederichs et al. (2015)
Chitooligosaccharides	*Humicola grisea*	–	Kumar et al. (2017)
Rubber extraction	*Thermomyces lanuginosus*	90 mg/g Dry TK root	Sikandar et al. (2017)

2000). However, ferulic acid was extracted from corn cobs using thermostable xylanases and esterases from *Thermobifida fusca* (Huang et al. 2011). The process was achieved by cloning a gene (*axe*) encoding the thermostable acetyl xylan esterase (AXE) from *Thermobifida fusca* NTU22 into a *Yarrowia lipolytica* host strain and the recombinant expression resulted in extracellular esterase production at levels as high as 70.94 U/mL, approximately 140 times higher than that observed in a *Pichia pastoris* expression system. Further, the incubation of corncob with *T. fusca* xylanase (Tfx) for 12 h and then with the (Acetyl xylan esterase) AXE for an additional 12 h resulted in accumulation of 396 μM ferulic acid in the culture broth (Huang et al. 2011).

Two *Aspergillus* sp. (*A. terreus* and *A. oryzae*) yielded fumaric acid (0.54 mg) and itaconic acid (0.11 mg) by solid-state fermentation and simultaneous saccharification and fermentation (Jiménez-Quero et al. 2016).

24.7.2.3 Xylitol

Saccharomyces cerevisiae and *Candida tropicalis* were used separately and as co-culture for simultaneous saccharification and fermentation of 5–20% corn cobs. The authors obtained 21, 20, and 15 g/L of xylitol from 200 g/L corn cobs from cultures of *C. tropicalis*, co-culture, and *S. cervisiae*, respectively (Latif and Rajoka 2001). Fernandes and co-workers also cloned xylitol and L-arabitol dehydrogenase genes heterologously from thermophilic fungus *Talaromyces emersonii* expressed in yeast. The authors suggested that the genes may be valuable in the production of xylitol, L-arabitol, and ethanol from renewable resources rich in pentose sugars (Fernandes et al. 2010).

24.7.2.4 Glycolic Acid

Glycolic acid has attracted attention as platform chemical, especially as building block for polyglycolate (PGA), a polymer with high gas permeability and mechanical strength, and therefore excellent properties as packaging material (Grayson et al. 2004). De novo synthesis of glycolic acid from renewable resources, apparently more favorable, has been achieved in the yeasts *S. cerevisiae* and *Kluyveromyces lactis* (Koivistoinen et al. 2013).

24.7.2.5 Lactic Acid

Lactic acid is an important platform chemical for producing polylactic acid (PLA) and other value-added products (Grayson et al. 2004). In this regard, lactic acid-producing bacteria (LAB) have received wide attention for production of lactic acid because of their high growth rate and product yield but these bacteria have complex nutrient requirements because of their limited ability to synthesize B-vitamins and

amino acids, making supplementation of sufficient nutrients such as yeast extracts to media necessary (Chopin 1993). Moreover, LAB produce both the isomers of lactic acid (D-Lactic acid and L-Lactic acid). On the other hand, fungal *Rhizopus* species have also attracted a great interest for lactic acid production as unlike the LAB, lactic acid-producing *Rhizopus* strains generate L-lactic acid as a sole isomer of lactic acid (Yoshihara et al. 2003). Lactic acid exists naturally in two optical isomers: D(−)-lactic acid and L(+)-lactic acid. Elevated levels of the D-isomer are harmful to humans and thus L(+)-lactic acid is the preferred isomer for food-related and pharmaceutical industries (Zhang et al. 2007). Furthermore, fermentation with filamentous fungi makes separation of fungal biomass from the fermentation broth easier because of their filamentous or pellet forms, leading to a simple and inexpensive downstream processing. In addition, as a by-product from lactic acid production, fungal biomass of *Rhizopus* strains can also be used for fungal chitosan production (Yoshihara et al. 2003) which can be used as an additive in animal feeds to improve the feed quality (Kusumaningtyas et al. 2006). Many studies have explored the possibility of producing lactic acid from lignocellulosic substrates by *Rhizopus* species (Maas et al. 2006; Miura et al. 2004; Ruengruglikit and Hang 2003; Woiciechowski et al. 1999).

24.8 Conclusions

The issue of environmental crisis, sustainability of future generations, as well as increasing prices of existing nonrenewable reserves have led to the development of fuels and chemicals from alternative renewable energy resources. Lignocellulosic biomass is a potential low-cost renewable raw material for the production of chemicals and biofuels through bioconversion of the three major chemical components: cellulose, hemicellulose, and lignin. Deconstruction of these lignocellulosic components with the aid of microbes and their enzymes for the production of biochemicals and biofuels makes the foundation of biorefineries. Use of fungal enzyme cocktails is one of the most promising ways to convert the lignocellulosic biomass into the reducing sugars for industrial utilizations, due to the fungi's capability to secrete high titers of lignocellulolytic enzymes. However, expensive enzyme production processes, poor stability, and low efficiency of currently used enzymes in industrial conditions still present a major obstacle in development of commercial biorefineries. In this regard, thermostable enzymes that hydrolyze lignocellulose to its component sugars at elevated temperatures have many advantages for improving the conversion rate of biomass over their mesophilic counterparts. Their robust thermostabilities make them better suited for the harsh industrial conditions as well as for better and efficient deconstruction of lignocellulose to fermentable products. Therefore, it can be concluded that the establishment of biorefineries using thermophilic fungi and their enzymes is the most sought after and advantageous alternative to the success of modern day biorefineries.

24.9 Future Perspectives

Exploration of highly efficient thermostable enzyme systems which improve the efficiency and economics of bioconversion of lignocellulosic biomass into value-added products is very crucial for the implementation of commercial biorefineries. Bioengineering of fermentative mesophilic organisms to enhance their thermostability for biofuel production in consolidated bioprocessing is a promising approach to enhance bioconversion efficiency and reduction of cost involved. Although a lot of progress has been made on these lines with respect to biofuel production, development of commodity chemicals from biomass using thermophilic fungi and their enzymes is still under progress and a lot more efforts are needed to develop efficient bioprocess for the production of platform chemicals in a biorefinery approach. This will involve the development of "one-step biorefineries" using fermentative thermotolerant fungi, which secrete all the three enzymes required for lignocellulose deconstruction as well as production of biofuel and platform chemicals from biomass in a single pot. Use of modern genetic tools for metabolic engineering may further enhance the productivity, thereby making the process cost effective.

Chapter 25
Acidomyces acidophilus: Ecology, Biochemical Properties and Application to Bioremediation

Wai Kit Chan, Dirk Wildeboer, Hemda Garelick, and Diane Purchase

25.1 Introduction

Extremophilic fungi have been successfully isolated from highly polluted or extreme environments such as mining wastewaters of pH 1.1 (Oggerin et al. 2013), a uranium mine (Vázquez-Campos et al. 2014) and a volcanic geothermal system (Chiacchiarini et al. 2010). Hitherto, the data on extremophilic fungi diversity in extremely acidic conditions is limited; however, melanised and meristematic fungi have been found to be the prevailing groups in such habitats (Baker et al. 2004; López-Archilla et al. 2004; Selbmann et al. 2008; Hujslová et al. 2010). For example, *Hortaea acidophila* was isolated from brown coal that contains humic and fulvic acid at pH around 0.6 (Hölker et al. 2004); two acidophilic strains, *Hortaea werneckii* and *Acidomyces acidophilum,* were isolated from Rio Tinto in Spain, where the mean pH value was 2.3, and which contained high concentrations of Fe, Cu, Zn, As, Mn and Cr (Zettler et al. 2002). Another black fungus, *Exophiala sideris*, was isolated from an ancient gold arsenic mine polluted with akylbenzenes in Złoty Stok, Poland, for which the authors claimed that it can be used potentially for the bioremediation of metalloids (Seyedmousavi et al. 2011).

Acidomyces acidophilus is a pigmented ascomycete capable of growing in extremely acidic conditions (Sigler and Carmichael 1974). Its melanin-containing cell walls offer the fungus protection from adverse environmental conditions such as extreme pH, temperature and toxins (Jacobson et al. 1995; Martin et al. 1990; Tetsch et al. 2005; Hujslová et al. 2013). This protection also provides the fungus a certain level of resistance to oxidative stress (Jung et al. 2006). *A. acidophilus* is an anamorphic fungus, hyphomycete, and phylogenetically belongs to the class

Dothideomycetes, order *Capnodiales*. The colonies are dark and compact, slow growing in neutral medium but faster in acidic medium. Their septate, scarcely branched, brown and thick-walled hyphae eventually convert into a meristematic mycelium. Conidia are produced by arthric disarticulation of hyphae. The morphologies of *Acidomyces* species were not easily described using microscopy because of its tendency to convert to highly melanised meristematic growth, produce scarcely disarticulating clumps of cells, or tend to appear without any conidiation but entirely hyphal (Selbmann et al. 2008).

The intracellular enzymatic regulation mechanisms in these extremophilic fungi, especially *A. acidophilus*, of low pHs, reactive oxygen species and extreme temperatures are now widely considered as valuable resources for their exploitation in novel biotechnological applications (such as cleaning of contaminated soils or water) and in the field of bio-catalysis (Tiquia-Arashiro and Rodrigues 2016). They also generated research interests on biomolecule stability investigation and the design and synthesis of proteins that are relevant for various industrial applications (Polizeli et al. 2005; Hess 2008; Selbmann et al. 2008).

To survive in such adverse conditions, *A. acidophilus* has developed various approaches and evolved different mechanisms to cope with and even thrive in these harsh ecological niches. Although *A. acidophilus* is a remarkable fungus, it is not well studied and there is a dearth of information in its biochemical properties and applications. This chapter aims to provide a better understanding of *A. acidophilus* and highlights its potential in sustainable environmental biotechnology. We explore the ecological niches of *A. acidophilus* as well as its remarkable adaptation to survival in the extreme environment, providing an insight into their evolutionary ability in using their flexible ecological plasticity to exploit and thrive in new environments. With the advancement of 'omics' tools, genetic and proteomics information of this fungus has begun to emerge, and we present up-to-date information on this much-neglected fungus. The chapter provides an in-depth review on *A. acidophilus* literature including a discussion of its potential in bioremediation and explores its application in other research areas. We hope to bring this fungus to a wider scientific attention.

25.2 Ecology of *Acidomyces acidophilus*

'Extreme' conditions are taken to be those that deviate from normal physicochemical limits supporting growth of any organisms. In extremely low pH and toxic conditions, stressing conditions can cause detrimental effects on microorganisms' metabolic processes and enzyme- and protein-mediated biological functions (Selbmann et al. 2013). However, many eukaryotes such as fungi have the ability to thrive under stressing conditions that are hostile to other living organisms. Many fungal species, of an unexpected degree of diversity, were discovered living in extreme habitats such as volcanic soils (Appoloni et al. 2008), extremely cold and

ice-free deserts in the Antarctica (Friedmann et al. 1993, Selbmann et al. 2008), in geothermal and humid soils (Hujslová et al. 2013), in acid mine drainage (Baker et al. 2004), in hypersaline environments (Plemenitaš et al. 2014) or in extremely polluted mining soils (Chan et al. 2018). Most of the acidophilic and psychrophilic black meristematic yeasts and fungi species are the best examples of common inhabitants in these stressful environments (Baker et al. 2004; Hujslová et al. 2010). Organisms that have the ability to adapt and grow in an extremely acidic environment, pH <4, are known as acidophiles. This ecological niche can usually be found in heavily polluted sites created by prolonged anthropogenic activities, which release toxic pollutants that contaminate and change the pH conditions of the surrounding soils or water.

This extreme environment is where the black fungus *Acidomyces acidophilus* was first isolated, from a highly acidic, sulphate-containing industrial water by Starkey and Waksman (1943). Subsequently, more *Acidomyces* species were isolated and identified successfully from various extreme environments. These are summarised in Table 25.1. All the *A. acidophilus* strains show the common feature of being acidophilic and thrive in highly acidic ecological niche between pH 1 and 3. Selbmann et al. (2013) showed that acidity plays a pivotal role in maintaining *A. acidophilus* growth, where optimal growth was observed between pH 3 and 5. Another species, *Acidomyces richmondensis*, was isolated from sulphuric ore acid mine drainage in Richmond, USA, at pH 0.5 and 0.9 and thermophilic temperature in the range of 35–57 °C by Baker et al. (2004). However, the optimal growth temperature for most *A. acidophilus* is 25 °C (Selbmann et al. 2008; Hujslová et al. 2013). *A. acidophilus* was not only able to tolerate extremely low pH, but it has also developed tolerance towards high concentration of toxic metals and metalloids stresses such as Al, As, Cu, Fe or U (Starkey and Waksman 1943; Gould et al. 1974; Gimmler et al. 2001; Yamazaki et al. 2010; Vázquez-Campos et al. 2014; Chan et al. 2018).

Fungi have developed immense stress resistance to cope with and tolerate extreme conditions through different adaptation strategies and mechanisms. Generally, fungi have the ability to adapt to new environments, due to their remarkable phenotypic plasticity, by performing a process called ‘ecological fitting’, as proposed by Agosta and Klemens (2008). As Capnodiales black yeast-like fungi, *A. acidophilus* strains are characteristically polymorphic and display extraordinary ecological, biological and morphological plasticity. In the presence of various stress factors, fungi can perform specific adaptation strategies such as meristematic growth, melanisation, alterations of cell wall structure or isodiametric expansion, ensuring optimisation of the volume-to-surface ratio and allowing them to tolerate and thrive under stress conditions (Hujslová et al. 2013; Selbmann et al. 2013; Gunde-Cimerman et al. 2005; Wollenzien et al. 1995; Sterflinger and Hain 1999).

The high degrees of melanisation, phenolic polymers and thick cell walls (Figueras et al. 1996) in *A. acidophilius* result in oxygen-containing functional groups such as carboxyl, sulphhydryl, phosphate, methoxyl and carbonyl enhancing their survival and their ability to withstand extreme pH and toxic compounds

in their habitual environment (Chan et al. 2018). All the *A. acidophilus* isolated from extreme environment showed to be highly melanised (Selbmann et al. 2008), indicating that melanin is an important protective factor in increasing their resistance to reactive oxygen species (ROS), toxic metals, extreme pH and temperature, and UV radiation. The highly melanised cell wall of *A. acidophilus* is shown in Fig. 25.1b. The hydrophobicity and negative charges of melanin offer the fungus protection from oxidative stress (Jung et al. 2006). Another interesting property of melanin is that it can shield organisms from ionising radiation. Since melanin has a stable free radical population, it is thought that the radio-protective properties are due to the scavenging of free radicals generated by radiation (Eisenman and Casadevall 2012). In addition, the controlled dissipation of high-energy recoil electrons by melanin prevents secondary ionisations and the generation of damaging free radical species (Schweitzer et al. 2009). The dynamic architecture of thick cell wall found in *A. acidophilus* possesses an intracellular pH controlling system and in extreme pH conditions it maintains the cytoplasm to a near-neutral pH (Hesse et al. 2002; Bignell 2012). These features coupled with its ability to change polarity (Yoshida et al. 1996) in *A. acidophilus* morphologies resulted from convergent evolution of its long-term exposure to extreme ecological niches (Selbmann et al. 2008).

25.3 Biochemical Properties of *A. acidophilus*

The biochemical properties expressed by *A. acidophilus* are some of the key strategies leading to their remarkable survival ability in extreme environment. In a mine in Richmond, USA, an isolated *Acidomyces* sp. (*A. richmondensis*) produced a variety of novel putative fungal glycosyl hydrolases and secreted other enzymes extracellularly to resist the highly acidic (pH <1), elevated metal concentration (≈200 mM Fe) and thermophilic (40–50 °C) conditions of the acid mine drainage (Baker et al. 2004). As for the ability to degrade aromatic compounds, some *A. acidophilus* strains (CBS 270.74, CBS 335.97 and CBS 899.87) tested by Selbmann et al. (2013) have shown the ability to use 4-hydroxybenzene (4HB) and protocatechuic acid (PCA) in acidic condition and phenylacetic acid (PAA) was efficiently metabolised at pH 7. This illustrates the potential of *A. acidophilus* to utilise these compounds as their carbon source. It is also noted that strain CBS 335.97 is the only candidate that showed a slight growth on catechol (CAT) in acidic condition. All the tested *A. acidomyces* strains were able to produce the enzymes lipase and amylase even in acidic condition such as pH 3. Another study by Ervin and Wolfe (2016) suggested that *Acidomyce*s sp. isolated from a geothermal spring lake contains viable sets of hemicellulose- and lignin-degrading extracellular enzymes that function in acidic and thermophilic conditions for lignocellulosic degradation.

In a metabolomic study performed on *A. richmondensis,* from acid mine drainage (AMD) biofilm (Mosier et al. 2016), its genome revealed a gene that was involved in the biosynthesis and degradation of taurine metabolites. When exposed to environmental stressors, taurine is involved in several physiological roles such as protecting proteins, nucleic acids and membranes against ROS (Andres and Bertin 2016). Besides taurine, *A. richmondensis* also contained genes that were involved in the biosynthesis and degradation of trehalose, including a betaine-aldehyde dehydrogenase gene. These encoded genes play important roles in the metabolism of compatible solutes, especially in the high-ionic-strength AMD waters (Druschel et al. 2004). Genome-encoded complete tricarboxylic acid (TCA), glycolysis and pentose phosphate pathways were found in the *A. richmondensis* during the metaproteogenomic analysis by Mosier et al. (2016) as well as many genes that were involved in the metabolism of fructose, mannose, galactose, starch and sucrose. In a proteomic functional analysis on *A. richmondensis*, it was predicted that its genes encode for 350 carbon active enzymes (CAZymes), and either involve in degradation, modification or creating glycosidic bonds (Lombard et al. 2014). These CAZymes include glycosyl transferases, glycoside hydrolases, carbohydrate esterases and carbohydrate-binding modules, and are involved in the formation of glycosidic bonds, hydrolysis/rearrangement of glycosidic bonds, hydrolysis of carbohydrate esters and carbohydrate-binding activity, respectively (Mosier et al. 2016). As one of the key components of acid-stable enzyme cocktails, *A. richmondensis* is still able to produce these glycosyl hydrolases compared to other non-extremophilic fungi that are involved in the bioenergy production even under extreme pH and toxic conditions.

25.4 Application to Bioremediation

The rich biochemical properties of *A. acidophilus* enable it to tolerate not only extreme pH but also toxic compounds in highly contaminated soil or water. It shows a great biotechnological potential, especially in bioremediation applications (Selbmann et al. 2013; Chan et al. 2018). Several extremophile fungi *such as Coniochaeta fodinicola, Hortaea acidophilia, Teratosphaeria acidotherma* and *A. acidophilus* were able to produce novel enzymes and other metabolites to survive in harsh environments which can be applied in bioremediation, primarily by removing toxic metals and metalloids from soil and water contamination caused by anthropogenic activities such as mining (Tetsch et al. 2005; Stierle et al. 2006; Wang et al. 2010; Luo et al. 2010; Yang et al. 2011; Selbmann et al. 2013; Boonen et al. 2014; Hujslová 2015).

The study carried out by Mosier et al. (2016) showed that *A. richmondensis* encoded for and expressed a great number of genes that are involved in heavy metal transport and detoxification. The proteomic and transcriptomic analyses on *A. richmondensis* revealed a wide range of metal transporters specific to iron, copper, zinc, magnesium, calcium and nickel. Besides these transporters, it also contained genes that are significant in heavy metal chelation, including a ferrochelatase; a siderophore-dependent iron transporter, sideroflexin; and several transcripts for ferric-chelate reductase. Detoxification of exogenous cyanide and/or cyanide by-products of other cellular metabolic reaction genes such as cyanide hydratase, cyanide nitrilase and cyanate lyases was encoded and expressed by *A. richmondensis*. They also found other genes encoded within *A. richmondensis* that are involved in arsenic detoxification process such as arsenate reductase (ArsH, an NADPH-dependent FMN reductases), membrane-associated arsenite permeases (ArsB or ACR_3) and arsenite-translocating ATPases (ArsA). Other biotransformation genes involved in arsenate reduction such as arsenite methyltransferase, genes encoded for methylarsonite methyltransferase activity as well as genes encoding glutathione S-transferase were also expressed. These proteins found in *A. richmondensis* are heavily involved in the reduction of arsenate to arsenite (Zakharyan et al. 2005; Ventura-Lima et al. 2011; Pantoja Munoz 2014; Andres and Bertin 2016).

The study by Chan et al. (2018) on biosorption of arsenic and antimony by *A. acidophilus* WKC-1 showed that –OH, –NH, –CH, $–SO_3$ and PO_4 functional groups are identified as the key biosorption binding sites for As^{5+} and Sb^{5+}. The isolate WKC-1 showed a high resistance to and high percentage of As^{5+} removal of 70.30%, one of the highest reported in *A. acidophilus* species, when cultivated in 100 mg L^{-1} As^{5+} concentration after 21 days. The tolerance of the isolated *A. acidophilus* WKC-1 strain to low pH and high As concentration together with its capacity to remove approximately 170 mg As^{5+} per gram dry biomass made it a potential candidate to be used in bioremediation of As.

Despite the robustness of this fungus and its ability to survive in extremely adverse environment, *A. acidophilus* remained a poorly researched organism, and further work is required to fully explore its potential in bioremediation and other biotechnological applications.

25.5 Future Perspectives

The remarkable tolerance of *A. acidophilus* to adverse conditions and its significant variability and ability to mediate in extreme acidity ecosystems where most forms of life cannot may open up research opportunities and exploration for planetary and astrobiological studies in the search of life on acidic and hot planets such as our sister planet, Venus.

Although *A. acidophilus* has proven to be effective in removing metalloids such as arsenic in soil in laboratory settings, in order to apply it to remediate contaminated soil effectively it needs to be scaled up accordingly. The slow growth rate of *A. acidophilus* is the bottleneck in scaling up; however it has been shown by Chan et al. (2018) that growing the fungi on a rotator using liquid medium has significantly reduced the growth period (from 28 to 3 days). Recent advances in molecular biology and biotechnology techniques can be applied to genetic modify *A. acidophilus* to improve its remediation capabilities. The genes involved in detoxification of heavy metals in *A. acidophilus* can be cloned and expressed in a fast growing host. Various genetic engineering approaches have been developed to optimise mycoremediation by engineer-improved fungi and enzymes. *A. acidophilus* contains several genes that encode glutathione S-transferase and through genetic splicing or gene regulations these important genes that reduce the toxicity of arsenic from arsenate to arsenite can be overexpressed or used to construct new metabolic pathways in other fungi, allowing the novel enzymes/genes that are produced by *A. acidophilus* to be used to remediate not only metals but also other pollutants.

With the advancement of proteomics and metagenomics studies, researchers are now able to identify stress-associated gene biomarkers and/or enzymes that are regulated and expressed in the *A. acidophilus* genome when exposed to extreme conditions. These novel pharmaceutical extremozymes and biologically active compounds produced by *A. acidophilus* that can tolerate and perform biological activity in low pH could have important applications in other applied scientific areas such as ecotoxicology.

25.6 Conclusions

The extreme ecology *of A. acidophilus* has allowed it to develop different adaptive mechanisms to persist in hostile environments through evolutionary processes. The morphology of *A. acidophilus* such as its melanised thick cell wall, phenotypic plasticity and ability to produce novel enzymes play vital roles to its survivability by providing protection and performing specific adaptation strategies to cope stressing conditions. Heavy metal transporters and various detoxification genes found in *A. acidophilus* drive its great mycoremediation potential in removing toxic compounds in the environment. However, their biotechnological capabilities are not fully utilised. Understanding their ecology and biochemistry in extreme environments could help to provide an insight into and maximise the potential application of this remarkable fungus.

Chapter 26
Bioremediation Abilities of Antarctic Fungi

María Martha Martorell, Lucas Adolfo Mauro Ruberto, Lucía Inés Figueroa de Castellanos, and Walter Patricio Mac Cormack

26.1 Introduction

Cold environments represent a special challenge for life, even for the ubiquitous and metabolically versatile microorganisms. Therefore, bioremediation processes are hardly limited by low temperature. Most of the reported bioremediation-related information refers to temperate regions. However, during the last 20 years the research regarding such processes in cold environment has been reported for different cold regions all around the world, including the Alps, the Arctic, and Antarctica (de Jesús et al. 2015). Despite their amazing growth potential as well as enormous catabolic capabilities yeasts have been, among microorganisms, poorly studied as bioremediation tools.

This book chapter focuses on one specific extreme and permanently cold environment, Antarctica. General information on bioremediation and its use in cold environments is introduced. Also, the main contaminants in the Antarctic continent are summarized. For bioremediation in this continent, we propose, as a study case,

the use of autochthonous yeasts with multiple bioremediation abilities, as they can be used to treat several sources of contamination in this region which is under a strong policy (Antarctic Protocol of Environmental Protection) related to management and environmental protection.

26.2 Bioremediation in Cold Environments

Bioremediation is defined as the use of living organisms or its components (such as enzymes) to reduce, eliminate, or transform toxic compounds from the environment (Tyagi et al. 2011). The goal of bioremediation is to speed up the natural biodegradation process that happens in most contaminated environments by optimizing some conditions through bioaugmentation or biostimulation. Bioremediation is considered an eco-friendly and economically effective cleanup system, and for these characteristics it is worldwide considered as a socially accepted process (Margesin 2014).

For organic contaminants, bioremediation is mainly based on the ability of microorganisms to use these organic compounds as their carbon and energy source (biodegradation) and therefore transform these contaminants in less harmful compounds. The main goal of bioremediation is to mineralize the contaminants to CO_2 and H_2O but, when this objective cannot be achieved with some contaminants, their transformation to less toxic components is also desirable (Margesin 2014).

Over 80% of planet earth is considered cold, having temperatures permanently below 5 °C. Microorganisms able to live in these environments must be adapted to such conditions and can be classified using the three cardinal growth temperatures (minimal, optimal, and maximal). Some organisms are classified as psychrophiles if they are able to grow between 0 and 20 °C, having an optimal growth temperature below 15 °C. Other organisms, frequently referred to as psychrotolerants or psychrotrophics, are able to grow at low temperatures, but present an optimal and maximal growth temperatures above 15 °C and 20 °C, respectively (Margesin 2009). These microorganisms present metabolic adaptations that allowed them to live under these extreme cold conditions (De Maayer et al. 2014) and therefore they play a key role in the nutrient cycle and mineralization of organic components in cold ecosystems. These activities commonly involve the production of several extracellular enzymes known as cold-adapted or cold-active enzymes. These enzymes are characterized by a higher catalytic efficiency than their mesophilic counterparts at temperatures lower than 20 °C (Collins et al. 2008; Tiquia-Arashiro and Rodrigues 2016).

Bacteria are the most studied extremophile microorganisms (Tiquia and Mormile 2010), whereas the world of fungi and yeasts has been explored in a minor proportion (Margesin and Miteva 2011). Kingdom of fungi represents a very diverse group and, considering their presence in extreme environments, it is one of the main examples of poorly explored microorganisms with biotechnological potential.

Psychrophilic yeasts are thought to be better adapted to low temperatures than bacteria. These eukaryotic microorganisms are heterogeneous in their nutritional abilities and can survive in a broad range of habitats such as deep sea, moist and uneven surfaces, polluted waters, and dry substrates and in the presence of high concentrations of salt and sugar. The survival at low temperatures (below 20 °C) is explained on the basis of the melting points of major membrane fatty acids present in yeasts; furthermore, it was proposed that the psychrophilic yeasts would be able to grow at temperatures as low as −10 °C (Shivaji and Prasad 2009). For this reason, the number of reports describing the isolation of yeasts from cold environments is increasing (Connel et al. 2008; Shivaji and Prasad 2009; Margesin and Feller 2010; Thomas-Hall et al. 2010; Carrasco et al. 2012; Rovati et al. 2013; Zalar and Gunde-Cimerman 2014; Turchetti et al. 2008). Most of these reports are focused on their biotechnological potential and putative industrial uses (Buzzini et al. 2012; Hamid et al. 2014).

26.3 Contamination in Antarctica

Antarctica is considered a remote and harsh place, harboring great and fragile cold wilderness preserved from human disturbance. Unfortunately, some Antarctic environments are no longer pristine and, like other remote regions on earth, Antarctica does not escape from the impact produced by local and global human activities (Bargagli 2008).

The development of activities on Antarctica (research, tourism, fishing, and logistic) during the last 50 years resulted in a sharp increase in human presence on this continent. Until 1980–1990, wastes produced at most Antarctic stations were dumped in landfill sites close to the stations, or alternatively disposed into the sea or ice or burnt in the open air. The Protocol on Environmental Protection to the Antarctic Treaty for protection of the Antarctic environment (ATCM 1991) provided strict guidelines for environmental management and protection and established, among several points, the compromise to clean up abandoned and polluted work sites. Several countries began the assessment of environmental pollution passives at scientific stations and the development cleanup and remediation strategies. The Protocol establishes principles for the planning and carrying out of all activities in Antarctica. However, local impacts caused by human presence are difficult to avoid. The use of fuels (for transportation and energy production), waste incineration, sewage production, and accidental oil spills are the main sources of contaminants in Antarctica (Bargagli 2008). Also, several toxic compounds, such as heavy metals, antibiotics, pesticides, and other persistent pollutants, can be transferred to the Antarctic continent through natural processes of mass transfers in the atmosphere and oceans (Bargagli 2008). Despite the strict guidelines provided by the Protocol of Environmental Protection, all these factors result in the occurrence of several contamination events produced by improper disposal and management of

wastes generated at the research stations as well as those produced in the past (Corsolini 2009; Lo Giudice et al. 2013).

26.3.1 Hydrocarbon Contamination

Human activities on the Antarctic continent require, among other relevant factors, power generation. Fossil fuels are the main source to provide this energy. The transportation, storage, and use of such fuels, frequently carried out under hard climate conditions, enhance the risk of spills and contamination events (Martínez Álvarez et al. 2017).

One of the main sources of contamination in Antarctica is represented by fuel spills. Spills occur mainly by human's errors during manipulation as well as due to material obsolescence. In Antarctica, the main oil blends used diesel fuel and JP is composed primarily of C9-C14 aliphatic hydrocarbons.

Once spilled on cold soils, the persistence of hydrocarbons, including light alkanes and aromatics, is high, mainly in the subsurface, where they are not subject to evaporation and photooxidation. This fact indicates that *in situ* rates of hydrocarbon degradation are slow (de Jesús et al. 2015). Therefore, the activity of the indigenous hydrocarbon-degrading microbes is limited, likely by a combination of unfavorable conditions including low temperature and moisture, nutrient limitation, alkalinity, and presence of potentially inhibitory hydrocarbons. Based on these previous observations, cold environments can be more severely affected by contaminants than other environments, even at the same contamination level, because the required cold adaptations make these environments more sensitive (de Jesús et al. 2015).

Hydrocarbon contamination on Antarctic continent is not a large-scale problem. However, some places close to research stations are considered to be chronically contaminated (Martínez Álvarez et al. 2015, 2017). In addition, some reports established that McMurdo Station (USA Antarctic station) presents high levels of hydrocarbon contamination (Kennicutt II et al. 2010). These situations might be the result of lack of regulations or the absence of adequate treatments of the generated waste in the past, when the environmental consciousness was not a common practice. This situation, combined with the hard climate present in the continent as well as other physicochemical conditions as low evaporation, photooxidation, low humidity, and nutritional limitations, led to the persistence of those compounds for decades after the spill.

Bioremediation is a complex process and is affected by several environmental factors. As was mentioned above, low temperature represents one of the main limiting factors for biological processes in polar environments and for this reason bioremediation in Antarctica must be carried out with cold-adapted microorganisms. The low concentrations of available N and P for bacterial growth in most Antarctic soils and the imbalance in the C:N:P ratio after the introduction of large amounts of hydrocarbons are other relevant factors to take into account. Biostimulation provides

adequate nutrient levels to increase degradation activity by the natural soil microflora. However, when hydrocarbon-degrading microbes (HDM) are scarce or absent, natural attenuation or biostimulation could not be enough for an efficient pollutant removal. In these cases, inoculation with previously isolated HDM (bioaugmentation) could significantly shorten the bioremediation period, providing catabolic capacity to the soil under treatment. However, bioaugmentation is not just a simple procedure which only involves inoculation of the soil with active HDB and waiting for the disappearance of hydrocarbons. Inoculum survival is not an easy task due to competition with indigenous populations and predation (Ruberto et al. 2010). It also depends on design factors such as microbial selection and inoculum size, which should be considered to avoid the frequently reported bioaugmentation failure (Coppotelli et al. 2008; Ruberto et al. 2009, 2010). In fact, in a previous report, working with chronically contaminated soils from Carlini Station, and using T-RFLP profiles for comparison of bacterial community structure from bioaugmented and non-bioaugmented land plots, we concluded that none of the two consortia used as inoculum survived at detectable levels in the soil (Vázquez et al. 2009).

26.3.2 Heavy Metals

Heavy metals (HM) naturally occur in the earth crust. Nevertheless, human activities have introduced high loads of these elements in the environment, making it difficult to differentiate between natural and anthropogenic contributions. Marine sediments allow a temporal profiling of environmental heavy metal levels, mainly because they act as a major harbor for metals, even though some sediments may also act as a natural source of contaminants (Ribeiro et al. 2011; Tiquia-Arashiro 2018). Furthermore, sediments have high physical-chemical stability and their characteristics usually represent the average condition of the system, often being representative of the average water quality. Soils and rocks are the terrigenous sources of elements to adjacent sediments and can indicate local alert signs (Lu et al. 2012; Oest et al. 2018; Patel et al. 2019).

Possible anthropogenic metal sources for Antarctic sediments are oil-derived fuel contamination, sewage disposal, and paint debris. Several metals (V, Ni, Zn, Cu, Cr, Pb, Ba, among others) are associated with petroleum contamination. Paints are another possible metal source (such as Pb, Cr, and Cu). Also, crushed batteries and scattered rubbish and buildings are sources of contamination by metals (Pb, Zn, and Cu) in soils, while burning fuel results in widespread contamination of lead. Sewage has also been considered an important source of metals for both lower latitudes and Antarctic regions (Statham et al. 2016). Near the McMurdo Station, for example, higher concentrations of metals were observed in sediments around the sewage outfall (Kennicutt II et al. 2010).

The operation of any facility on bare ground in Antarctica must be expected to leave an imprint of a variety of materials and disturbances on the soils. Most Antarctic

stations lack adequate facilities for the bulking of disused machinery and building materials. Often, limited logistics did and does not allow its removal, leading to the accumulation of large amounts of metal-made objects near Antarctic stations, occasionally on bare soil. Ageing of building foundations as well as fuel storage tanks are also sources of anthropogenic metal contamination.

Nearly 40 years of human activity at Scott Base resulted in the accumulation of Ag, As, Cd, Cu, Pb, and Zn (Smykla et al. 2018). The way of introduction onto and into the soils and the chemical and physical environment within the soils have resulted in differential movement of the metals, with the mobilization agents being surface and subsurface water flow, redistribution of surface material by wind, and movement of particulates carrying adsorbed heavy metals, in a process affected by freezing and thawing cycles, as well as by permafrost presence (Curtosi et al. 2007). In this sense, Curtosi et al. (2010) referred that in some restricted areas from Potter Cove, there exist evidences of a low but detectable influence of the Carlini scientific station, which is reflected mainly by levels of Pb, Cr, and Cd. For all these reasons, and due to the possibility of biomagnification through trophic chain, heavy metals are contaminants involving a major concern in coastal Antarctica.

26.4 Antarctic Fungi with Bioremediation Abilities

Fungi and its spores can colonize a great number of different substrates and are easily dispersed through air and water, mainly for the action of winds and oceanic currents, respectively. Because of these features and its surprising metabolic flexibility, fungi are present all over the earth.

Antarctica is also inhabited by fungi. Its mycodiversity seems to be enormous and to date remains almost unknown. This is truth not only for the white continent but also for many other regions having different climate conditions. Nevertheless, most microfungi found in Antarctica are ubiquitous instead of being endemic. Some of them are transported from different areas on the planet to the Antarctic continent but are unable to grow in such hard conditions (Ruisi et al. 2007). Others, sometimes called indigenous, were able to adapt, propagate, and reproduce there, completing their life cycles and therefore becoming adapted to the harsh climatic factors of the continent. In some places, like the Antarctic Dry Valleys, fungi have shown specific physiological and morphological adaptations and hence they are considered evolved Antarctic fungi (Ruisi et al. 2007). Many Antarctic fungi are adapted to low temperatures, repeated freeze and thawing cycles, low water availability, osmotic stress, desiccation, low nutrient availability, and high UV radiation. Antarctic microorganisms must face several simultaneous stresses and they adopt different strategies at the same time to address these stresses. Sometimes, single strategies are not specific for a single stress factor and allow these microorganisms to cope with more than one unfavorable condition (Ruisi et al. 2007).

Under this context, Antarctic fungi with bioremediation capacities have been reported at a fast pace during the last 20 years or more, driven mainly by the improvement in the accessibility for researchers to work in Antarctica. Some research groups

only take samples and do fungi isolation and bioprospection for remediation abilities back in their research laboratories, hundreds or thousands of kilometers away from Antarctica. Others, taking advantage of having research stations with appropriate facilities, perform several steps of the experimental work in the field, just minutes after sample is taken. In this way, bias associate with sample storing is avoided, resulting in a more representative screening. This is the case of Carlini Station, where adequate scientific facilities and marine as well as terrestrial Antarctic environment (Potter Cove and Peninsula, including the Antarctic Specially Protected Area 132) coincide in the same area.

26.5 Case of Study: Bioremediation Abilities of Yeasts Isolated from 25 de Mayo Island, Antarctica

Antarctica is one of the most suitable sites for the isolation and study of psychrophilic microorganisms. Although permanently exposed to temperatures that rarely exceed the freezing point of water, its geographic location, its difficult access, and the international diplomatic and political treatment of their lands and seas make Antarctica a very little explored region of the world in terms of microbial biodiversity (Fernández et al. 2017).

Considering this information and based on the experience of our research group, the focus of this book chapter is on yeasts isolated from several samples collected near Argentinean Scientific Research Station, Carlini, located on the Potter Cove, 25 de Mayo/King George Island, South Shetland Islands, Antarctica (62°14′18″S, 58°40′00″W) (Fig. 26.1). Thirty-one samples from areas with and without human impact (including soil near fuel storage tanks) were collected. After the isolation procedure, 60 yeasts were evaluated for their bioremediation abilities in cold environments.

26.5.1 Organic Pollutant Bioremediation Ability of Antarctic Yeasts

Yeast assimilation of two chemical compounds, considered as pollutants, was evaluated in liquid media: phenol (2.5 mM) as a model of aromatics and n-hexadecane (1 gL^{-1}) as a model of aliphatic hydrocarbons. Culture media without carbon source were included as controls. After 7 and 14 days, optical density (OD) of the cultures was measured at $\lambda = 600$ nm. Cultures with cell density exceeding by 50% or more those showed by control cultures were considered as positives. Phenol and n-hexadecane assimilation is an important feature to consider the use of these yeasts for bioremediation processes (Fernández et al. 2017). Results obtained with the isolated (60) Antarctica yeasts when evaluated for their bioremediation abilities and their classification based on its growth temperature are presented in Table 26.1.

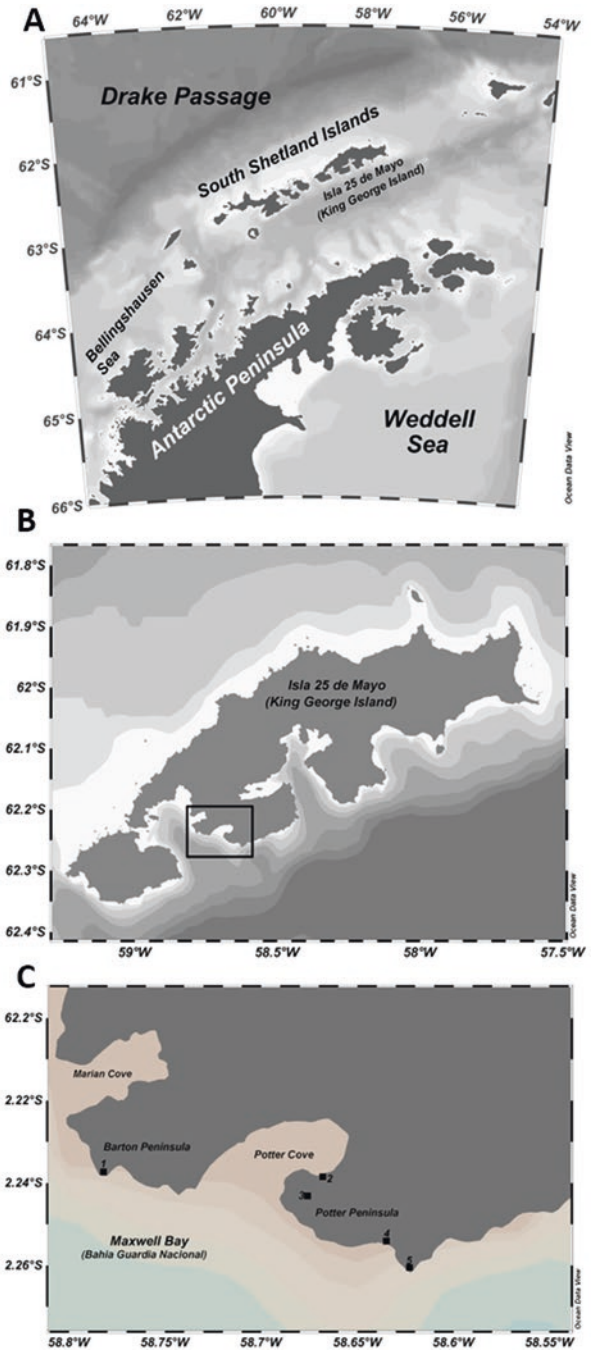

Fig. 26.1 (**a**, **b**) The studied area in King George Island/Isla 25 de Mayo, South Shetland Islands, with indication of the sampling site, Potter Peninsula (62°14′18″S, 58°40′00″W). (**b**) Sampling sites: *1*, nesting penguins in Barton Peninsula; *2*, Carlini Station facilities; *3*, Tres Hermanos Hill; *4*, Elephant Refuge; *5*, Stranger Point

Special attention was paid to those yeasts able to assimilate phenol as it is a common constituent of wastewater from several industries and, for this reason, is considered as a pollutant of major concern. In our evaluation, over 48% of the yeasts were able to assimilate phenol at an initial concentration of 2.5 mM. These yeasts belonged to both asco- and basidiomycetous genera. Some of the detected genera were *Metschnikowia*, *Candida*, *Cryptococcus*, *Fellomyces*, *Guehomyces*, *Leucosporidum*, *Mrakia*, *Nadsonia*, *Pichia*, and *Rhodotorula*. Due to their toxicity to microorganisms, phenolic compounds can cause the breakdown of wastewater treatment plants by inhibition of microbial growth (Basha et al. 2010). For this reason, these phenol-degrading yeasts represent a valuable tool as potential cold-tolerant components of the microbial community for wastewater treatment plants able to deal with phenolic compounds (Viswanath et al. 2014).

In the case of n-hexadecane assimilation, 85% of the yeasts presented this ability. These yeasts were isolated not only from hydrocarbon-contaminated environments but also from pristine areas (Fernández et al. 2017), evidencing the ubiquity of these cold-adapted hydrocarbon-degrading microorganisms. Other authors reported isolation of microorganisms able to efficiently degrade crude oil-derived hydrocarbons (Das and Chandran 2011; Hassanshahian et al. 2010) and phenol (Bonfá et al. 2013) from uncontaminated environments. This ability could be related with the catabolism of natural hydrocarbons produced by different organisms present in non-contaminated sites (Schirmer et al. 2010). However, Aislabie et al. (2001) working with Scott Base and Marble Point soils detected culturable yeasts only in oil-contaminated soils but not in pristine control soils. They attributed the significant enhancement in numbers of culturable yeasts and filamentous fungi in oil-contaminated cold soils to the important role of fungi in the degradation of hydrocarbons or their metabolites. Their population would increase due to the availability of C provided by the contaminant.

The aerobic biodegradation at low temperatures of many petroleum hydrocarbon components, including n-alkanes and mono- and polycyclic aromatic hydrocarbons (PAHs), has been reported for Arctic, Alpine, and Antarctic environments (Si-Zhong et al. 2009; Yang et al. 2009). A wide variety of bacteria, fungi, and algae can metabolize aliphatic and aromatic hydrocarbons (Alexander 1999). Filamentous fungi are mainly known for their potential to degrade PAHs (Haritash and Kaushik 2009). There is, however, little information about the hydrocarbon-degradative potential of yeasts, although these microeukaryotic organisms could be a useful and efficient tool for the development of processes for the bioremediation of fuel-spilled soils from cold regions.

In our work, one of the isolates showed a wide catabolic capability. Isolate number 171 (*P. caribbica)*) was able to grow using several hydrocarbons: undecane (nC11), dodecane (nC12), tridecane (nC13), tetradecane (nC14), and Antarctic diesel fuel at 15 °C, under aerobic conditions in liquid culture. It should be noted that a negative relationship between the carbon chain length and yeast growth was observed in this case (Martorell et al. 2017). This yeast species was previously reported as a biosurfactant producer (Joshi-Navare et al. 2014), which could be

related with its ability to assimilate n-alkanes and gasoil as carbon sources. Such ability could be advantageous for a better solubilization and an enhanced bioavailability of hydrocarbons in soils and waters.

26.5.2 Metal Tolerance by Antarctic Yeasts

Divalent copper and cadmium (Cu(II) and Cd(II)) and hexavalent chromium (Cr(VI)) yeast tolerance was separately evaluated in agarized YM medium containing 1 mM (final concentration) of each metal ion. Isolates were inoculated, incubated at 15 °C, and checked for growth for up to 14 days. Plates without metal ions were also inoculated as controls (Fernández et al. 2013).

The analysis of data from heavy metal tolerance assays showed that 61%, 80%, and 86% of the isolates were tolerant to Cr(VI), Cd(II), and Cu(II), respectively, but a half of the yeasts tolerated all of them. In addition, 11% could be classified as sensitive, showing no growth after 14 days in the presence of any of the metals under study.

Heavy metal-contaminated soils and water are one of the first steps for the accumulation of these harmful compounds in living organisms through the food chain, causing a negative effect on physiological activities of plants, animals, and humans (Suciu et al. 2008; Bowman et al. 2018). It is important to consider that a significant fraction of industrial plants generating phenol-rich effluents also discharge heavy metals as associate pollutant, being a complex and difficult mixture to deal with. This combination frequently results in the inhibition of growth of most phenol-degrading microorganisms used for the associated wastewater treatments (Thavamani et al. 2012; Wong et al. 2015). Thus, much attention should be paid to the phenol removal performance of these microorganisms in media with the presence of heavy metals. It was found from previous study that bacterial strains *Pseudomonas rhodesiae* and *Bacillus subtilis* could remove phenol and survive in heavy metal-polluted environments (Satchanska et al. 2015). Regarding fungi, several reports mentioned their resistance to metal ions (Fernández et al. 2013). Our results showed that almost 34% of the isolated yeasts exhibited some degree of tolerance to the three studied metals and can use phenol as carbon source. These strains, mainly those showing high levels of metal tolerance, are adequate to be used for the low-temperature treatment of effluents containing phenol and high levels of metal ions.

26.5.3 Enzymes from Antarctic Fungi Related to Bioremediation

Lipase and esterase activities were tested on the isolates growing on solid media at 15 °C. For this propose, activity was quantified as the halo diameter (of either coloration or decoloration) around the colony (Martorell et al. 2017).

Oligotrophic microorganisms are usually related to the ability to degrade a broad spectrum of substrates, while copiotrophic microorganisms are related to the efficient degradation of easily accessible substrates (Rovati et al. 2013). These concepts should be a guideline for the development of the isolation scheme and the screening process toward selecting the most promising yeasts for low-temperature biotechnological process. In a previous work, Martorell et al. (2017) reported several isolates showing multiple extracellular enzymatic activities. Those yeasts were obtained from sites with high organic matter content, either as a consequence of the human impact (soil that suffered fuel spills from the storage tanks throughout the years) or from natural origin (complex substrates as those present in soils around lichens and *Deschampsia* spp. or mud near creeks).

In this chapter only lipase and esterase producers are discussed, as these activities are related to hydrocarbon degradation (Margesin and Feller 2010) and for this reason constitute a relevant catabolic ability with potential application in bioremediation of hydrocarbon-polluted matrices in cold environments. The analysis of the locations where the lipase/esterase-positive isolates were obtained showed that several producing yeasts (*C. Adeliensis*, *G. pullulans*, *P. caribbica*, and *Ph. glacialis*) came from soils near the diesel fuel storage tanks. Although microorganisms able to efficiently degrade oil hydrocarbons have been isolated from uncontaminated environments (Si-Zhong et al. 2009), their numbers (including fungi) significantly increase in oil-contaminated soils. In this sense, Aislabie et al. (2001) attributed the significant enhancement in numbers of culturable yeasts and filamentous fungi in oil-contaminated cold soils to the important role of these microorganisms in the degradation of hydrocarbons or their metabolites, where they can take advantage of the additional C source provided by the carbonated pollutant.

Among isolates, one ascomycetous yeast was selected (*P. caribbica*), as it showed all the evaluated enzymatic activities. This strain was isolated from soil near fuel storage tanks, which contained a high amount of hydrocarbons, accumulated as a consequence of the chronic leakage of gas/oil throughout the years. This chronic presence of hydrocarbons represented a high selective pressure, determining a soil microbiota with dominance of microorganisms able to tolerate and catabolize these recalcitrant organic compounds. This observation was previously reported for the studied area (Mac Cormack et al. 2011; Martínez Álvarez et al. 2015, 2017; Ruberto et al. 2009, 2010). As was mentioned above, this isolate can assimilate several aliphatic hydrocarbons and also Antarctic diesel fuel. This yeast was selected for further studies based on their biotechnological potential, primarily for hydrocarbon bioremediation in cold environment.

26.6 Conclusions

Antarctic yeasts tested for pollutant assimilation, heavy metal tolerance, and some extracellular enzymatic activities have been reported in the past years. They belong to widely reported, cold-adapted yeast taxa, most of them included into

oligotrophic, slow-growing, and metabolically diverse basidiomycetous genera. The reason for the prevalence of basidiomycetous yeast in Antarctic samples remains unclear, but could be related to soil and water oligotrophy, as well as to the isolation scheme employed. As was previously emphasized, oligotrophic microorganisms are usually related to the ability to degrade a broad spectrum of substrates, while copiotrophic microorganisms are related to the efficient degradation of easily accessible substrates. Despite the genus of yeasts isolated from cold environments, research in the field of cold-adapted yeasts from Antarctica is relatively young. It is generally accepted that information regarding cold-adapted yeasts will have a continuous increase, especially with the development of new microbiological and molecular methodologies. The tolerance to heavy metals of the phenol-degrading cold-adapted yeasts, and the production of bioremediation-related enzymes, as lipase and esterase, evidenced that the yeasts selected might be promising in treating some kinds of phenol-polluted industrial wastewater containing heavy metals, such as effluents from petroleum refineries in cold environments. Further studies on cold-tolerant yeasts isolated from Antarctica must be done in order to provide additional information for its use in bioremediation processes at low temperatures and also to infer their possible ecological role under such extreme conditions.

26.7 Future Perspectives

The bioremediation processes in the Antarctic continent are, as in other places, site and contaminant specific. They also perform better under aerobic conditions. Beyond yeast isolation and characterization, there is a need for prior studies of contaminated sites that can be done ex situ (e.g., soil analysis and preliminary studies through microcosms). Nevertheless, next step must involve field experiments performed in situ, to ensure the accuracy of the results as well as applicability of this technology. On the other hand, an ecological approach must be included to assess the possible interactions between inoculated yeast and indigenous microbiota.

The studies conducted to date reveal that despite our knowledge of the fungal microbial strains that can degrade contaminants in Antarctic soils, studies regarding its actual use are just a few. This is, to our knowledge, the next step for Antarctic soil bioremediation using psychrotolerant metal-tolerant yeast.

Chapter 27
Haloalkaliphilic Fungi and Their Roles in the Treatment of Saline-Alkali Soil

Yi Wei and Shi-Hong Zhang

27.1 Introduction

The main source of all salts in the soil is the primary minerals in the exposed layer of the earth's crust. During the soil-forming process which involves chemical, physical, and biological processes, the salt constituents are gradually released and made soluble. The released salts are transported away from their source of origin through surface or groundwater streams. The salts in the groundwater stream are gradually concentrated as the water with dissolved salts moves from the more humid to arid and semiarid areas, which is the primary cause of the soil salinization.

Soil salinization leads to serious environmental problems on a global scale (Wang et al. 2003; Yadav et al. 2011; Liang et al. 2015). The problems of soil salinity are most widespread in the arid and semiarid regions but salt-affected soils also occur extensively in subhumid and humid climates, particularly in the coastal regions where the ingress of seawater through estuaries and rivers and through groundwater causes large-scale salinization. Soil salinity is also a serious problem in areas where groundwater of high salt content is used for irrigation. The most serious salinity problems are being faced in the irrigated arid and semiarid regions of the world and it is in these very regions that irrigation is essential to increase agricultural production to satisfy food requirements.

Two main groups of the salt-affected soils have been distinguished (Szabolcs 1994): (1) Saline soils—soils containing sufficient neutral soluble salts to adversely affect the growth of most crop plants: The soluble salts are chiefly sodium chloride and sodium sulfate. (2) Saline-alkali—soils containing sodium salts capable of alkaline hydrolysis, mainly Na_2CO_3 and $NaHCO_3$: these soils have also been termed as sodic-, alkali-, or soda-affected soils once in a while. As a matter of fact, the

various sodium salts in nature do not occur absolutely separately, but in most cases either the neutral salts or the ones capable of alkaline hydrolysis exercise a dominant role on the soil-forming processes and therefore in determining soil properties. In most agricultural cases, the jeopardizing of soda-affected soil is more serious than that of other saline soils. It is the accumulation of solutes, primarily Na_2CO_3 and $NaHCO_3$, that induces primary soil alkalization: soda saline-alkali soil leads to many negative effects on soil organic matter decomposition and uptake of available nutrients (Rietz and Haynes 2003; Karlen et al. 2008), which subsequently affect plant survival, health, and development (Rady 2011). Therefore, accumulation of excess salts in the root zone results in a partial or complete loss of soil productivity.

Soda saline-alkali soils occur within the boundaries of at least 75 countries (Szabolcs 1994), and the severity of this issue has increased steadily in several major agricultural areas around the world (Ghassemi et al. 1995). The well-known typical saline soils are, respectively, located in Vitoria in Australia, California in the United States, Mexico City in Mexico, and Baicheng city in China (Wang et al. 2009). In Victoria, sodic soils are estimated to occupy at least 13.4 Mha, representing at least 73% of Victoria's agricultural land, and the largest sodicity class is "alkaline sodic," dominated by a diverse range of soils (Ford et al. 1993). The soil of the former Lake Texcoco in Mexico is a unique extreme environment (called a soda desert) located near one of the biggest cities in the world, Mexico City. Large parts are saline-alkaline with pH more than 10 and electrolytic conductivity (EC) more than 150 dS m^{-1} (Dendooven et al. 2010). Nowhere in China is the issue more serious than in the Songnen Plain of northeastern China (Fig. 27.1). Soil alkali is the major ecological gradient in the Songnen Plain, as well as the primary factor limiting its food security (Gao et al. 1996). Therefore, effective strategies to remediate soda saline-alkaline soil are urgently needed.

Fig. 27.1 Songyuan soda saline-alkali land in Zhenlai County, Baicheng city, Jilin province, China (the aerial photography was taken by an unmanned plane at 150 m in the air in 2016). The white snow-like crusts on the land are soda salt that has returned to the soil surface (in a soil level extending from 0 to 20 cm depth: sodium salt = 18 g/kg, pH = 10.1; measured by Dr. Shi Yang, 2016)

Physical tillage operations, chemical amendments, leaching with water, and plant-associated phytoremediation have been utilized to attempt to ameliorate soil salinity (Qadir et al. 2007). On account of the significant ecological, environmental, and economic effects of the former three techniques, phytoremediation is widely considered to be the best method for ameliorating soil salinity (Ilyas et al. 1993; Ghaly 2002; Nouri et al. 2017). Thus far, the primary factors influencing the success of phytoremediation have been the selection and application of appropriate plants, such as salt-resistant or -tolerant species, and their cropping sequence. At this point, the upper limit of plant resistance to salt restricts the application range of soil phytoremediation.

Salt-affected soils generally exhibit poor structural stability due to low organic matter content; therefore, ecosystems in severely saline soils are rather simple and fragile. Plant species are extremely scarce in severely saline soil, while microbes, including fungi, are rare. An alternative technique for saline soil remediation, which can be regarded as an auxiliary measure for phytoremediation, is the application of organic matter conditioners, which can both ameliorate salinity and increase the fertility of saline soils (Melero et al. 2007). Some studies have indicated that the structural stability of soil can be improved by the addition of organic materials (Tiquia et al. 2002; Tiquia 2003; Tejada et al. 2006; Wang et al. 2014; Oo et al. 2015). Above all, the addition of maize straw to saline soil can decrease the severity of the negative effects of salinity on mineralization and the microbial community in the soil (Wichern et al. 2006).

Soil microorganisms generally have the ability to adapt to or tolerate salinity; and examples of microbes thriving in ponds with very high salt concentrations demonstrate the evolutionary potential of microorganisms (Casamayor et al. 2002). The biodiversity of microorganisms in soda environments has indicated that abundant bacterial communities, which also act as primary producers, are usually dominated by cyanobacteria species (Antony et al. 2013). In addition, the N-fixing cyanobacterium, *Anabaena torulosa*, has been applied in remediating soil salinity during crop growth (Apte and Thomas 1997). However, fungi tend to be sensitive to salt stress, as indicated by decreasing ergosterol content in soil as its salt content is increased (Sardinha et al. 2003). In addition, it has been reported that long-term salt stress reduces fungal diversity (Bruggen et al. 2000). In general, the negative impact of elevated salinity on fungi is stronger than its effect on bacteria. The negative effects of salt stress on soil fungi reduce the microbial biomass and microbial activity of the soil and impair turnover of organic matter, which creates a vicious cycle that reduces soil fertility and eventually produces soil incapable of supporting crops. Obviously, in order to remediate the saline-alkali soil, our primary task must be to increase the beneficial fungi that can survive in the saline-alkali land.

Fortunately, within the last few decades, a series of halophilic and alkaliphilic fungi capable of living in highly saline and alkaline environments (or both) have been identified. This chapter is focused on the isolation and characterizations of extreme haloalkaliphilic fungi, and their roles in saline-alkali soil mycoremediation. In addition, we highlight the abiotic stress resistance genes and cellulase genes in

extremophilic fungi, and application strategies for anti-abiostress and stable cellulose degradation genetic engineering are discussed.

27.2 Haloalkaliphilic Fungi and Their Biological Characteristics

Halophilic fungi require salt concentrations of at least 0.3 M (sodium salt, e.g., NaCl) to grow optimally, and they are capable of thriving in high-salt environments. Halotolerant fungi, however, do not necessarily require certain concentrations of salt, although they were often found in saline areas. To halotolerant fungi, salinity can directly affect sporulation and growth of fungi: at higher salinities (>5%) there tends to be increased sporulation with more chlamydospores observed, an inhibition of conidiogenesis, and fewer hyphae (Mulder et al. 1989; Mahdy et al. 1996; Mulder and El-Hendawy 1999; Mandeel 2006). On the other hand, halophilic fungi do not always have to be in saline habitats; thus there is no need to make a strict distinction between halotolerant and halophilic fungi (Arakaki et al. 2013). In this chapter, we consider halophilic fungi as a general designation.

Alkaliphilic fungi are a class of extremophilic microbes that are capable of survival in alkaline (pH roughly 8.5–11.0) environments and grow optimally even at a pH of approximately 10. Halophilic fungi growing in alkaline environments that are adapted to high pH and high concentrations of sodium ions are described as haloalkaliphilic, rather than merely halophilic or alkaliphilic. Soda-affected soils form as a result of sodium carbonate accumulation. Water evaporation reinforces the process of soda accumulation. Thus, soda soils are usually affected by both saline and alkaline as double-abiotic factors. Therefore, halophilic fungi inhabiting soda soils are most likely alkaliphilic fungi (Gunde-Cimerman et al. 2009; Grum-Grzhimaylo et al. 2016).

Most halophilic fungi live in marine aquatic bodies, seashore, and inland terrestrial soils with high salt concentrations, such as the Dead Sea, the Antarctic Ocean, and the Great Salt Plains, and a large number of studies on biodiversity and physiology have focused on the characterization of halophilic fungi present in the saline and hypersaline ecosystems, among which species of *Ascomycetes*, as well as some *Basidiomycetes*, have been described in detail (Gunde-Cimerman et al. 2000; Butinar et al. 2005a, b; Zalar et al. 2005; Evans et al. 2013; Gunde-Cimerman and Zalar 2014; Zajc et al. 2014a, b; Tiquia-Arashiro and Rodrigues 2016a; Gonçalves et al. 2017). Hypersaline fungal communities are dominated by *Aspergillus* and *Penicillium* species, with melanized dematiaceous forms commonly observed in inland lands (Moubasher et al. 1990; Grum-Grzhimaylo et al. 2016; Martinelli et al. 2017), similar to the communities observed in marine environments (Buchalo et al. 1998, 2000; Gunde-Cimerman et al. 2000; Butinar et al. 2005a, b; Kis-Papo et al. 2003, 2014; Gunde-Cimerman and Zalar 2014).

The Dead Sea, a typical high-salt habitat for microorganisms, contains 340 g/L of dissolved salt; a variety of filamentous fungi have been isolated from the Dead Sea by the Nevo group. *Gymnascella marismortui* is a remarkable salt-tolerant fungus that has been isolated from the surface water down to a depth of 300 m in the Dead Sea (Buchalo et al. 1998). *G. marismortui* grows optimally at NaCl concentrations between 0.5 and 2 M (Buchalo et al. 1998, 2000), suggesting that it is adapted to high-salt conditions and requires high salt concentrations. Among 476 fungal isolates from the Dead Sea, *Aspergillus terreus*, *Aspergillus sydowii*, *Aspergillus versicolor*, *Eurotium herbariorum*, *Penicillium westlingii*, *Cladosporium cladosporoides*, and *Cladosporium sphaerospermum* were isolated consistently and probably form the stable core of the fungal community (Kis-Papo et al. 2003, 2014), and approximately 43% of fungal isolates from the Dead Sea were found to belong to the genera *Eurotium* and *Aspergillus* (Yan et al. 2005).

The large diversity of the fungal species has been reported to inhabit high-salt environments; however, most of them can be regarded either as halotolerant or as extremely halotolerant. Halotolerant fungi can grow without NaCl added to the medium but tolerate up to saturated NaCl levels (30%) (Gunde-Cimerman et al. 2000). Up till today, only *Wallemia ichthyophaga*, *Wallemia muriae*, *Phialosimplex salinarum, Aspergillus baarnensis*, *Aspergillus salisburgensis and Aspergillus atacamensis* are obligate halophilic fungi that strictly require NaCl from 5 to 10% (Piñar et al. 2016; Martinelli et al. 2017). Actually, *Gymnascella marismortui* (Buchalo et al. 1998), *Trichosporium* spp.(Elmeleigy et al. 2010), *Aspergillus unguis* (Nazareth et al. 2012), and *Aspergillus penicillioides* (Nazareth and Gonsalves 2014) have also been reported to be obligate halophiles according to their minimum saline requirement.

Aspergillus penicillioides are commonly found in saline habitats, suggesting that the species are extensively adaptable to varied environments. Among 39 tested isolates of *A. penicillioides*, most strains had a minimum salt requirement of 5% for growth; one strain grew only on media supplemented with at least 10% solar salt (Nazareth and Gonsalves 2014). Given that *A. penicillioides* species do not reproduce sexually (Tamura et al. 1999; Gostinčar et al. 2010), which consequently inhibits their gene flow, this species has significant promise in environmental remediation applications.

As mentioned above, some halophilic fungi, such as *A. niger* and *C. cladosporoides*, have been isolated from sand and mud on the shore of salty aquatic bodies or from inflowing freshwater from floods and springs (Kis-Papo et al. 2003, 2014; Grum-Grzhimaylo et al. 2016; Martinelli et al. 2017). We also isolated the halophilic fungus *Aspergillus glaucus* CCHA from air-dried wild vegetation from the surface periphery of a solar salt field (Liu et al. 2011); this species shows extreme salt tolerance, with a salinity range of 5–32% (NaCl) required for growth (Liu et al. 2011). To our surprise, *A. glaucus* CCHA survives in solutions with a broad pH range of 2.0–11.5, indicating that it is a haloalkaliphilic fungus. Further investigation indicated that increasing the pH value (>8.0) can induce *A. glaucus* CCHA to produce a variety of organic acids, including citric acid, oxalic acid, and malic acid. In addition, *A. glaucus* CCHA shows resistance to aridity, heavy metal ions, and

high temperature. The extremophilic nature of *A. glaucus* CCHA suggests that it has great promise in soil remediation applications.

Just like the proportion of the halophilic and halotolerant fungi isolated from saline environment, fewer alkaliphilic fungi have been identified in comparison with alkalitolerants. Hozzein and colleagues isolated 117 alkaliphilic and alkaline-resistant microorganisms from 30 soil samples collected from six localities around Wadi Araba, Egypt. By adjusting the pH to 10 after sterilization (using sterilized 10% Na_2CO_3 solution), they only identified 4 fungal isolates among 117 alkaliphilic and alkaline-resistant microorganisms (Hozzein et al. 2013); unfortunately, the authors did not determine the species of the isolates. Alkaliphilic fungi have also been isolated from industrial effluents. For example, *Aspergillus nidulans* KK–99 (isolated from the industrial effluents of Shreyans Paper Industry Limited, Ahmedgarh, Punjab, India) is adapted for growth in an alkalescent environment (pH 10.0) (Taneja et al. 2002). Another alkaliphilic fungus, *Myrothecium sp.* IMER1, also grows well under alkali conditions (pH 9.0) (Zhang et al. 2007).

Grum-Grzhimaylo and collaborators (2016) identified more than 100 strains of alkalitolerant and alkaliphilic fungi isolated from the alkaline soils with different degrees of salinity in Russia, Mongolia, Kazakhstan, Kenya, Tanzania, and Armenia. They found the alkaliphilic/strong alkalitolerant phenotype in about 2/3 of our recovered strains from soda soils, and uncovered that the alkaliphilic trait in filamentous fungi has evolved several times through phylogenetic analyses. Among the alkaliphilic/strong alkalitolerant fungi, the *Sodiomyces* species (*Plectosphaerellaceae*), *Acrostalagmus luteoalbus* (*Plectosphaerellaceae*), *Emericellopsis* alkaline (*Hypocreales*), *Thielavia sp*. (*Chaetomiaceae*), and *Alternaria sect. Soda* (*Pleosporaceae*) grew best at high ambient pH, but the pH tolerance of *Chordomyces antarcticum*, *Acrostalagmus luteoalbus*, and some other species was largely affected by the presence of extra Na ion in the growth medium, further suggesting that the frequency of alkaliphilic fungi is low, while alkalitolerants seem to be far more widespread in soil (Grum-Grzhimaylo et al. 2016).

Research aimed at isolating and characterizing halophilic fungi has progressed rapidly in China (Table 27.1). A series of promising halophilic fungi, including *A. glaucus* CCHA, have been reported. Three marine-derived isolates were collected in Wenchang, Hainan Province, China, and identified as extremely halotolerant fungi: *Wallemia sebi* PXP-89 (Peng et al. 2011a), *Penicillium chrysogenum* PXP-55 (Peng et al. 2011b), and *Cladosporium cladosporioides* PXP-49 (Xu et al. 2011). The work focusing on isolating halotolerant/alkaliphilic/haloalkaliphilic fungi is being carried out in our laboratory, and actually several halotolerant species with alkaliphilic trait, such as *Aspergillus sp.*, were recently identified based on a specimen collected from the saline-alkali soils in Songnen Plain of northeastern China. China has remarkable biodiversity and many typical hypersaline environments, including Caka Salt Lake and Qarhan Salt Lake in Qinghai, Barkol Salt Lake in Xinjiang, Yuncheng Salt Lake in Shanxi, and the Baicheng soda saline-alkali area in Jilin. All of these environments are suitable for extremophilic fungi and other microorganisms; therefore, isolating and identifying extremophilic fungi

NR No report

in China could lead to the development of promising new methods of remediating saline-alkali soil.

27.3 Saline-Alkaline Stable Enzymes Secreted from Haloalkaliphilic Fungi

Fungal and other microbial activities are central to the formation and stabilization of soil aggregates (Rietz and Haynes 2003). Soil-derived fungi produce and secrete a series of active enzymes to the soil, and these soil enzymes are closely related to soil properties, soil types, soil heath, and environmental conditions.

Salinity, sodicity, and both have extremely adverse effects not only on soil chemical and physical properties and on crop growth but also on the species and quantity of fungi, let alone on the activities of the soil enzymes and microbial biomass, and even on biochemical processes essential for maintenance of soil quality. Correspondingly, this will result in a reduction in the rate of soil organic matter decomposition and in the mineralization of carbon (C), nitrogen (N), and phosphorus (P). The resulting reduced nutrient availability will be an additional growth-limiting factor to crop production in salt-affected soils (Zhang SH et al. 2014a).

The soil enzymes are now widely used as important indicators of soil quality and soil biological activities just because most soil enzymes are not stable to the harmful salinity and sodicity. Among all the enzymes, urease, alkaline phosphatase, and catalase activity are more sensitive to soil environmental conditions. Urease specifically catalyzes the hydrolysis of nitrogen-containing organic matter. The high salinity and sodicity cause urease to be completely inactivated, and then the formation pathway of N in the soil is blocked (Liang et al. 2003, 2014). P in soil is mainly in the organic form. Alkaline phosphatase is the main enzyme involved in the cycling of P because it can transform organic P into inorganic P which is the available nutrient for plants (Dick and Burns 2011). Alkaline phosphatase reacts to external environments sensitively and is an indicator of the organic P mineralization and biological activity of soils (Krämer and Green 2000; Zhang T et al. 2014b; Zhang TB et al. 2014c). Catalase can enable the peroxide produced during metabolism to decompose, thus preventing its toxic effects on organisms. These enzyme activities play an important role in the cycling of soil C, N, and P. In addition, they participate in a great number of soil biochemical processes and they are directly involved in various biochemical reactions in the soil. The sensitivity of these enzymes to salt and alkali further illustrates the role of haloalkaliphilic fungi in soil treatment.

In the context of the C cycle, the available organic matter in soil is mainly derived from degradation of crop remains such as fallen leaves and stalks. However, as mentioned above, the microbial community of saline-alkaline land is simple and fragile, and elevated salinity reduces the abundance of fungi more effectively than that of bacteria. Reduced fungal abundance leads to decreased soil microbial biomass and activity, which further slows the turnover of organic matter. Therefore, fungi with salt and alkali resistance, as well as the ability to produce and secrete cellulose-degrading enzymes, are badly needed.

Salt and alkali resistance genes are capable of genetically improving soil fungi and enhancing their resistance to extreme environments. In order to be beneficial to the soil, fungi must possess the ability to produce and secrete a large number of hydrolytic enzymes that degrade plant organic matter (e.g., maize, wheat, or rice straw) such as cellulose, hemicellulose, lignin, and pectin (Castillo and Demoulin 1997; Santos et al. 2004; Arakaki et al. 2013; Batista-García et al. 2014; Wei and Zhang 2018).

The cellulase complex includes endoglucanases (EC 3.2.1.4), exoglucanases (EC 3.2.1.91), and β-glucosidases (EC 3.2.1.21). Endoglucanases randomly attack the internal chain of cellulose to produce cellulo-oligosaccharides. Exoglucanases

catalyze the hydrolysis of crystalline cellulose from the ends of the cellulose chain to produce cellobiose, which is ultimately hydrolyzed to glucose by β-glucosidases (Béguin and Aubert 1994; Tomme et al. 1995). *Trichoderma reesei* and *Penicillium janthinellum* are known to be excellent cellulase producers, but their cellulases are not stable under alkali conditions (Mernitz et al. 1996; Wang et al. 2005; Qin et al. 2008). *Aspergillus niger*, one of the most efficient identified cellulose-degrading microorganisms, secretes large amounts of different cellulases during fermentation (Schuster et al. 2002). Endoglucanase B (EGLB), encoded by the endoglucanase gene (GenBank GQ292753) of *Aspergillus niger* BCRC31494, has been used in the fermentation industry because of its alkaline and thermal tolerance (Li et al. 2012). EGLB is a member of glycosyl hydrolase family 5 of the cellulase superfamily. When the recombinant EGLB cDNA was expressed in *Pichia pastoris*, a purified protein of 51 kDa in size was obtained. The enzyme was specific for substrates with β-1,3 and β-1,4 linkages, and it exhibited optimal activity at 70 °C and pH 4 (Li et al. 2012). Interestingly, the relative activity of recombinant EGLB at pH 9 was significantly better than that of wild-type EGLB. The advantages of endoglucanase *EGLB*, particularly its tolerance to a broad range of pH values, indicate that this enzyme has significant promise as a means of genetically improving fungi for haloalkaline soil remediation.

Based on an analysis of the genomic sequence of haloalkaliphilic fungus *A. glaucus* CCHA, we found that *A. glaucus* CCHA expresses only one gene belonging to the GH5 family, AgCel5A. The open reading frame of *Agcel5A* consists of 1509 base pairs that encode a polypeptide of 502 amino acids. AgCel5A has four potential N-glycosylation sites and three O-glycosylation sites, which indicates high similarity to the characterized GH5 β-glucosidases from *Aspergillus niger* (65%) and *Trichoderma reesei* (31%). AgCel5A was cloned and heterologously expressed in *Pichia pastoris* GS115. Recombinant AgCel5A exhibited maximal activity at pH 5.0. AgCel5A is much more stable than PdCel5C from *Penicillium decumbens* (Liu et al. 2013); it retains more than 70% of its maximum activity at pH 8.0–10.0. In addition, AgCel5A exhibited stable degradation activity under high-salt (NaCl) conditions. In the presence of 4 M NaCl, AgCel5A retained 90% activity even after 4 h of preincubation. Interestingly, the activity of AgCel5A increased as the NaCl concentration was increased. The high resistance of AgCel5A to saline and alkaline conditions suggests that the *AgCel5A* gene is an ideal candidate for genetic improvement of soil fungi and industrial applications (Zhang et al. 2016).

Few cellulase genes with tolerance to highly saline and alkaline environments from fungi have been reported, but several genes of this type have been studied in bacteria (e.g., *Paenibacillus sp.*, *Thermomonospora sp.*) (Zarafeta et al. 2016; Kanchanadumkerng et al. 2017). For example, CelDZ1, a recently identified thermotolerant and exceptionally halostable GH5 cellulase from an Icelandic *Thermoanaerobacterium* hot spring isolate, is a glycoside hydrolase with optimal activity at 70 °C and pH 5.0 (Zarafeta et al. 2016). On the other hand, CelDZ1 exhibits high halotolerance at near-saturating salt concentrations and high tolerance for metal ions and other denaturing agents (Zarafeta et al. 2016). These findings

show that cellulases from extremophilic bacteria should also be considered for utilization in genetic improvement of fungal resistance to salt and alkali.

27.4 The Molecular Base of Saline-Alkali Resistance in Haloalkaliphilic Fungi

The application of soil microbes to ameliorate salinity is gaining popularity because of its effectiveness and low economic and environmental costs. The applications of haloalkaliphilic fungi like *Aspergillus glaucus* CCHA are restricted by the low number of well-characterized species. Under this realistic condition, genetic improvement of normal soil fungi is a good choice. To enable improvement of the saline and alkaline resistance of normal fungi, genes related to resistance to salt, alkali, or both stresses must first be identified in extremophilic fungi.

Debaryomyces hansenii, the multiple functional salt-loving fungus, has been extensively investigated in recent years. *D. hansenii* can accumulate high concentrations of sodium without undergoing damage; in addition, it grows well under stress factors such as high temperature and extreme pH in the presence of 0.25 M NaCl (Almagro et al. 2000). By screening *S. cerevisiae* transformants containing genes from a genomic library prepared from *D. hansenii* (Prista et al. 2002, 2005), a series of genes associated with salt tolerance were identified and characterized. The *DhGZF3* gene, which encodes GATA transcription factor homologs Dal80 and Gzf3 in *S. cerevisiae*, has been functionally analyzed in *D. hansenii*, but the gene was verified to be a negative transcription factor when it was expressed in *S. cerevisiae* (García-Salcedo et al. 2006). Using a cDNA library from stress-tolerant basidiomycetes yeast *Rhodotorula mucilaginosa*, more than 100 *S. cerevisiae* transformants with tolerance to high concentrations of various osmolytes were screened by Gostinčar and Turk (2012). Among the sequenced clones, 12 genes mediated increased stress tolerance in *R. mucilaginosa* transformants. Recently, Pereira and colleagues (Pereira et al. 2014) analyzed nine candidate polyol/H(+) symporters from the *D. hansenii* genome database via heterologous expression in *S. cerevisiae*. Five distinct polyol/H(+) symporters were confirmed, among which two symporters were specific for uncommon substrates galactitol and D-(+)-chiro-inositol.

Few stress tolerance genes have been identified in extremophilic fungi, and their functions merit additional research because they could be of significant importance in transgenic biotechnology. Most importantly, abiotic stress resistance genes isolated from extremophilic fungi generally function better than homologs from non-extremophiles in extreme environments. *EhHOG*, as mentioned above, is an *E. herbariorum* MAPK kinase gene similar to HOG1 homologs from *A. nidulans*, *S. cerevisiae*, *Schizosaccharomyces pombe*, and most other fungi (Brewster et al. 1993; Delgado-Jarana et al. 2000); however, a hog1 mutant complemented with EhHOG outperformed wild-type yeast under high-salt and freezing/thawing conditions (Yan et al. 2005).

Interestingly, several genes isolated from halophilic fungus *A. glaucus* are more resistant to osmotic stress in comparison with those of common fungi such as *S. cerevisiae* and *Magnaporthe oryzae*. A yeast expression library containing full-length cDNAs from *A. glaucus* was constructed and used to screen salt resistance transformants in our laboratory at Jilin University (Liu et al. 2011; Fang et al. 2014). Ribosomal protein L44 (RPL44), a part of the 60S large ribosomal subunit, was identified based on its association with salt resistance. In comparison with yeasts expressing MoRPL44, the RPL44 homolog of *M. oryzae*, yeasts expressing *AgRPL44* from *A. glaucus* were more resistant to salt, drought, and heavy metals. In addition, when *AgRPL44* was introduced into *M. oryzae*, the transformants displayed significantly enhanced tolerance to salt and drought, indicating that RPL44 plays a role in osmosis resistance in halophilic fungi (Liu et al. 2014; Xie 2013). Similar results were also obtained in studies of another ribosomal protein subunit, AgRPS3aE (Liang et al. 2015), as well as in studies of AgglpF (Liu et al. 2015).

ATP-dependent Lon proteases are highly conserved in diverse species and perform multiple roles. MAP1/Lon protease, the mitochondrial Lon protease homolog of *M. oryzae*, produced a positive effect on salt resistance (Li et al. 2015; Cui et al. 2015). Recently, the genetics of two ATP-dependent Lon proteases from thermophilic fungus *Thermomyces lanuginosus* were studied (Cui et al. 2017). Mitochondrial and peroxisomal Lon proteases were found to exhibit synergistic effects on resistance to multiple stressors, including salt and alkali, in *T. lanuginosus*. The common features of the genes described above are highly conserved and not specific to extremophilic fungi; however, their effects on the tolerance of transgenic cells and organisms surviving under stressful conditions are unambiguous and consistent, suggesting that additional tolerance-related genes with potential value remain to be identified and tested.

27.5 The Mycoremediation Mechanisms of Saline-Alkali Soil

The beneficial effect of microbial application on saline-alkali soil has been reported by Sahin et al. (2011). In the study, suspensions of three fungal isolates (*Aspergillus* spp. FS 9 and 11 and *Alternaria* spp. FS 8) and two bacterial strains (*Bacillus subtilis* OSU 142 and *Bacillus megaterium* M3) at 10^4 spore/mL and 10^9 CFU/mL, respectively, were mixed with leaching water and applied to the soil columns in the Igdir plain of northeastern Turkey (Sahin et al. 2011). Gypsum is an economical alternative for replacing sodium with calcium in remediating saline-alkali soils (Gharaibeh et al. 2009; Oad et al. 2002). In the experimental process, gypsum was applied for the saline-alkali soil pretreatment, and the microorganisms are not halotolerant or halophilic (Aslantas et al. 2007; Turan et al. 2006); thus the final results they obtained should not just be out of the function of microbes. Anyway, this study gives us an enlightened example for mycoremediation of saline-alkali soil by using haloalkaliphilic fungi.

Organisms at simultaneous high salt concentration and high pH value require special adaptive mechanisms, which during the course of evolution would be both facilitative and essential for life-supporting processes. Few researches focus on how haloalkaliphilic fungi cope with extremes of salt and pH value. We assume that haloalkaliphilic fungi adopt comprehensive strategies to survive in the extreme environment; in other words, under saline-alkali conditions, soil fungi must possess certain mechanisms to alleviate the influence or damage of both salt and alkali. In terms of soil effects, only reducing soil-soluble salt and regulating the pH value of soil solution can achieve the purpose of restoring saline-alkali soils.

1. Soil fungi have the ability to accumulate cation contents in cells. Saline soil will be improved with the accumulation of salt cation contents into fungal cells. *Hortaea werneckii*, the black yeast-like fungus isolated from hypersaline waters of salterns as their natural ecological niche, has been previously defined as halophilic fungus (Butinar et al. 2005a, b). *H. werneckii* cells were grown in liquid media at different salinities, ranging from 0 to 25% NaCl. The measurements of cation contents in cells grown at constant salt concentration have shown that the amounts of K^+ and Na^+ in *H. werneckii* were changing according to the NaCl concentration of the medium. When *H. werneckiio* was grown in a medium without added NaCl, it accumulated a very low amount of Na^+. But with the increasing NaCl concentration of the medium, the amounts of the Na^+ content increased and in the end reached a higher value (Kogej et al. 2005).
2. Soil fungi produce different organic acid patterns (Scervino et al. 2010). The released organic acids allow the formation of organic mineral complexes (Richardson et al. 2001); on the other hand with the release of organic acids, protons are produced that contribute to the acidification of the alkali soil solution.

   The saline-alkali soils and most cultivated soils are deficient in available forms of phosphorus. The release of these organic acids and other compounds in the rhizosphere by these microorganisms may be important in the solubilization of various inorganic phosphorus compounds (Scervino et al. 2010). In spite of this, based on the principle of acid-base neutralization, the organic acids also adjust the pH value of soil solution to a lower level.

   The reactions of the citric acid cycle are carried out by eight enzymes that completely oxidize acetate, in the form of acetyl-CoA, into two molecules each of carbon dioxide and water. Organic acids citrate, iso-citrate, succinate, fumarate, malate, and oxaloacetate are produced during each turn of the cycle. The high pH tolerance of *A. glaucus* has led to its utilization as an organic production strain (Barnes and Weitzman 1986). When *A. glaucus* CCHA was cultured in an alkaline medium, key enzymes (e.g., citrate synthase, isocitrate dehydrogenase, succinyl-CoA synthetase, malate dehydrogenase) of the citric acid cycle were significantly upregulated, suggesting that these genes contribute to the high pH tolerance of *A. glaucus* (Wei et al. 2013; Liu 2014; Zhou 2016; Wei and Zhang 2018).The case of organic acid production does not just

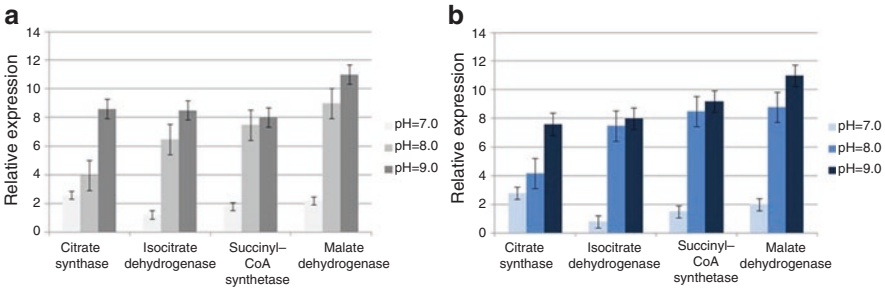

Fig. 27.2 Gene expression analysis of the citric acid cycle key enzymes at different pH value in *A. terreus* S108 (**a**) or *A. niger* S211 (**b**). *Aspergillus* strains were cultured in PD liquid medium (20% NaCl), and pH value was adjusted to 7, 8, or 9, respectively; all cultures were performed at a temperature of 35 °C for 3 days, and then mRNA was extracted for qRT-PCR; the four key enzymes of citric acid cycle (citrate synthase, isocitrate dehydrogenase, succinyl-CoA synthetase, and malate dehydrogenase) were detected through qRT-PCR. Each gene was searched from the genome sequence of *A. terreus and A. niger* (https://blast.ncbi.nlm.nih.gov/Blast) by using the corresponding mRNA sequence searched from the genome sequence of *A. niger* NRRL3 (http://genome.fungalgenomics.ca): citrate synthase (XM_022547762.1, homologous to NRRL3_00547), isocitrate dehydrogenase (XM_022550523.1, homologous to NRRL3_05263), succinyl-CoA synthetase (XM_022540546.1, homologous to NRRL3_00603), and malate dehydrogenase (XM_022546357.1, homologous to NRRL3_03476)

specifically occur in the CCHA strain; when other strains such as *Aspergillus terreus* S108 or *Aspergillus niger* S211 were selected as materials, we got the similar result (Fig. 27.2). Accordingly, alkali resistance might be improved in all these saline-alkali resistance fungi by overexpressing enzymes involved in the citric acid cycle.

3. Halophilic and alkaliphilic fungi are of biotechnological interest, as they produce extremozymes, which are useful in medical and environmental field because of their ability to remain active under the severe saline and alkaline conditions (Tiquia-Arashiro and Rodrigues 2016b). The enzymes secreted by haloalkaliphilic fungi possess the bioreduction effect on salt ions of soil. This bioreduction of metal particles by certain biomasses is regarded as an organism's survival mechanism against toxic metal ions and occurs via an active or passive process or a combination of both (Ibrahim et al. 2001; Durán et al. 2005). Correlation between soil properties and soil enzymes from fungi or other microorganisms has been substantiated; and these enzyme activities are now widely used as important indicators of soil quality and soil biological activities (Rietz and Haynes 2003). As described above, high salt and pH value induce the secretion of organic acids. Similar to this case, cellulases and other so-called soil enzymes are also induced with the increasing of salt concentration and pH value. When hydrolytic enzymes are secreted into soil solution, soil properties will be improved accordingly. Take cellulases for instance; on the one hand, soil cellulases can enhance the organic matters by degrading cellulose, and on the

other hand cellulases in salt soils or salt solutions have been detected to form biotical nanoparticles (Riddin et al. 2006; Tiquia-Arashiro and Rodrigues 2016b; Mohite et al. 2017). Recently, nanoparticles of varying size (10–300 nm) and shape (hexagons, pentagons, circles, squares, rectangles) were produced at extracellular levels by *Aspergillus glaucus* CCHA in our lab (unpublished data), indicating that the formation of nanoparticles by haloalkaliphilic fungus is associated with saline-alkali soil remediation.

4. The mechanisms employed by most of the soil fungi (non-mycorrhizal fungi) at the cellular level to tolerate soil salt ions are probably similar to some of the strategies employed by ectomycorrhizal fungus, namely binding to extracellular materials (Tam 1995; Aggangan et al. 2010; Gomes et al. 2018) or sequestration in the vacuolar compartment (Blaudez et al. 2000).

In brief, soil fungi buffer salinity and alkalinity by absorbing and/or constraining salt ions, secreting organic acids and/or macromolecule degradation enzymes, and providing biomass; all of these effects of fungi reduce plant stress. Therefore, haloalkaliphilic fungi are excellent biological resources for soil mycoremediation (Fig. 27.3).

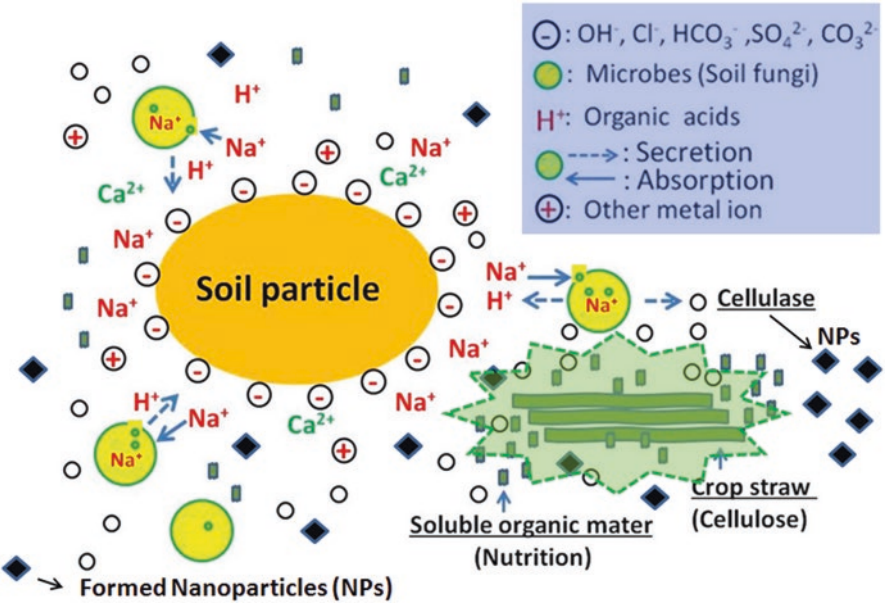

Fig. 27.3 Model of the mechanism through which mycoremediation of saline-alkali soil is achieved by adding haloalkaliphilic fungi and crop straw to soil

27.6 Conclusions and Future Directions

Bioremediation based on planting is one of the most effective methods of soil remediation because of its significant ecological, environmental, and economic effects (Ilyas et al. 1993; Ghaly 2002; Nouri et al. 2017), but the method requires persistent management to produce meaningful changes in soil characteristics. Application of organic matter conditioners, which can ameliorate and increase the fertility of saline soils, is an alternative soil remediation technique (Wang et al. 2014).

Fertile soil is a vital complex that involves numerous species and immense biomass; soil organisms have significant effects on the soil ecosystem. Soil-inhabitant fungi build a metabolic bridge between insoluble organic matter and soil nutrients by producing cellulose degradation enzymes such as cellulase, as well as performing other biological processes. However, saline-alkaline soils generally lack fungi, which ordinarily play important roles in degrading insoluble organic matter such as crop straw into soluble and easily absorbed nutrients; therefore, applying organic matter supplemented with fermentation fungi to saline-alkali soil is a feasible strategy for soil remediation.

Haloalkaliphilic fungi are excellent biological candidates for soil mycoremediation, but to date very few species with both abilities to produce effective soil enzymes and to grow in saline-alkaline environments have been reported. To get better remediation effect, natural soil fungi require to be genetically modified at their degradation ability or saline-alkali resistance. Generally, several enzymes involved in salt and/or alkali resistance, such as the alkaline-stable endoglucanases B from *Aspergillus niger* BCRC31494 (Li et al. 2012), the alkaline xylanase from *Aspergillus nidulans* KK–99 (Taneja et al. 2002), and the bilirubin oxidase from *Myrothecium sp*. IMER1 (Zhang et al. 2007), are highly abundant in fungi found in saline-alkali soil, but such fungi usually have a relatively low capacity for cellulose degradation, whereas fungi found in fertile soil show opposite characteristics. Thus, we propose two strategies to create novel haloalkaliphilic fungi with high cellulase activity: (1) Using naturally isolated haloalkaliphilic fungi as transformational receptors for cloned high-activity cellulase genes from fungi isolated from fertile soil should produce haloalkaliphilic fungi with salt/alkali resistance and high cellulase degradation activity. (2) Using fertile soil fungi as transformational receptors for salt and alkali resistance genes should produce fungi endowed with high resistance to saline-alkali environments, which would be promising candidates for saline-alkali soil remediation.

A series of salt and/or alkali resistance (or tolerance) genes have been characterized to provide a list of candidate genes to be applied in efforts to genetically improve soil fungi (Zhang 2016). In order to enhance the cellulose degradation ability of haloalkaliphilic fungi, additional cellulases with salt and alkali stability must be identified. Using cellulases with salt and alkali tolerance, two strategies can be employed to obtain saline/alkaline-resistant fungi with enhanced enzyme secretion. Indeed, natural strains remain the first choice for soil remediation;

Fig. 27.4 Mycoremediation of soda saline-alkali soil using amendments supplemented with haloalkaliphilic fungi (*A. glaucus* CCHA, *A. terreus* S108, *Eurotium herbariorum*, and *A. niger* S211 (ratio = 12:9:4:4)). The area on the right received the soil amendments mixed with haloalkaliphilic fungi, but the area on the left received salt-sensitive isolates. The experiment was conducted in soda saline-alkaline soil in Zhenlai County, which is located in the Songnen Plain of northeastern of China (see Fig. 27.1). The properties of the saline soil before organic amendments were applied indicate that it was classified as heavy soda saline-alkali soil (at a soil depth of 0–20 cm, sodium salt = 18 g/kg, pH = 10.1, measured by Dr. Shi Yang in 2016). (The aerial photography was performed by an unmanned plane at 150–200 m in the air in 2016)

therefore, isolating and screening suitable strains from extreme natural environments is still an important long-term task.

Haloalkaliphilic fungus *Aspergillus glaucus* CCHA, a fungal species with extreme tolerance to saline and alkaline conditions, has significant potential value in industrial and agricultural applications. Our group has been assessing the potential of *Aspergillus glaucus* CCHA in the mycoremediation of saline-alkaline soil in the Songnen Plain of northeastern China (one of the three most famous saline and alkaline lands in the world) for 3 years (Shi and Zhu 2016). This study primarily indicates that the applied amendments mixed with haloalkaliphilic fungi significantly encourage steady growth and yield of rice in comparison to that achieved in the control plot (Fig. 27.4).

Chapter 28
Potential Role of Extremophilic Hydrocarbonoclastic Fungi for Extra-Heavy Crude Oil Bioconversion and the Sustainable Development of the Petroleum Industry

Leopoldo Naranjo-Briceño, Beatriz Pernía, Trigal Perdomo, Meralys González, Ysvic Inojosa, Ángela De Sisto, Héctor Urbina, and Vladimir León

28.1 Introduction

In spite of the laudable financial, technical, and scientific efforts focused on the development of new environmental friendly energy sources, it is unquestionable that the world is running on petroleum. In fact, the present world oil requirements to sustain the actual growth behavior of the global population are estimated in more than 95 million barrels per day (OPEC, Annual Statistical Bulletin 2017).

The increasing global demand for fuel and the reduction of conventional crude reserves have generated a great interest on the exploitation of unconventional crude reserves worldwide. These unconventional sources of fossil fuel cannot be extracted, transported, and refined by conventional methods. The certified crude oil reserves worldwide are estimated in more than 1.5 billion barrels, of which 70% are constituted by unconventional crudes, such as the Orinoco Oil Belt (OOB), the biggest certified reserve of EHCO worldwide located in Venezuela with over 300 billion barrels (OPEC, Annual Statistical Bulletin 2017).

The enormous reserves of unconventional crudes contain high concentrations of toxicity pollutants and high-molecular-weight compounds, such as asphaltenes, which are heterogeneous and complex mixtures insoluble in n-heptane or n-pentane, and soluble in benzene or toluene, which contain heteroatoms (nitrogen, sulfur, and oxygen) and heavy metals such as nickel and vanadium in their structure (Waldo et al. 1991; Strauz et al. 1992; Uribe-Álvarez et al. 2011; Ayala et al. 2012; Naranjo et al. 2007; León et al. 2007).

Unconventional crude oils have been characterized as recalcitrant (very low availability and degradation by microorganisms), polar, and water insoluble, and contain sulfur and/or heavy metals in association; hence there is a high demand for the development of technologies that aim to alleviate environmental impacts during the extraction, production, and refinement of unconventional crude oils.

The sustainable development of the oil industry requires the development of novel environmental friendly technologies, which could offer both higher economic income with environmental remediation of anthropogenic intervened ecosystems and conservation of natural ecosystems. Complementary use of modern biotechnology in the oil industry provides new tools to improve their processes and products in the production chain, decreasing operational costs and increasing productive capabilities with minimum environmental impact (Naranjo et al. 2007, 2008, 2013).

Aromatic hydrocarbons ranging from the single benzene ring to the high-molecular-weight polycyclics are generally biodegraded via one or more of the three independent enzymatic systems. The intracellular P450 monooxygenases that detoxify harmful chemicals are universally present in the microsomes of eukaryotic cells, while lignin-degrading fungi specifically produce extracellular peroxidases and laccases that biodegrade aromatic hydrocarbons (Prenafeta-Boldú et al. 2018). The low functional specificity and high redox potential of peroxidases and laccases enable the oxidation of a broad range of aromatic hydrocarbons and other recalcitrant contaminants (Prenafeta-Boldú et al. 2018).

In this sense, the study and application of the powerful extracellular oxidative lignin-degrading enzyme system (LDS) secreted by fungi have a great potential as biocatalysts (as whole cells or enzymatic catalyst) in mycoremediation and EHCO bioupgrading processes, through three main pathways: (1) de-aromatization of high-molecular-complexity compounds into more soluble compounds with concomitant reduction of viscosity and enhanced bioavailability by microorganisms; (2) biodesulfurization of sulfur heteroatoms; and (3) de-metallization of heavy metals such as nickel (Ni) and vanadium (V), among others.

Here, we want to contribute and promote the sustainable development of the petroleum industry with the complementary use of the biotechnology of fungi with respect to their ability to degrade and/or transform hydrocarbons, laying special emphasis on the fungal biodiversity associated to extreme environments and the selection of promissory extremophilic and hydrocarbonoclastic fungi.

The term extremophile was first proposed by MacElroy in 1974 to describe a broad group of organisms which lived optimally under extreme conditions (MacElroy 1974; Zhang et al. 2018). Their taxonomic range has been expanded from prokaryotes to all three domains Archaea, Bacteria, and Eukarya (Zhang et al. 2018). An extreme environment is a place that contains conditions that are hard to survive in for most known life forms. These conditions may be extremely high or low temperature (extremely hot or cold), high concentration of a salt (hypersaline), high acidity or alkalinity (acidic or alkaline), desiccation (without water), extremely high pressure (under pressure), high or low content of oxygen or carbon dioxide in the atmosphere (with or without O_2 or CO_2), high levels of radiation (UV emission, radioactivity), and places anthropogenically impacted, such as soil, sediment, or water contaminated by petroleum or other toxic and contaminant substances (altered by humans).

According to different extreme habitats, extremophiles are classified into seven categories (Arulazhagan et al. 2017; Zhang et al. 2018). Organisms whose optimal growth temperature ranges from 50 to 80 °C or exceeds 80 °C are called thermophiles or hyperthermophiles, respectively. Psychrophiles are organisms that grow at low temperatures ranging from 0 to 15 °C. Halophiles require >3% of NaCl to grow and are classified as halotolerant or slight halophiles (2–5% NaCl), moderate halophiles (5–20% NaCl), and extreme halophiles (20–35% NaCl). Acidophiles or alkaliphiles show optimal growth at pH values 1–5 and pH >9, respectively. Piezophiles or barophiles reside under high hydrostatic pressure which have been isolated from the deep-sea sediments (>3000 m depth and pressures of up to 110 MPa). Finally, xerophiles are organisms that grow under low water content (aw 0.60–0.90). In addition, these organisms are normally polyextremophiles and are adapted to live in habitats where various physicochemical parameters reach extreme values (Rampelotto 2013).

In extreme habitats, microorganisms require a large adaptation process until reaching optimal growth and reproduction. This evolutional redesign involves novel morphophysiological characteristics and modifications of genes and proteins, with subsequent changes in regulatory and metabolic pathways until epigenetic modifications, which have a great interest for biotechnological purposes. In fact, Zhang et al. (2018) reported a total of 314 new bioactive fungal natural products from 56 Ascomycota extremophilic fungi (asexual stage), including terpenoids/steroids, alkaloids/peptides/amides, quinones/phenols, esters/lactones, xanthones, and polyketides. Likewise, this is particularly true for their enzymes, which remain catalytically active under extremes of temperature, salinity, pH, and solvent conditions. Interestingly, some of these enzymes display polyextremophilicity (i.e., stability and activity in more than one extreme condition) making them widely functional in industrial biotechnology (Rampelotto 2013).

The exploitation, production, refining, and transportation of oil and its derivatives occasionally lead to technical and operational accidents with serious harm to the environment, some with irreversible destruction (León et al. 2009; Pernía et al. 2012, 2018). Polycyclic aromatic hydrocarbons are generated from both natural and anthropogenic processes, and are ubiquitous environmental pollutants with cytotoxicity, mutagenicity, and carcinogenicity capabilities. Due to their hydrophobic nature, they persist in the environments. More than two decades ago, the United States Environmental Protection Agency (USEPA) considered that some PAHs are toxic and possibly human carcinogens (Nadon et al. 1995).

There is wide fungal biodiversity with diverse enzymatic mechanisms that transform different hydrocarbon chemical structures, from short-chain aliphatics to heavy-weight polycyclic aromatics (Prenafeta-Boldú et al. 2018). The hydrocarbonoclastic fungi are a fascinating group of microorganisms with the unique ability to metabolize hydrocarbons as a sole source of carbon and energy, despite their low biodegradability due to their littler solubility and high hydrophobicity that limit their transport into microbial cells (Arulazhagan et al. 2017).

The term extremophilic hydrocarbonoclastic fungi is proposed here to describe a large and heterogeneous group of cultivable fungi which live optimally under extreme conditions, as well as are characterized by having a high ability to grow using hydrocarbons as the sole carbon source and energy. Usually, these fungi are isolated from soils, sediments, fluids, vapor, or water impregnated by petroleum or its derivatives. These extreme environments are mainly the consequence of anthropogenic activities, and usually have hard conditions to survive in for most known forms of life, such as high concentration of salt (hypersaline); high acidity or alkalinity (acidic or alkaline); high concentrations of high-molecular-weight compounds and toxicity pollutants (i.e., asphaltenes); heavy metals and heteroatoms such as sulfur; and high levels of PAHs with high toxicity. Thus, extremophilic hydrocarbonoclastic fungi are normally polyextremophiles, adapted to live in habitats under pressure of various physicochemical conditions considered “extreme.”

Besides their polyextremophiles characteristics, these fungi have the unique ability to use hydrocarbons as a sole source of carbon and energy, despite their high toxicity and hydrophobicity properties; hence extremophilic hydrocarbonoclastic fungi play a pivotal role in the degradation/transformation of petroleum and its derivatives. This is the reason why the use of extremophilic hydrocarbonoclastic fungi as biocatalysts at great scale requires the maintenance and vegetative reproduction in the laboratory and industrial levels in the absence of a sexual stage. The asexual reproduction by mitotic division in fungi is commonly used to produce fungal mycelium to colonize the environments, which generates new identical individuals by remaining haploid, resulting in a progeny with the same genetic information as its own parental inoculum (Moore et al. 2011). Hence, the mitotic division guarantees researchers a simple, fast, and profuse vegetative reproduction of the fungal biocatalysts at the same time keeping their original hydrocarbonoclastic and polyextremophile characteristics.

The scope of this chapter is to demonstrate the application of the fungal biotechnology in the degradation and bioconversion of unconventional crude and its pos-

sible applications for the sustainable development of the petroleum industry. Contrary to other publications that are focused on bioremediation of light crude oils, here we present promising fungi with degradation potential of recalcitrant crudes like EHCO, a type of crude oil that is considered nonbiodegradable by microorganisms. At the same time, we demonstrate for the first time the potential of hydrocarbonoclastic fungi isolated from extreme environments (EHCO, hydrocarbon pits, crude distribution pipes, and the natural asphaltene Lake of Guanoco) to tolerate high concentration of EHCO, dibenzothiophene (DBT), phenanthrene, naphthalene, and pyrene in vitro conditions. We also described the relationship between lignin-degrading enzyme system (LDS) and the EHCO bioconversion by several extremophilic hydrocarbonoclastic fungi studied.

28.2 Biotechnology as the Measurement of Human Being and Biodiversity: Potential Applications for Sustainable Development of the Petroleum Industry

Since ancestral times, and based on its own essence, biotechnology started from the logic of human being, the observation, learning, and exploiting of nature to a benefit, pursuing a better quality life. This initiative was originally contemplative and through the centuries, based on success and error testing, formidably was ahead of its time and was evolving in the same way that knowledge evolved through the course of time. Thus, it could be considered that biotechnology occurs empirically from the activities of daily living of our ancestors, becoming implicit to the human being as a thinking and dynamic element of nature, which blooms before his eyes, building a magical altar of incommensurable bio-possibilities, helping to solve their most basic needs. Therefore, biotechnology dates from the same origin of human evolution as a thinking creature that expands human possibilities. Likewise, biotechnology could be considered as the oldest technology ever practiced by humans. In this process of singular complexity, the human being as subjects and from its knowledge obtains benefits from nature and its biodiversity, while, in the same act, nature *as subject and not as an object* is observed, acquired, and learned by humans. In this unique process, the bio-possibilities were greater and greater as the knowledge of the human kind was approaching to nature, and its exuberance biodiversity.

The harmonizing use of conventional oil production technologies with petroleum biotechnology emerges as an innovative strategy to help to ensure a sustainable development and the conservation of the environment. However, very little has been described concerning the medullary areas inside the petroleum industry where the biotechnology could have potential applications (Foght 2004). To identify medullary areas not only the products but also the operational processes associated to the petroleum industry in its whole-value chain should be known and the clear increase of the exploitation, production, and processing of unconventional crude oils should

be considered. However, it is also important to understand the essence that fundamentally supports any biotechnological development: a specific problem or requirement to be solved, knowledge and technology, and biodiversity.

In principle, the petroleum biotechnology could be defined as *the study and rational use of the biodiversity, its genetic, enzymatic, and metabolic resources, to give high-added value to the products and processes of the petroleum industry in its whole-value chain, and to contribute to mitigate the environmental impact of its operational activities*. Major aims of the possible contribution of the complementary use of biotechnology in the petroleum industry would be focused on (1) the improvement of its productive capabilities (efficiency and productivity); (2) a comprehensive security of its operational processes (sustainability, safeguarded processes, and productivity); and (3) the remediation of its associated environmental liabilities (environmental sanitation, conservation, and sustainability).

Prenafeta-Boldú et al. (2018) commented that applied research on hydrocarbonoclastic fungi includes dedication to preventing biodeterioration as well as the potential application of fungal enzymatic capabilities for bioremediation purposes. Although there are numerous benefits and applications of hydrocarbonoclastic fungi, in this chapter only four main research and development areas are discussed (Fig. 28.1):

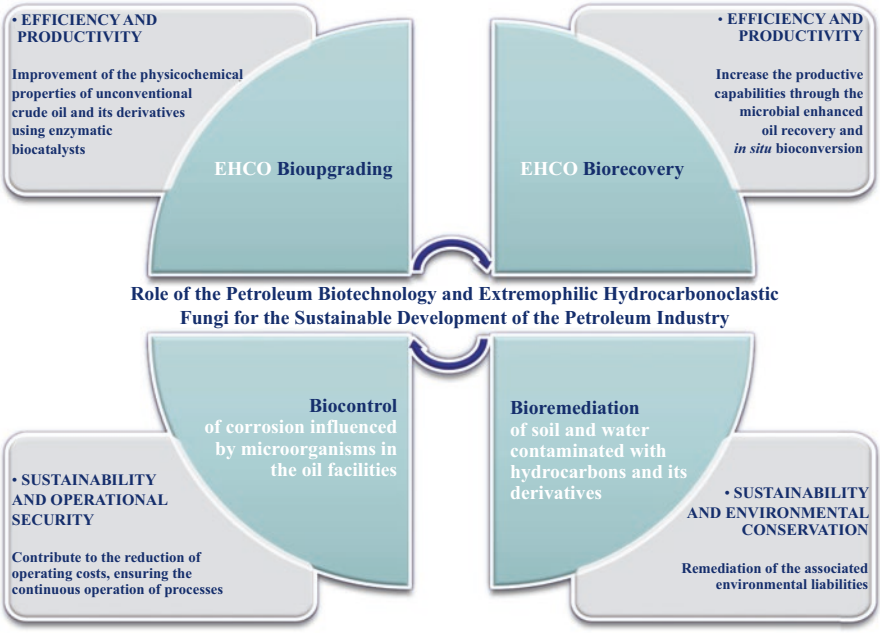

Fig. 28.1 Some contributions of the complementary use of biotechnology in the petroleum industry

1. Improvement of the physicochemical properties of unconventional crude oil and its derivatives using enzymatic biocatalysts, nanostructured support, and other coupled processes of bioconversion (**bioupgrading**)
2. Improvement of the recovery factor of oil in reservoirs by using promissory extremophile microorganisms and biodegradable polymers (MEOR, microbial enhanced oil recovery) (**biorecovery**)
3. Bioremediation of soil and water contaminated with hydrocarbons, oil pits, drilling waste, and industrial pollutants (**bioremediation**)
4. Contribution to the reduction of operating costs, ensuring the continuous operation of processes by the detection, monitoring, and control of microbial influenced corrosion, biofouling, and biodeterioration in oil facilities (**biocontrol**)

28.3 Fungal Biodiversity with Hydrocarbonoclastic Potential: From the Meta-analysis to the Tangible Reality Show

The work of Pernía et al. (2012) represents the first study where a meta-analysis was applied to the study of fungal diversity isolated from crude oil, its derivatives, and hydrocarbon-contaminated environments, including their hydrocarbonoclastic capabilities, through a detailed review of scientific literature published during the last century (from 1900 to 2012) in this passionate field of science. The results of this meta-analysis showed that the substrates with the highest fungal diversity were soils impacted with crude and natural asphalt, obtaining the lowest diversity in soil contaminated with diesel and gasoline in agreement with their high toxicity. The total fungal diversity isolated was constituted mainly by phylum Ascomycota (83%) followed by Zygomycota (10%), Basidiomycota (1%), and others (6%). In the phylum Ascomycota, the most common orders obtained were the Eurotiales (54%), followed by the Hypocreales (18%), Microascales (6%), and Saccharomycetales (5%), and the most predominant genera were *Penicillium* (18%), *Aspergillus* (17%), and *Fusarium* (6%).

Based on the percentage of degradation of total petroleum hydrocarbons (TPH), the group that presented greater degradation, TPH: 52 ± 3.53%, was formed by the genera *Aspergillus*, *Bjerkandera*, *Coriolus*, *Emericella*, *Phanerochaete*, *Pleurotus*, *Rhizopus*, and *Trametes*; with respect to degradation rate of the saturated and aromatic fractions, two groups were obtained by the genera: (1) *Beauveria*, *Coriolopsis*, *Emericella*, *Fusarium*, *Phanerochaete*, *Pleurotus*, and *Trametes*, (74.43 ± 3.40%), and (2) *Coriolopsis*, *Fusarium*, *Pleurotus*, and *Trametes* (97.75 ± 2.25 %). Likewise, evidence of degradation of resin and asphaltene fractions (10–28% and 10–40%, respectively) was found by the genera *Aspergillus*, *Candida*, *Emericella*, *Eupenicillium*, *Fusarium*, *Graphium*, *Neosartorya*, *Paecilomyces*, and *Meyerozyma* (Pernía et al. 2012).

28.3.1 Exploring Culturable Extremophilic Fungal Biodiversity with Potential Applications in the Sustainable Development of the Petroleum Industry: Knowing the Bio-possibilities

Fungi have essential roles in natural ecosystems through diverse forms of lifestyles, such as parasitism, mutualistic symbiotic associations with plant roots (e.g., arbuscular mycorrhizal fungi, ectomycorrhizal fungi, Orchid- and Ericoid-mycorrhizal fungi) and other organisms, as well as decomposers of the organic matter; hence fungi directly contribute to biogeochemical cycles (e.g., carbon, nitrogen, and phosphorous nutrients) and influence the greenhouse gas balance in the atmosphere on the global scale. In fact, the incorporation of mycorrhizae in global carbon cycle models is crucial in order to accurately predict ecosystem responses and feedbacks to climate change (Terrer et al. 2016).

The fungal decomposers can downgrade complex organic molecules such as cellulose, hemicellulose, lignin, pectin, starch, and non-synthesized xenobiotic compounds by natural metabolic processes, whose toxicity lies in their chemical nature and is persistent in the environment due to their low bioavailability (Dávila and Vázquez-Duhalt 2006, Naranjo et al. 2007, Pernía et al. 2018). The metabolism of organic compounds to less structurally complex products can directly or indirectly affect the growth of other surrounding microorganisms (Amund et al. 1987, Bartha and Atlas 1977, Brock 2015, Obire 1993, Odokuma and Opokwasili 1993, Pernía et al. 2018).

In the oil production value chain (processes of exploitation, production, refining, transportation of petroleum and its derivatives) there are occasional technical and operational accidents that release xenobiotic compounds into the environment promoting a selective pressure on the microbiota (Atlas and Bartha 1972; Calomiris et al. 1986; Pernía et al. 2018). The fungal catabolic activity (intracellular or extracellular) modifies bio-availability features of the xenobiotic compounds and derivatives, affecting the dynamics of autochthonous microbial communities (Coyne 2000). Subsequently, a selective enrichment process occurs for certain degraders and/or tolerant species, and the disappearance of those that do not have these capabilities (Benka-Coker and Ekundayo 1997).

In the study of the autochthonous fungal communities associated with oil-polluted environments it's essential to describe their microbial and functional biodiversity. However, for the selection of powerful extremophilic fungi as biocatalysts, the studies of both hydrocarbonoclastic potential and their tolerance to xenobiotic and toxic compounds abilities are crucial. Despite the unquestionable importance of the microbial and functional diversity studies that include the cultivable and non-cultivable microorganisms by means of metagenomics tools, in this work our effort was focused on the analyses of the cultivable extremophilic fungi from the extreme environments due to their potential use as promising biocatalysts for the sustainable development of the petroleum industry.

In this way, our research team started an exhaustive study on the fungal diversity associated with different types of samples: (1) Carabobo EHCO (samples taken directly from an oil well), (2) oil-polluted soil adjacent to an oil pit, (3) the natural asphalt Lake of Guanoco, and (4) petroleum naphtha distribution system (Fig. 28.2). The tolerance to EHCO and polyaromatic hydrocarbon (PAH) compound models, such as naphthalene, phenanthrene, DBT, and pyrene, was also investigated at inter- and intraspecific species levels. The isolation, maintenance, growth, and molecular identification of the fungal strains were performed according to Naranjo et al. (2007, 2013). The descriptive analysis into the functional group of fungi was carried out according to Pernía et al. (2012).

28.3.2 Isolation of Cultivable Fungal Biodiversity from Extreme Environments: Identifying the Cultivable Fungal Communities

At first, the relative frequencies of the different phylum and orders of the fungal strains isolated from the extreme environments were determined as mentioned above. All sites or samples studied were considerate extreme environments because they showed various physicochemical conditions unfavorable for survival of most known life forms.

In the case of the natural samples of asphalt and EHCO, these contain a heterogeneous mixture of organic compounds with a high concentration of asphaltenes and toxicity pollutants such as heavy metals and sulfur. Asphaltene's recalcitrancy is explained by the high degree of aromaticity combined with the presence of short alkyl chains (Naranjo et al. 2013). Carabobo EHCO assays have heavy American Petroleum Institute (API) gravity of 8.5°, sulfur concentration of 3.9%, and heavy metal Ni and V concentration of 480 mg/L (Pernía et al. 2018).

Oil-polluted soil from oil pits possesses a significant risk to wildlife and humans, due to its enormous mixture of organic compounds and chemical pollutants with high toxicity levels. During extraction and production processes in the Orinoco Oil Belt in Venezuela, oil pits generally store high volumes of sludge, oil spill, chemical treaters, formation water (brine), and drilling waste impregnated with EHCO and highly salinized water-based drilling fluids, which are mainly constituted by a wide range of corrosive compounds such as sodium bicarbonate, sodium carbonate, potassium chloride, potassium hydroxide, glycol, sodium hydroxide, thickeners, and lubricants, among others, xenobiotics that radically increase the alkalinity and salinity levels of the soil destroying its structure (Arellano et al. 2008, Naranjo et al. 2013).

Petroleum naphtha is a highly volatile and flammable intermediate hydrocarbon liquid stream derived from the refining of crude oil that contains paraffins, naphthenes (cyclic paraffins), and aromatic hydrocarbons. In this case, we refer to olefin-containing naphtha derived from the fluid catalytic cracking, visbreakers, and

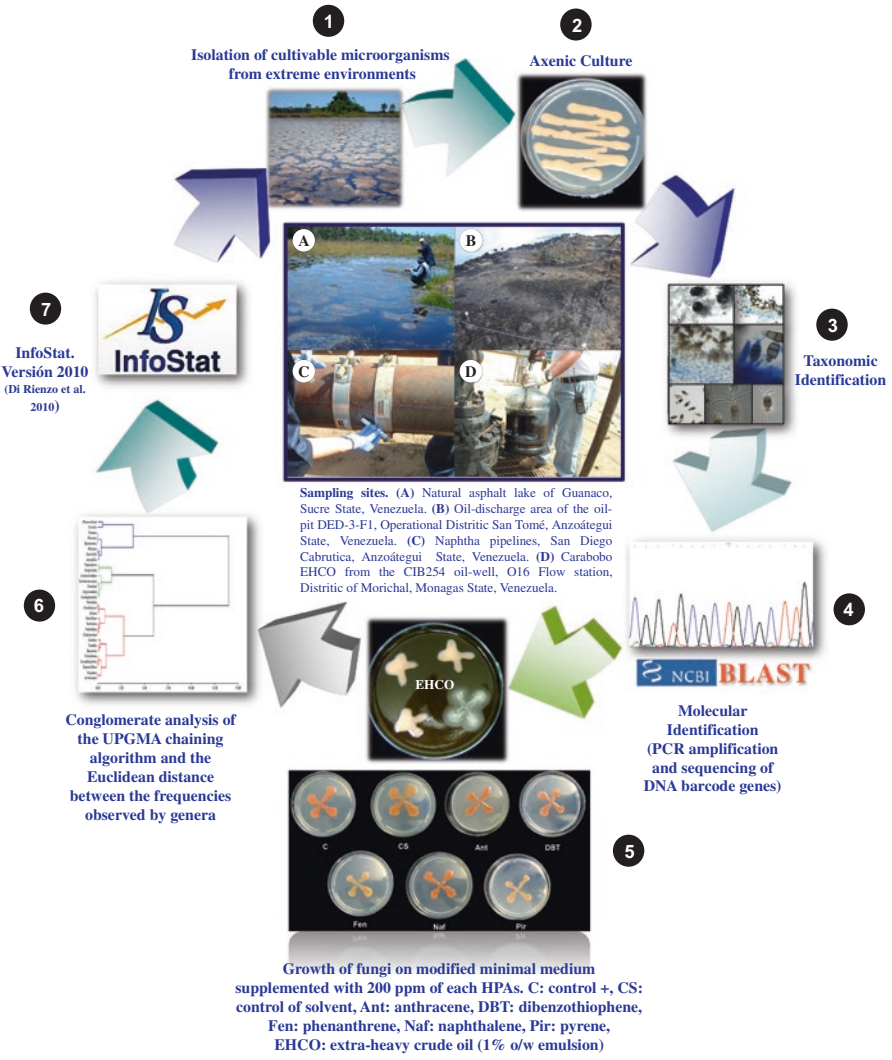

Fig. 28.2 Sampling sites and biotechnological strategy proposed. The samples were taken from (**a**) the natural asphalt lake of Guanaco, Sucre State, Ven; (**b**) the oil-discharge area of the oil pit DED-3-F1, Operational District San Tomé, Anzoátegui State, Ven; (**c**) the naphtha pipeline distribution system, San Diego Cabrutica, Anzoátegui State, Ven; (**d**) Carabobo EHCO from the CIB254 oil well, O16 Flow station, District of Morichal, Monagas State, Venezuela

coking processes used in many refineries (named cracked naphtha) that is broadly used by the Venezuelan petroleum industry as a solvent that decreases the high viscosity levels of the EHCO from OOB. According to the National Institute for Occupational Safety and Health (NIOSH), petroleum naphtha is immediately dangerous to life and health (CDC-NIOSH. 2015).

The biotechnological strategy proposed for identification of fungal communities from extreme environments is indicated in Fig. 28.2. Results showed, in terms of biodiversity, the most diverse substrate was the natural asphalt Lake of Guanoco, where 11 different fungal genera were isolated (including one basidiomycete fungus), followed by the oil-polluted soil (7 genera), and EHCO and naphtha, where only 3 genera and 1 genus were isolated, respectively (Table 28.1).

As reported by Pernía et al. (2012), the most isolated fungal group was phylum Ascomycota (91.66%) and only 8.33% belong to phylum Basidiomycota (Fig. 28.3a). In the phylum Ascomycota, the most common orders obtained were the Eurotiales (61.36%), followed by the Hypocreales (20.45%), Saccharomycetales (6.81%), Dothidiales (2.27%), Xylariaceae (2.27%), Pleosporales (2.27%), Microascales (2.27%), and incertae sedis (2.27%), which in this case correspond to the genus *Staphylotrichum* (Fig. 28.3b). Likewise, the Ascomycota genera with a higher number of species (in parenthesis) were *Aspergillus* (11), *Penicillium* (7), *Fusarium* (6), *Neosartorya* (4), *Trichoderma* (3), *Candida* (2), and *Byssochlamys* (2). The rest of the fungal strains were represented by only one species. The phylum Basidiomycota was represented by two orders Sporidiobolales (75%) and Polyporales (25%), which were comprised by the yeast-like fungi *Rhodotorula* (3) and *Pycnoporus sanguineus* (1), respectively (Fig. 28.3c).

From the list of isolated fungi (Table 28.1), some species have been reported as cosmopolitan fungi with worldwide distribution, such as *Aspergillus fumigatus* and *Aspergillus terreus*, *Penicillium glabrum* (formerly *Penicillium frequentans*) and *Penicillium oxalicum, Neocosmospora* (=*Fusarium*) *solani, Cladosporium sphaerospermum, Trichoderma viride*, and *Trichoderma inhamatum* (Domsch et al. 1980). *Penicillium oxalicum* was isolated from crude oil-impacted soil in the Borneo Islands (Chaillan et al. 2004). *Aspergillus fumigatus* has been widely reported as an inhabitant of soils polluted with hydrocarbons such as crude oil, kerosene, and diesel (April et al. 1998; Bento and Gaylarde 2001; Chaillan et al. 2004; Gesinde et al. 2008; Hemida et al. 1993; Oudot et al. 1993). In addition, *A. fumigatus* was reported as capable of degrading 20% of crude oil (Oudot et al. 1993). *Aspergillus terreus* was isolated from oil-polluted soils, gasoline, and kerosene (Chaillan et al. 2004; Colombo et al. 1996; Hemida et al. 1993; Uzoamaka et al. 2009), and possesses the capability of degrading up to 30% of crude oil (Algounaim et al. 1995). *Neocosmospora solani* was isolated from oil-polluted soils, asphalt, and kerosene (Colombo et al. 1996; Hemida et al. 1993; Naranjo et al. 2007, 2008) and could degrade up to 19% of the crude oil in 30 days (Chaineau et al. 1999).

Interestingly, only yeast-like fungi were isolated from EHCO (sample taken directly from an EHCO well), such as *Candida tropicalis, Candida viswanathii, Rhodotorula mucilaginosa*, and *Cyberlindnera* (=*Williopsis*) *saturnus*. *Candida tropicalis* was isolated previously from oil-polluted soils (April et al. 1998; Chaillan et al. 2004), in agreement with a prior report in which the yeasts *Candida palmioleophila* and *Meyerozyma* (=*Pichia*) *guilliermondii* were capable of the degradation of resins and asphaltenes (Chaillan et al. 2004).

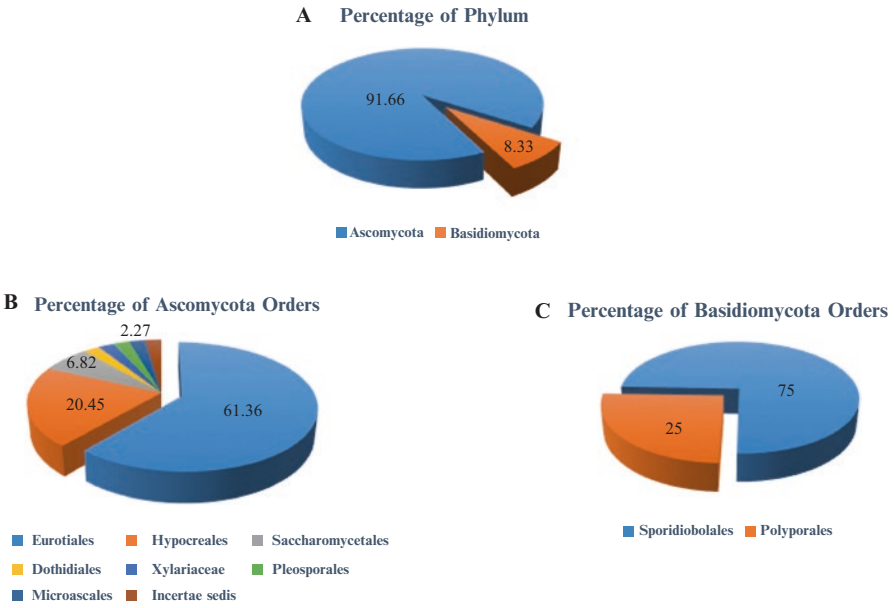

Fig. 28.3 Percentage of fungi isolated from extreme environments according to phylum and order

Surprisingly, the common species isolated from all petroleum substrates was *R. mucilaginosa* which, as further discussed, is one of the most tolerant species to EHCO and PAHs. *Rhodotorula mucilaginosa* was also isolated by Gallego et al. (2007), reporting that it could degrade linear alkanes, C11-C33, branched alkanes, isoprenoids, and cycloalkanes. Other investigations have described *R. mucilaginosa* as halotolerant (it's able to grow in concentrations higher than 2.5 M of NaCl); it tolerates a wide pH range of 2–10, and is capable of degrading nitrobenzene (Gross and Robbins 2000; Lahav et al. 2002; Turk et al. 2011; Zheng et al. 2009; Urbina and Aime 2018). More recently, Naranjo et al. (2015) described the isolation and molecular identification of fungal strains from naphtha systems in the oil industry, where the naphtha-tolerant *R. mucilaginosa* was the most predominant yeast-like fungal species.

The rest of the fungal species, such as *Byssochlamys laguncularіae* (formerly *Byssochlamys nivea*), *Fusarium venenatum*, *Trametes coccinea*, and *Staphylotrichum* sp., are new reports for science as species capable of inhabiting EHCO or oil-polluted soils that also have a great potential to be used for mycoremediation or EHCO bioconversion purposes.

28.3.3 *Fungal Screening to Determine Hydrocarbonoclastic Potential and Tolerance to EHCO and HPAs: Obtaining the Powerful Biocatalysts*

Our in vitro results show that all isolated fungi were tolerant to 1% EHCO. The most toxic compounds for fungi were DBT and phenanthrene, which showed a growth inhibition of more than 50%. These findings are presented in a cladogram where fungal species are discriminated by functional groups according to their tolerance to EHCO and PAHs (Fig. 28.4) as follows:

Group No. 4 is the most tolerant capable of growth at 100% rate in all hydrocarbons studied in comparison to the control medium. Interestingly, this group is constituted by the filamentous fungi species *B. laguncullariae* 87, *Penicillium* (=*Eupenicillium*) *javanicum*, and *Penicillium* sp. 37, and the unicellular fungi *C. tropicalis*, *C. viswanathii*, *R. mucilaginosa* (three strains), and *Ci. saturnus*. All these unicellular fungi were isolated from EHCO and, in the case of *R. mucilaginosa*, were also isolated from oil-polluted soils and naphtha distribution system. These results strongly suggested that the fungal strains with greater hydrocarbonoclastic and tolerance capabilities are associated with EHCO wells and belong to unicellular fungi.

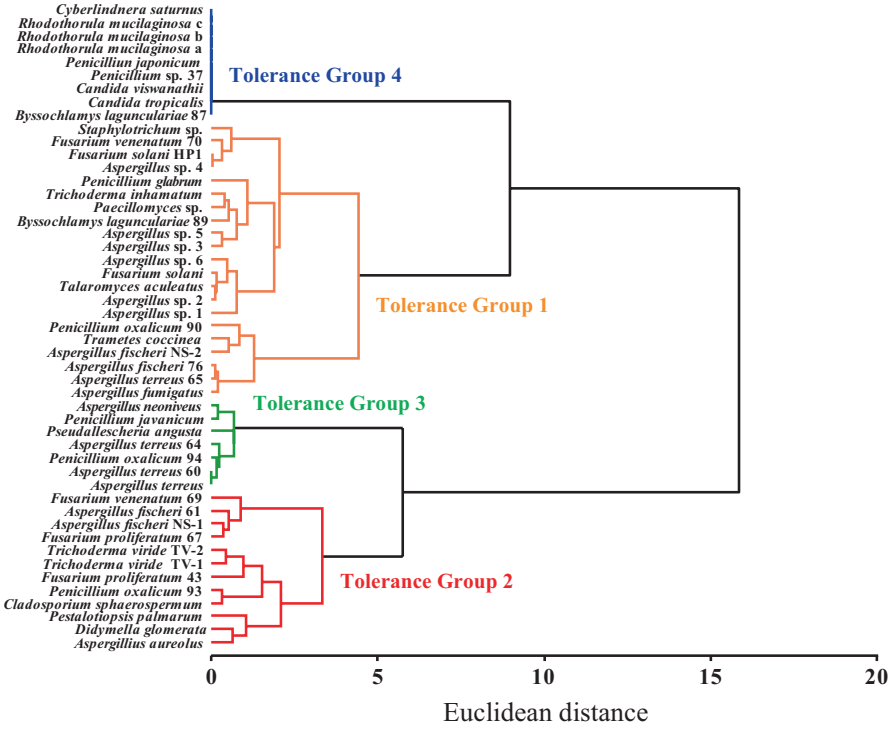

Fig. 28.4 Dendrogram of tolerance groups of fungal species according to their tolerance to PAHs

Group No. 1, the second most tolerant group, comprised of fungi that could grow at 95.81 ± 2.35% rate in EHCO, 92.62 ± 2.32% rate in naphthalene, and 80.14 ± 3.52% rate in pyrene. However, their growth was inhibited at approximately 50% rate in DBT and phenanthrene. This group clustered the major amount of fungal strains studied and was constituted by *Aspergillus* sp. (1–6), *A. fumigatus*, *A. terreus, B. lagunculariae* 89, *N. solani*, *Fusarium venenatum* 70, *A. fischeri* (formerly *Neosartorya pseudofischeri* and *Neosartorya spinosa)*, *Paecilomyces* sp., *Talaromyces* (=*Penicillium*) *aculeatum*, *Penicillium glabrum* (formerly *Penicillium frequentans*), *Penicillium oxalicum*, *Trametes coccinea*, *Staphylotrichum* sp., and *Trichoderma inhamatum*. The rest of the tolerance groups (Nos. 2 and 3) were the less tolerant, and their growth was inhibited to more than 50% rate in the same conditions.

According to ranges of HPA tolerance, Group No. 4 has a 100% tolerance for all PAHs studied. Group No. 3 tolerates CEP and DBT 100% but it is less tolerant to phenanthrene (12–45%), naphthalene (38–57%), and pyrene (38–54%). Group No. 2 tolerates CEP in 19–61%, DBT (0–57%), phenanthrene (0–60%), and pyrene (0–100%). Finally, Group No. 1 showed a low tolerance to CEP (11.25–62%) but with a wide range of tolerance to the rest of the PAHs studied: DBT (0–100%), phenanthrene (9–100%), naphthalene (75–100%), and pyrene (50–100%).

The discrimination of the different tolerance groups of fungi according to their tolerance rate to EHCO and PAH compounds was also evaluated (Fig. 28.5). Group No. 4 clustered fungi with the same proportion tolerance for all the hydrocarbons, while Group No. 3 showed a greater tolerance for EHCO, and finally fungal species in Groups No. 1 and 2 had greater tolerance to naphthalene alone. Likewise, this analysis corroborates the fact that DBT and phenanthrene were the most toxic PAHs for the fungi isolated in this study.

Another important result observed at the present work was the difference observed in tolerance to hydrocarbons between species of the same genus, including the difference between strains of the same species (Fig. 28.6). It is known that a functional group is composed of microorganisms that, regardless of their taxonomic classification, present an identical pattern of biochemical responses in the use and transformation of organic substrates.

In the case of the genus Aspergillus, any of its species could tolerate DBT and phenanthrene, and their growth was inhibited to more than 50% rate (Fig. 28.6a). Among Aspergillus species, the most tolerant were *Aspergillus* sp. 4–6, which were isolated from an oil-polluted soil adjacent to an oil pit. As can be appreciated, the species isolated from this site also showed a higher tolerance for DBT, phenanthrene, and naphthalene, in comparison to the species isolated from the natural asphalt Lake of Guanoco.

In the case of Fusarium species, the most tolerant species was *N. solani*, widely reported as a hydrocarbon degrader (León et al. 2007; Naranjo et al. 2007, 2008), and *F. venenatum*, which has not been previously reported as a hydrocarbon degrader (Fig. 28.6b). Interestingly, different strains of *F. venenatum* isolated from natural asphalt Lake of Guanoco showed different degrees of tolerance to EHCO as strain 70 grew at 100% rate while strain 69 only grew at 19% rate, compared to the control medium.

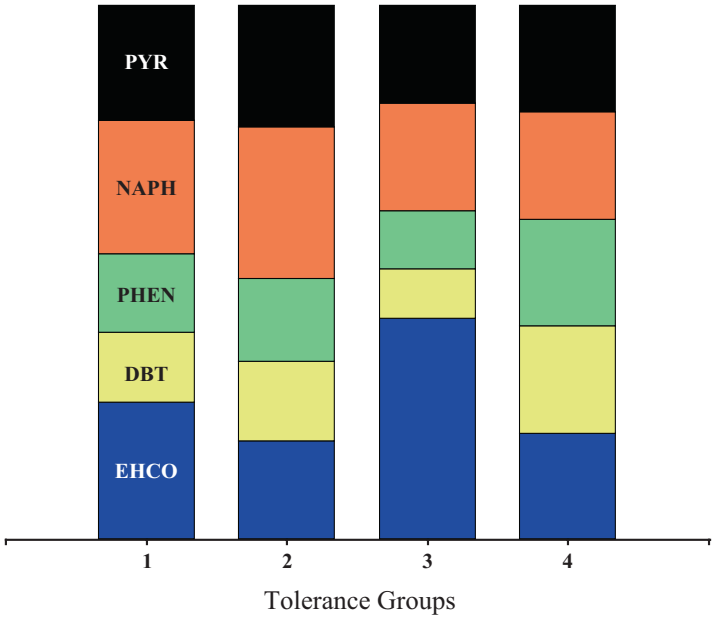

Fig. 28.5 Proportion of tolerance to the different PAHs by fungal group corresponding to the dendrogram. *PYR* Pyrene, *NAPH* Naphthalene, *PHEN* Phenanthrene, *DBT* Dibenzothiophene, *EHCO* Extra-heavy crude oil

In the case of Penicillium species, the most tolerant species were *Penicillium* sp. 37 and *Penicillium javanicum*, both able to grow at 100% rate in all hydrocarbons tested (Fig. 28.6c). However other species of this same genus (such as *P. oxalicum*) were not able to tolerate hydrocarbons with growth inhibitions greater than 50% rate.

The results showed here strongly suggested that the fungal strains belonging to the same species do not necessarily have the same hydrocarbonoclastic abilities and characteristics to tolerate xenobiotic compounds derived from petroleum. Likewise, fungal strains belonging to the same species but isolated from different places do not necessarily have the same characteristic and behavior.

28.4 Relationship Between the LDS and EHCO Bioconversion in Mitosporic Extremophilic Hydrocarbonoclastic Fungi: Inducing a Powerful Exoenzymatic System

The LDS includes a large range of oxidoreductases and hydroxylases, such as laccases (LACs) and high-redox-potential ligninolytic peroxidases like lignin peroxidase (LIPs), manganese peroxidases (MNPs), versatile peroxidases (VEPs), and others. Lignin peroxidases are able to directly oxidize non-phenolic units, while

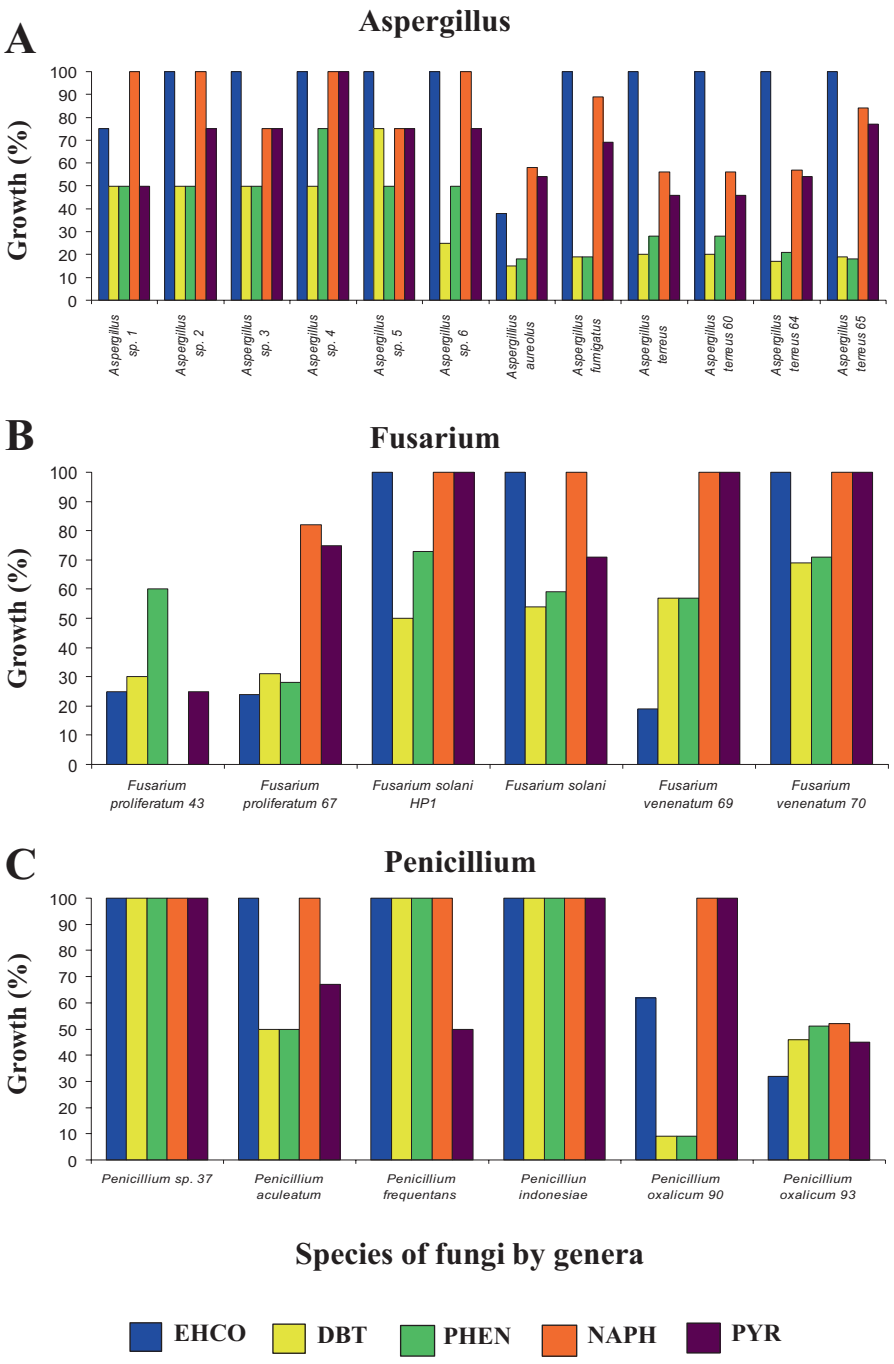

Fig. 28.6 Percentages of growth in the presence of PAHs compared with the control of fungal species of the genera: (**a**) *Aspergillus*, (**b**) *Fusarium*, and (**c**) *Penicillium*. *PYR* Pyrene, *NAPH* Naphthalene, *PHEN* Phenanthrene, *DBT* Dibenzothiophene, *EHCO* Extra-heavy crude oil

MNPs and LACs oxidize preferentially phenolic units, but also act on non-phenolic units when mediators (e.g., 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid), commonly known as ABTS) are present in the reaction mixture, whereas VEPs are able to combine the catalytic properties of LIPs and MNPs (Martínez et al. 1996, 2005; Ruiz-Dueñas et al. 1999; Saparrat et al. 2002; Gianfreda and Rao 2004).

Concurrently, research is focused on the conversion of heavy oils to lighter oils mediated by biocatalyst. A few of the biotechnological strategies to improve the EHCO physical-chemical properties have promoted an increase in their commercial value. Our research team proposed 13 years ago the use of the extracellular oxidative enzymes (EOE) of the LDS present in extremophilic fungi as biocatalysts (Naranjo et al. 2007, 2008; León et al. 2007) based on the following facts: (1) lignin is a complex biopolymer structurally similar to asphaltenes, molecules responsible for the high viscosity of EHCO (Fig. 28.7), and (2) ligninolytic fungi have a unique and powerful LDS that includes a wide range of unspecific oxidoreductases and hydrolases which are involved in the transformation and degradation processes of

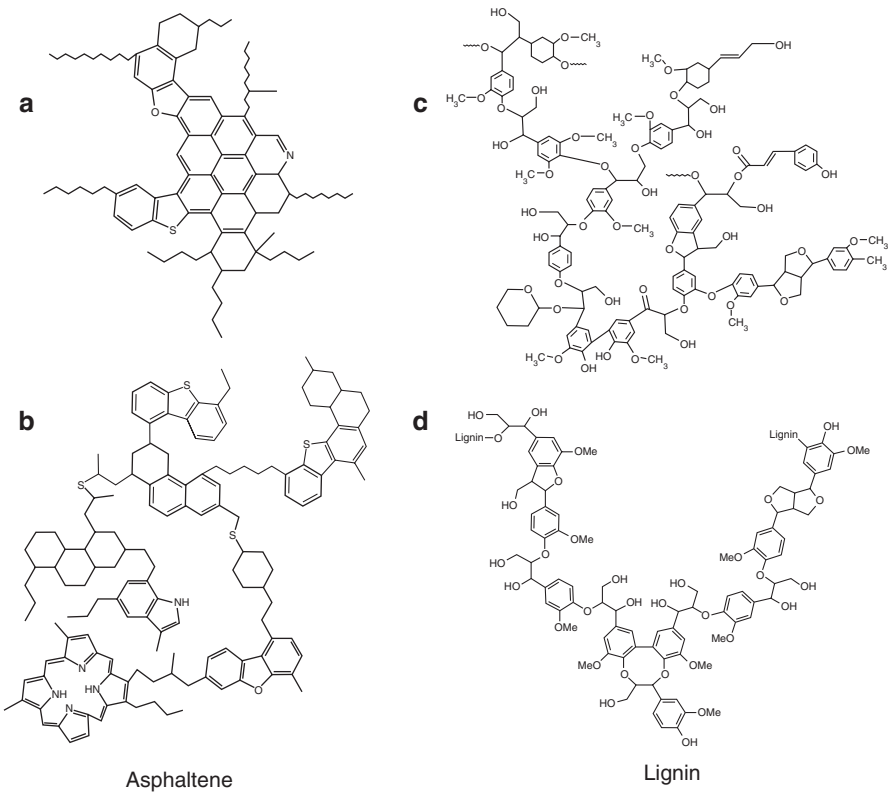

Fig. 28.7 Representative molecular structures of asphaltenes and lignin. (**a**) A single condensed polycyclic aromatic core; (**b**) multiple smaller polycyclic aromatic cores with aliphatic bridges; (**c**, **d**) lignin structures

polymeric substances in partially degraded and oxidized soluble products that can be easily assimilated by microorganisms (Gianfreda and Rao 2004, Naranjo et al. 2007, 2013). Studies dealing with the interactions between extremophilic microorganisms and crude oil have led to the identification of biocatalysts which, through multiple biochemical pathways, carry out the desulfurization, denitrogenation, and demetallation reactions in oils.

The efficiency of the degradation process by biological systems depends on the susceptibility of these compounds to be degraded and converted into less toxic compounds; therefore, supposed susceptibility is directly related to the chemical structure, concentration, and physical properties of the hydrocarbon (Foght 2004, Gianfreda and Rao 2004; Naranjo et al. 2007, 2013). If the hydrocarbons are soluble, they can be assimilated by the microorganisms more easily and, if they are insoluble they must be transformed into soluble compounds so that they can be used later. However, the first step in the transformation of insoluble compounds is usually catalyzed by extracellular oxidative enzymes of microorganisms, which are released by the cells to the surrounding environment (Foght 2004).

The fungal mineralization and transformations of EHCO and/or its asphaltene fraction by fungi have been documented previously; however they are still controversial. The ability of the fungi *Aspergillus flavipes*, *Aspergillus* (=*Emericella*) *nidulans*, *P. javanicum*, and *Parascedosporium putredinis* (=*Graphium*) *putredinis* to degrade resins (15–28%) and asphaltenes (15–40%) was described by Oudot et al. (1993). Chaillan et al. (2004) reported the ability of filamentous fungi *Albonectria rigidiuscula* (formerly *Fusarium decemcellulare*) and *Paecilomyces variotii*, and the yeasts *Candida palmioleophila* and *M. guilliermondii* to degrade a range of 10–15% of resins and asphaltenes. Transformations of petroporphyrins and asphaltenes by chloroperoxidase (CPO) of *Caldariomyces fumago*, a protein with high peroxidase activity and versatility that can halogenate aromatic molecules like polycyclic aromatic hydrocarbons (PAHs), were described by Fedorak et al. (1993).

Later, García-Arellano et al. (2004) showed through Fourier-transform infrared spectroscopy (FT-IR) that a chemically modified cytochrome C catalyzed the oxidation of carbon and sulfur atoms in the rich fraction of petroporphyrins of the asphaltenes, with 74% and 95% Ni and V removal, respectively. The chemical modification of the surface of the protein with polyethylene glycol resulted in the formation of a conjugate polymer-protein soluble in organic solvents, and the methyl esterification of the heme group increasing the hydrophobicity of its active site. In fact, the highest activity was detected in a tertiary mixture of solvents with 5% water. In this case, the enzymatic biotreatment of asphaltenes represents an interesting alternative for the elimination of heavy metals and the reduction of poisoning catalysts after cracking and hydrocracking of crude oils.

Recently, Uribe-Álvarez et al. (2011) described for the first time the ability of *A. fischeri*, isolated from natural asphalt Lake of Guanoco in Venezuela, of growing on asphaltenes as the sole carbon and energy source and to mineralize 13.2% of asphaltenes. Ayala et al. (2012) described the biotransformation of porphyrin-free asphaltene fraction catalyzed by CPO-based biocatalyst to reduce coke formation during thermal decomposition in the oil industry. On the other hand, Hernández-

López et al. (2016) evaluated the capacity of *A. fischeri* to transform high-molecular-weight polycyclic aromatic hydrocarbons (HMW-PAHs) and asphaltenes as the sole carbon source by reverse-phase high-performance liquid chromatography (HPLC), nano-LC mass spectrometry, and IR spectrometry, together with a comparative microarray study and the complete genome of *A. fischeri*. The formation of hydroxy and ketone groups on the PAH molecules and the internalization of aromatic substrates into fungal cells suggested oxidation of these recalcitrant compounds mediated by the cytochrome P450 system.

Finally, Pourfakhraei et al. (2018) described using saturate, asphaltene, resin, and aromatic (SARA) analysis chromatograms that the wood-decaying fungus *Daedaleopsis* sp. can degrade asphaltene and aromatic fraction with a reduction of 88.7% and 38%, respectively, with an increase of 44.8% in the saturate fraction. They also reported that LAC-, LIP-, and MNP-specific activities from LDS were induced in the presence of heavy crude oil (HCO) as the sole carbon source and energy.

In order to confirm the relationship between LDS and bioconversion of EHCO claimed by Naranjo et al. (2013), the study of the enzymatic activities of specific LACs, LIPs, and MNPs induced in minimal medium Czapek supplemented with EHCO as the sole source of carbon and energy was performed. The fungi *Fusarium proliferatum* (BM-02), *Pestalotiopsis palmarum* (BM-04), *Aspergillus terreus* (BM-36), and *Pseudallescheria angusta* (BM-39) were randomly selected from the list of fungal strains isolated from extreme environments studied (Table 28.1). At first, a screening was carried out to confirm their hydrocarbonoclastic capabilities against several PAH compounds (naphthalene, phenanthrene, dibenzothiophene, and pyrene) according to Naranjo et al. (2013). The phenotypic results showed that all fungi were able to grow using EHCO and all PAHs with the exception of *F. proliferatum* (BM-02) and *Ps. angusta* (BM-39) that were unable to grow using phenanthrene (Table 28.2, Fig. 28.8). Regarding the study of the enzymatic activities, the results showed that all fungi induced the enzymatic activities studied in the presence of EHCO compared with the control (Fig. 28.9a, b and c). However, interest-

Table 28.2 Filamentous fungi isolated from extreme environments and their abilities to grow using PAHs or EHCO as the sole source of carbon and energy

Specie	Strain No.	Growth in modified minimal culture medium Czapek compared with the control					
		Naphthalene	Phenanthrene	Pyrene	DBT	EHCO	Sucrose (+)

No growth: −; weak growth: +; moderate growth: ++; good growth: +++

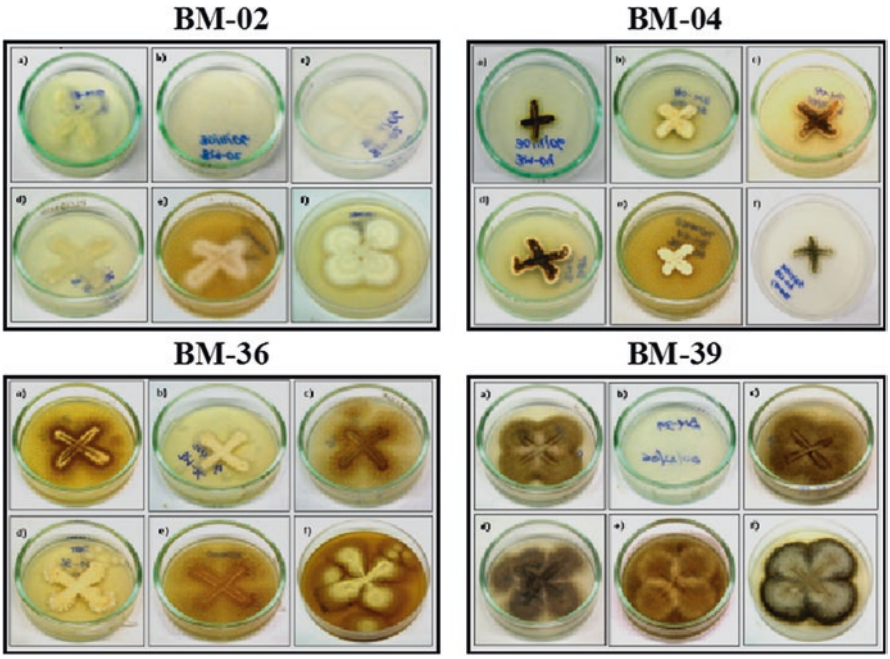

Fig. 28.8 Growth in minimal modified culture medium Czapek supplement with several PAHs as the sole carbon source, such as naphthalene, phenanthrene, pyrene, dibenzothiophene (DBT), and extra-heavy crude oil (EHCO). The fungi *Fusarium proliferatum* (BM-02), *Pestalotiopsis palmarum* (BM-04), *Aspergillus terreus* (BM-36), and *Pseudallescheria angusta* (BM-39) were randomly selected from the list of extremophilic fungi isolated from extreme environments

ingly, the lignin peroxidase was strongly induced with EHCO in the fungi *Pestalotiopsis palmarum* (BM-04), *Aspergillus terreus* (BM-36), and *Pseudallescheria angusta* (BM-39), with the exception of *Fusarium proliferatum* (BM-02), which showed a few inductions in all activities studied (Fig. 28.9c).

28.5 Conclusions and Future Perspectives

It is unquestionable that the modern world was created to the image of petroleum with a concomitant reduction of conventional crude oil reserves and a rising of global demand for fuels and oil derivatives. Consequently, with the increasing of exploitation of unconventional crude reserves, the development and improvement of clean-alternative fuel technologies are required with the mandatory establishment of innovative protocols for unconventional hydrocarbon exploitation. The studying and application of the petroleum biotechnology with promissory microorganisms, specially extremophilic hydrocarbonoclastic fungi and their powerful LDS, in the

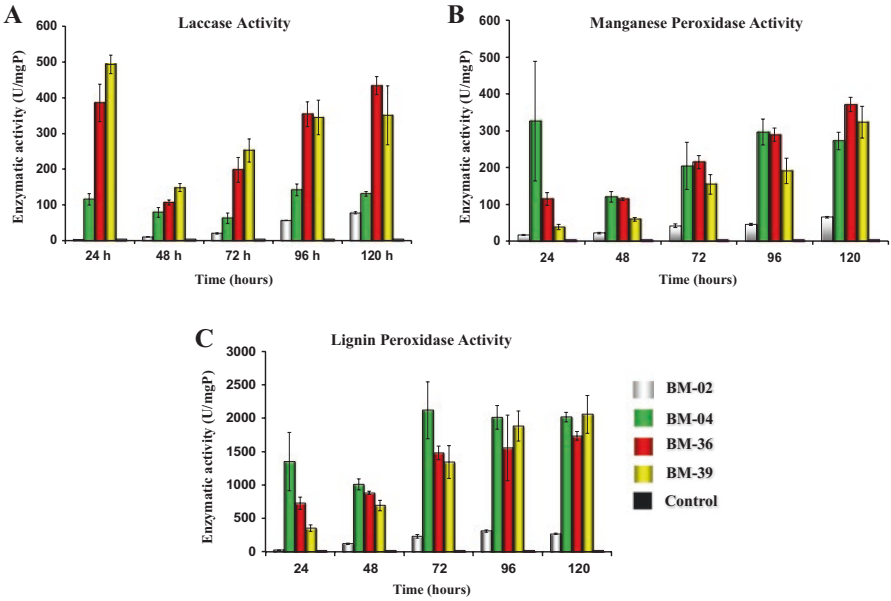

Fig. 28.9 Relationship between the LDS and the bioconversion of EHCO in the fungi *Fusarium proliferatum* (BM-02), *Pestalotiopsis palmarum* (BM-04), *Aspergillus terreus* (BM-36), and *Pseudallescheria angusta* (BM-39)

whole oil industry production chain, is a pathway for improving products and processes, guaranteeing the decreasing of operational costs with increased productivity capabilities with minimum environmental impact. Here, we introduced the term extremophilic hydrocarbonoclastic fungi as a large and heterogeneous group of cultivable fungi which can live optimally under extreme conditions and are characterized by having a high ability to grow using hydrocarbons as the sole carbon source and energy.

Treatment of the unconventional hydrocarbons under extreme conditions plays a vital role to save the ecosystems for anthropogenic intervention which leads to sustainable development. This book chapter shows, through a sequential and comprehensible explanation, a biotechnological strategies to study cultivable fungal biodiversity inhabiting in extreme environments for the isolation of powerful biocatalysts, following a simple and fast screening to determine both their hydrocarbonoclastic potential and tolerance to EHCO and HPAs.

The exploration of cultivable fungal communities from the extreme environments studied allows us to identify phylum Ascomycota as the most isolated fungal group, being Eurotiales the most common order obtained, followed by Hypocreales and Saccharomycetales, and the genera with the most number of species *Aspergillus* (11), *Penicillium* (7), *Fusarium* (6), *Neosartorya* (4), *Trichoderma* (3), *Byssochlamys* (2), and *Candida* (2), respectively.

Only a few strains of the phylum Basidiomycota were isolated, composed mainly by the orders Sporidiobolales followed by the Polyporales, which are constituted by the yeast-like fungi *Rhodotorula* (3) and *Pycnoporus sanguineus* (1), respectively. However, surprisingly the more common species isolated from all of the extreme environments studied was *R. mucilaginosa*.

It is well understood that the study of microorganisms with potential in oil biotechnology requires research of both their hydrocarbonoclastic potential and tolerance abilities to EHCO and HPAs. These abilities have been pointed out here as crucial for the appropriated selection of powerful hydrocarbonoclastic extremophilic fungi as biocatalysts. In our research, the fungal strains with greater hydrocarbonoclastic and tolerance capabilities were isolated from Carabobo-EHCO wells and belonging mainly to unicellular fungi, such as *C. tropicalis*, *C. viswanathii*, *Ci. saturnus*, and *R. mucilaginosa*. These yeast-like fungi are the most tolerant species to EHCO and PAHs.

Another important result observed during our investigations was the difference obtained in tolerance to hydrocarbons between species of the same genus, including the difference between strains of the same species, such as *Aspergillus*, *Fusarium*, and *Penicillium*. Likewise, fungal strains belonging to the same species but isolated from different extreme environments do not necessarily have the same hydrocarbonoclastic characteristic and behavior.

On the other hand, the relationship between the powerful LDS and EHCO bioconversion in extremophilic hydrocarbonoclastic fungi was confirmed, where a strong induction of the lignin peroxidase activity and a low induction of the laccase activity were obtained repetitively, in all the fungal strains studied.

Further research is required to develop new visions and perspectives, novel clean technologies, confident alternatives, and strategies to ensure an economically profitable development with social justice, and ecological sustainability, safeguarding the future and quality of life for the next generations. The perspective of this chapter is the potential application of the promissory extremophilic hydrocarbonoclastic fungi to be used as biocatalysts for mycoremediation or EHCO bioupgrading process under stressed conditions to increase the revenues for the industry dedicated to the exploitation of unconventional crudes.

Chapter 29
Thermophilic Fungi in Composts: Their Role in Composting and Industrial Processes

Sonia M. Tiquia-Arashiro

29.1 Introduction

Composting is a natural biological process, carried out under controlled aerobic conditions (requires oxygen) (Tiquia and Tam 1998a, 2002; Tiquia et al. 2000; Zhang et al. 2016; Wei et al. 2018). In this process, the organic matter is transformed into a more stable organic matter, with a final product sufficiently stable for storage and use in agriculture as fertilizer, in gardening, or in landscaping (Richard and Tiquia 1999; Tiquia et al. 2002a; Krause et al. 2003; Pampuro et al. 2017). A typical aerobic composting is a self-heating process in which microbial metabolism drives the temperature above 50 °C, followed by sustained high temperatures between 60 and 80 °C, and then followed by gradual cooling of the compost pile (Tiquia et al. 1996, 1997a; Tiquia 2005a, b; Kumar 2011). The high temperature (50–80 °C) oxidizes phytotoxins and destroys animal and plant pathogens (Senesi 1989; Tam and Tiquia 1994; Tiquia 2000, 2010a; Tiquia and Tam 1998b; Tiquia et al. 1998a). The composting process represented a combined activity of a wide succession of environments, as one enzyme/microbial group overlapped the other and each emerged gradually due to the continual change in temperature and progressive breakdown of complex compounds to simpler ones (Tiquia et al. 1997b, 2001; Tiquia 2002a; Yu et al. 2018). Composting has been suggested as a potential strategy to eliminate antibiotic residues (Gou et al. 2018; Liu et al. 2018a).

Microbes play a key role as degraders during the composting process; the mesophilic microorganisms constitute the pioneer microflora, while thermophilic microorganisms are the dominant microflora that contribute significantly to the quality of compost (Tiquia et al. 1998c; Tiquia 2003, 2005b; Liu et al. 2018b). These mesophilic and thermophilic microbial consortia have distinct physiological requirements

and tolerances, consistent with the continuously changing environment throughout composting (Tiquia et al. 2002b; Tiquia 2005a; Federici et al. 2011; Jurado et al. 2014; Waqas et al. 2018). Bacteria including those that belong to the groups *Proteobacteria*, *Firmicutes*, *Bacteroidetes*, and *Actinobacteria* are by far the most important decomposers during the most active stages of composting (Partanen et al. 2010; Neher et al. 2013; Zhang et al. 2016), partly because of their availability to grow rapidly on soluble proteins, and other readily available substrates, and partly because they are the most tolerant of high temperatures (Kuok et al. 2012). Most fungi are eliminated above 50 °C; only a few have been recovered that can grow at all up to 62 °C (Tiquia 2005a; Langarica-Fuentes et al. 2014), which suggests that their degradative activities during the thermophilic stages of composting are minor compared to those of bacteria (Martins et al. 2013; Langarica-Fuentes et al. 2014). As peak heats are attained in composts, fungi tend to disappear from the central zone of the compost. In grass and straw composts where a peak heat of 70 °C was recorded, the thermophilic fungi disappear from the compost core for a period of 3 days (Chang and Hudson 1967). As compost temperatures fall below 60 °C, thermophilic fungi reappear in the middle of the compost (Chang and Hudson 1967). While current understanding tells us that bacteria are the dominant degraders in thermophilic composting processes, there is much to be said about the minority of thermophilic fungi during the composting process.

Composting is a promising source of new organisms and thermostable enzymes (Dougherty et al. 2012; D'Haeseleer et al. 2013; Nguyen et al. 2013; Tiquia-Arashiro 2014; Habbeche et al. 2014; Pomaranski and Tiquia-Arashiro 2016) that may be helpful in environmental management and industrial processes (Tiquia and Mormile 2010; Tiquia-Arashiro and Mormile 2013; Salar 2018). Fungi are known to have an important role in the composting process as degraders of recalcitrant materials such as cellulose and lignin and thermophilic fungi have been suggested as the main contributors to lignocellulose degradation. Despite the relevance of fungi in composting, especially the thermophilic fraction, most of the research on the diversity, composition, and succession of these microorganisms had been conducted several decades ago using classical culture-based methods (Chang and Hudson 1967; Kane and Mullins 1973; Klamer and Sochting 1998).

This chapter covers the diversity of thermophilic fungi during composting, their role, and potential applications in biotechnology. Readers may find that the available information on several aspects of compost ecosystem is scanty which is due to horizontal advancements in some areas and because compost represents a complex ecological system from the viewpoint of microbial distribution and activity.

29.2 Fungal Communities in Composts

Culture-independent methods, including denaturing gradient gel electrophoresis (DGGE) of PCR-amplified DNA fragments, terminal restriction fragment length polymorphism analysis (T-RFLP), clone library analysis, and more recently

high-throughput sequencing, have been used extensively to investigate microbial successions in composts (Ishii and Takii 2003; Tiquia 2005a, 2010b; Tiquia and Michel Jr. 2002; Tiquia et al. 2005; Szekely et al. 2009; De Gannes et al. 2013). However, few investigations have focused on fungal populations of large-scale composting processes using molecular techniques. Bonito et al. (2010) used DGGE to study windrow-type systems; Hultman et al. (2009) and Hansgate et al. (2005) utilized a clone library approach to study fungi in a rotating drum system and a reactor-type system, respectively; and Langarica-Fuentes et al. (2014) took advantage of high-throughput sequencing to monitor fungal succession in an in-vessel composting system. Gu et al. (2017) used the Dirichlet multinomial mixtures mode to analyze Illumina sequencing data to reveal both temporal and spatial variations of the fungi community present in the aerobic composting.

Bonito et al. (2010) identified fungi microflora associated with composting organic municipal wastes to gain a better understanding of the diversity of fungi at different stages of composting. A disproportionate number of yeast sequences have been detected from day-0 clone libraries, including the human pathogens *Candida tropicalis* and *Candida krusei* (*Saccharomycetales*). *Basidiomycetes* account for over half of the clones from the day-210 compost sample while *Cercophora* and *Neurospora* species account for most of the fungal clones from day-410 sample. Surprisingly, no *Zygomycetes* or *Aspergillus* species were detected.

Hansgate et al. (2005) employed F-ARISA (fungal-automated rRNA intergenic spacer analysis) and 18S rRNA gene cloning and sequencing to examine changes in fungal community structure during composting. Sequencing of the 18S rRNA portion of cloned F-ARISA products revealed the presence of four distinct fungal genera including *Backusella* sp., *Mucoraceae*, *Geotrichum* sp., and the yeast *Pichia* sp. Clone libraries constructed using fungus-specific 18S rRNA primers contained sequences similar to several other fungal genera including *Penicillium* sp., *Aspergillus* sp., *Hamigera* sp., *Neurospora* sp., and the yeast *Candida* sp.

Langarica-Fuentes et al. (2014) characterized the fungal community composition at different stages of in-vessel composting process. A complex succession of fungi is revealed, with 251 fungal OTUs identified throughout the monitoring period. The *Ascomycota* are the dominant phylum (82.5% of all sequences recovered), followed by the *Basidiomycota* (10.4%) and the subphylum *Mucoromycotina* (4.9%). In the early stages of the composting process, yeast species from the order *Saccharomycetales* are abundant, while in later stages and in the high-temperature regions of the pile, fungi from the orders *Eurotiales*, *Sordariales*, *Mucorales*, *Agaricales*, and *Microascales* are the most prominent. This study presents an in-depth view on the succession of fungi during the composting of municipal solid waste and provides a guide to those species that drive an in-vessel composting process towards a satisfactory product. Similar communities are likely to be observed in other composting plants where municipal solid waste is processed; however, differences in the process nature, length of composting, and conditions achieved (temperature, pH, water content, etc.) are likely to determine the exact succession and communities present.

Gu et al. (2017) characterized fungal diversity in the aerobic composting with Illumina sequencing. A total of 670 operational taxonomic units (OTUs) were detected, and the dominant phylum was *Ascomycota*. There were four types of samples of fungi communities during the composting process. Samples from the early composting stage (type I) were dominated by *Saccharomycetales* sp. Fungi in the medium composting stage (types II and III) were dominated by *Sordariales* spp. and *Acremonium alcalophilum*, *Saccharomycetales* sp., and *Scedosporium minutisporum*. Samples from the late composting stage (IV) were dominated by *Scedosporium minutisporum*. The results of their study indicate that time and depth influence fungal distribution and variation in the waste during static aerobic composting.

29.3 Thermophilic Fungi in Composts

Cooney and Emerson (1964) define thermophilic fungi as fungi with a maximum growth temperature of 50 °C or higher and a minimum growth temperature of 20 °C or higher. Thermotolerant species have a maximum growth temperature of about 50 °C and a minimum well below 20 °C (Cooney and Emerson 1964; Awasthi et al. 2014). Crisan (1973), however, defines thermophilic fungi as fungi with a temperature optimum of 40 °C or higher. Most thermophiles are isolated from composts (Tansey and Brock 1978; Awasthi et al. 2014; López-González et al. 2015; Sebők et al. 2016; Ahirwar et al. 2017; Wang et al. 2018); their prevalence in composts can be explained by the high temperatures, humidity, and aerobic conditions within the composts. Moreover, the supply of carbohydrates and nitrogen in composts favors the development of thermophilic microflora (Cooney and Emerson 1964). During the composting process, various organic materials are converted into simpler units of organic carbon and nitrogen (Tiquia 2002a, b, 2003; Tam and Tiquia 1999; Tiquia and Tam 2000; Tiquia et al. 1998b, 2002c). The overall efficiency of organic material degradation depends on the microbes and their activities (Tiquia et al. 2002b, c). Thermophilic fungi promote the degradation of organic materials by secreting various types of cellulolytic and xylanolytic enzymes. These fungi might have enzymes that maintain their activities at high temperatures. *Aspergillus*, *Chaetomium*, *Humicola*, *Mucor*, *Penicillium*, and *Thermomyces* spp. are the dominant fungi of compost ecosystems. Species of *Aspergillus* and *Mucor* are predominant in composting of biowaste (Ryckeboer et al. 2003). *Aspergillus fumigatus* and *Humicola grisea* var. *thermoidea* have been reported to be the dominant members of the spent mushroom compost. Other fungi reported from spent mushroom compost are *Aspergillus flavus*, *Aspergillus nidulans*, *Aspergillus terreus*, *Aspergillus versicolor*, *Chrysosporium luteum*, *Malbranchea cinnamomea* NFCCI 3724, *Melanocarpus albomyces*, *Mucor* spp., *Myceliophthora thermophila, Nigrospora* spp., *Oidiodendron* spp., *Paecilomyces* spp., *Penicillium chrysogenum*, *Penicillium expansum*, *Trichoderma viride*, and *Trichuris* spp. (Kleyn and Wetzler 1981; Ahirwar et al. 2017; Kertesz and Thai 2018).

Several known thermophilic fungi have been found in mushroom composting. Mushroom composting represents an interesting example of thermogenic solid-state fermentation process that results from succession of microbial communities. The composting process consists of two phases. Phase I is an outdoor fermentation process during which the raw materials are mixed, wetted, and stacked with considerable dry mass losses. Phase II is an indoor process of pasteurization to produce a selective and pathogen-free substrate (Noble and Gaze 1994). During phase I, fungal and bacterial activities produce large quantities of heat. Temperature ranges between ambient and 80 °C in distinct zones within the cross sections of the compost stack and ammonia disappear most rapidly in the range of 40–45 °C. Mushroom compost is an interesting example of a complete spectrum of microbial diversity. It is a rich reservoir of microbial types, comprising of mesophilic and thermophilic bacteria, fungi, and actinomycetes. In phase I, the pioneer thermophilic mycoflora of mushroom compost comprises fast-growing and rapidly sporulating fungi such as *Aspergillus fumigatus* and *Rhizomucor* spp. with a pH optimum below 7.0 and temperature optima of about 40 °C. When self-heating and ammonification start and pH reaches 9.0, the pioneer flora disappears and paves way for *Talaromyces thermophilus* and *Thermomyces lanuginosus*; during massive heat production these fungi possess moderate growth rate, as they exhibit high thermal death point and pH tolerance, but do not degrade cellulose. At the end of the composting process, about 50–70% of the compost biomass is constituted by thermophilic fungi (Sparling et al. 1982; Weigant 1991). While most of the species are eliminated, *Sporotrichum thermophilum* appears as near-exclusive species after phase II composting and constitutes a climax species in the mushroom compost along with thermophilic actinomycetes (Straatsma et al. 1994). The number of CFU of *S. thermophilum* in fresh matter of phase II is about 10^6 g^{-1} compost (Bilai 1984); however, actinomycetes and bacteria appear to play a decisive role in successful colonization by this thermophile. In the beginning of phase II of mushroom composting, thermophilic fungi and actinomycetes extensively colonize the plant matter until temperature reaches 60 °C, as an outcome of slow peak heating for about 2 days (Straatsma et al. 1994). The high temperature of the first indoor period of phase II kills most of the pathogenic and nonpathogenic microorganisms, except the spores of actinomycetes and thermophilic fungi such as *Scytalidium thermophilum* (Straatsma et al. 1991). Klamer et al. (1998) reported *A. fumigatus* and *Rhizomucor pusillus* as predominant species before peak heating and *P. variotii*, *S. thermophilum*, and *T. lanuginosus* as dominant forms after peak heating. Tewari (2000) reported the presence of *H. lanuginosa* and *S. thermophilum* during peak-heat stage of phase II composting. *S. thermophilum* is a natural inhabitant of compost ingredients, including drainage from compost, and has been documented to be present throughout composting. Dominance of *S. thermophilum* has been reported by several workers (Straatsma et al. 1991; Vijay 1996; Klamer et al. 1998; Rajni 1999), while *H. grisea* var. *thermoidea* and *H. insolens* have been described by others (Fergus 1964). They are inherently close partners in the degradation processes in compost and provide selectivity to compost (Straatsma et al. 1989; Opden Camp et al. 1990). Rajni (1999) and Rawat (2004)

observed nearly similar microbial distribution patterns in compost as reported by Straatsma et al. (1991), with predominance of *S. thermophilum* (Kertesz and Thai 2018). In mushroom compost, thermophilic fungi are responsible for the degradation of lignocellulose, which is a prerequisite for the growth of the edible fungus (Sharma 1989; Kertesz and Thai 2018). Thermophilic fungi grow extensively during the last phase of composting in mushroom compost from the spores that survive the pasteurization temperature (Straatsma et al. 1989). Thus, they contribute significantly towards the quality of compost.

29.3.1 Thermophilic Fungi in Straw Compost

Thermophilic fungi of wheat straw compost were studied in detail by Chang and Hudson (1967). Initial high population of mesophilic fungi results in peak heating in the central region of the pile wherein temperature rises rapidly and reaches a plateau around 50 °C. Thermophilic fungi rapidly develop replacing the mesophilic population and persist until the compost cools down. In wheat and broad bean straw composts, thermophilic fungi are not present at peak high temperature. However, when the composts cool down to 51.5 °C, *Penicillium dupontii*, *Myriococcum albomyces*, *Thermomyces lanugionsus*, and *Sporotrichum thermophile* are found in abundance (Moubasher et al. 1982; Zhang et al. 2015). Several critical factors reported to influence the colonization by thermophilic fungi include (1) existence of suitably high temperature to promote germination and growth arid multiplication of propagules; (2) ability of thermophilic fungi to break down complex carbon substances; and (3) absence of repressive activity among the compost-inhabiting organisms. In a complex of microbial interactions such as above, succession of individual species is governed by their traditional requirements and availability of suitable temperature and pH conditions. For example, due to simple nutritional requirements thermophilic mucoraceous members appear early in the composting process. *Humicola lanuginosa* develops early but exists throughout the composting process as it lives as a commensal with other thermophilic organisms (Hedger and Hudson 1974; Salar 2018). Besides, this organism can tolerate a wide range of temperatures on either side of optima and elaborates a variety of hydrolytic enzymes that help in continuous presence.

29.3.2 Thermophilic Fungi in Municipal Waste Composts

Municipal wastes generally contain, among other things, substrates rich in lignohemicellulose. Thermophilic fungi play a significant role in the conversion of these materials. Some species are unique in their ability to degrade plastic substances and hence special interest has been envisioned in their study from municipal waste compost. Thermophilic fungi isolated from municipal waste composts include

Thermomucor (Subrahmanyam et al. 1977; Singh et al. 2016), *Thermoascus aurantiacus* (Cooney and Emerson 1964; Sebők et al. 2016), and *Myceliophthora thermophila* (Sen et al. 1980; Sebők et al. 2016).

29.3.3 Thermophilic Fungi in Paddy Straw Composts

Paddy straw is an excellent substrate for the colonization of thermophilic fungi. In an extensive controlled study of this substrate, Satyanarayana and Johri (1984) observed that colonizing ability of thermophilic fungi on paddy straw was directly proportional to the inoculum concentration. For example, colonization by *Humicola lanuginosa*, *Sporotrichum thermophile*, and *Torula thermophila* (*Scytalidium thermophilum*) increased with higher inoculum concentration. *Aspergillus fumigatus* showed a strong competitive ability both in pure and mixed cultures. Decomposing ability of these organisms varied with C:N ratio and the length of paddy straw pieces. During peak heating period, only a few thermophilic fungal propagules were present but these exhibited high rate of respiration as suggested by the evolution of carbon dioxide.

29.4 Industrial Applications

The biotechnological applications of thermophilic fungi are numerous. Pure culture studies of thermophilic fungi have provided clear evidence that they possess a variety of extracellular enzymes capable of hydrolyzing polymers such as starch, protein, pectin, hemicellulose, cellulose, and lignin. They have also been reported to produce, among others, many antibacterial and antifungal substances, extracellular phenolic compounds, and organic acids. Some thermophilic fungi have already been used in industries involving food processing, bioconversion of organic materials, biodegradation of plastics, biosorption of metals/radionuclides, cancer treatment, and synthesis of nanoparticles (Bengtsson et al. 1995; Zafar et al. 2013; Aydi Ben Abdallah et al. 2015; Tiquia-Arashiro and Rodrigues 2016a; Salar 2018).

29.4.1 Production of Thermostable Enzymes

Thermostable enzymes have become the focus of biotechnological interest because they are more tolerant to the conditions in industrial processes and storage. The production of thermostable enzymes has grown through advances in isolating many thermophilic microorganisms. The advantage of the use of thermostable enzymes is the possibility of conducting biotechnological processes at elevated temperatures and thus reducing the risk of contamination by mesophilic microorganisms,

decreasing the viscosity of the reaction medium, increasing the bioavailability and solubility of organic compounds, and increasing the diffusion coefficient of substrates and products resulting in higher reaction rates (Kumar and Nussinov 2001).

Cellulose is one of the main components of plant cell wall material and is the most abundant and renewable nonfossil carbon source on earth. Degradation of cellulose to its constituent monosaccharides has attracted considerable attention to produce food and biofuels. Cellulose can be hydrolyzed to glucose and other soluble sugars by using cellulase enzymes of bacteria and fungi (Plecha et al. 2013). Thermophilic cellulases are key enzymes for efficient biomass degradation. Their importance stems from the fact that cellulose swells at higher temperatures, thereby becoming easier to break down. In industrial processes, cellulolytic enzymes have been employed in the extraction of pigments and flavor compounds in fruit juice and wine production; as additive of detergents for washing jeans; in the pretreatment of biomass to improve the nutritional quality of forage for animal feed; in the textile industry in the polishing process of cotton fibers; and for saccharification of lignocellulosic residues to obtain reducing sugar (Ando et al. 2002; Baffi et al. 2013). The interest in the use of cellulases to produce fermentable sugars from cellulosic wastes at present is focusing on biofuel production such as biogas, bioethanol, biodiesel, and fuel cells. The use of whole biomass to obtain alcohol-based fuels requires an efficient conversion of lignocellulosic material into fermentable pentose and hexose sugars. Thermal stability of several commercial cellulase preparations is an important parameter for the success of the process. Thus, the industries have been developing cellulases with higher thermal stability and especially stable at industrially relevant conditions. Many thermophilic fungi from composts (*Myriococcum thermophilum*, *Sporotrichum thermophile*, *Thermoascus aurantiacus*, and *Thermomyces lanuginosus*) have been isolated in recent years and the cellulases produced by these eukaryotic microorganisms have been purified and characterized at both structural and functional level (Lee et al. 2014; de Cassia Pereira et al. 2015; Mehta et al. 2016; Jain et al. 2017).

Several studies have reported the production of thermostable xylanase from thermophilic and hyperthermophilic organisms, prokaryotes, and eukaryotes. Among thermophilic compost fungi, *Mycothermus thermophilus* (Lee et al. 2014; Ma et al. 2017), *Talaromyces thermophilus* (Maalej et al. 2009), *Thermomyces lanuginosus* (Jiang et al. 2005; Lee at al. 2014), *Thermoascus aurantiacus* (Lee at al. 2014), and *Rhizomucor miehei* (Zhou et al. 2014) produce thermostable xylanases with action from 50 °C up to 80 °C. A large variety of xylanases produced by these thermophilic fungi have become a major group of industrial enzymes that are capable of degrading xylan to renewable fuels and chemicals, in addition to their use in food, paper, and pulp industries.

Pectinases are a group of enzymes that catalyze the degradation of pectic substances by depolymerization reaction and by de-esterification reactions. One of the most common applications of pectinases is in fruit processing for various purposes like musts, juices, pastes, and purées. These extraction processes are carried out at temperatures greater than 65 °C and subsequently cooled to 50 °C (Lea 1995); thus, the use of thermostable pectinases avoids the cooling step and so it could reduce the time and cost of processes (Zhang et al. 2011). Thermostable pectinases are also

very useful in the degradation of pectin waste from processing plant material industry, reducing BOD and COD (Kapoor et al. 2000). Pectinase from *Penicillium echinulatum* is associated with a cellulolytic enzyme complex and has improved sugarcane bagasse saccharification, suggesting a new application for these enzymes (Delabona et al. 2013). Several pectinolytic thermophilic fungi have been isolated so far including those belonging to the genera *Thermomyces*, *Aspergillus*, *Monascus*, *Chaetomium*, *Neosartoria*, *Scopulariopsis*, and *Thermomucor* (Martin et al. 2010). The thermophilic *Thermoascus aurantiacus* produces considerable amounts of pectinase in media based on citrus peel (Martins et al. 2002), which showed optimal activity at 70 °C and stability at 60 °C for 2 h.

In nature, lignocellulose accounts for the major part of biomass and, consequently, its degradation is essential for the operation of the global carbon cycle (Sánchez 2009). Lignocellulose, such as wood, is mainly composed of a mixture of cellulose (ca. 40%), hemicellulose (ca. 20 ± 30%), and lignin (ca. 20 ± 30%) (Bajpai 2016). Lignin is an integral cell wall constituent, which provides plant strength and resistance to microbial degradation (Ochoa-Villarreal et al. 2012). The ligninolytic capacity of most thermophilic fungi is largely known. However most of them are known to be able to degrade wood or other lignocelluloses, celluloses, or hemicelluloses (Sharma 1989; Kuhad et al. 1997; Dashtban et al. 2009). The thermophilic fungus *Thermoascus aurantiacus* has a high ligninolytic capacity (McClendon et al. 2012), and it has been isolated from composts.

29.4.2 Plastic Biodegradation

Polyurethanes (PUs) are synthetic plastics with a wide range of applications in the medical, automotive, construction, furnishing, and industrial sectors (Krasowska et al. 2012). They are known to be vulnerable to microbial attack as they contain ester linkages within the backbone of the polymer that are naturally vulnerable to esterases (Zafar et al. 2013). In contrast, polyether PUs, which contain ether linkages within the polymer backbone, are reported to be far more recalcitrant (Darby and Kaplan 1968). It has been reported that a number of fungal isolates are able to degrade impranil (liquid dispersion of PU) including thermotolerant and thermophilic fungi (Zafar et al. 2013), and a number of fungal species that are capable of degrading PU have been isolated and identified (Darby and Kaplan 1968; Pathirana and Seal 1984; Cosgrove et al. 2007; Mathur and Prasad 2012). Zafar et al. (2013) demonstrated that polyester PU is susceptible to fungal biodegradation in compost under both thermophilic (thermophilic stage) and mesophilic (maturation phase) conditions and that positive selection for rare taxa from the existing compost community on the PU surface occurs. The most dominant fungi identified from the surfaces of PU coupons by pyrosequencing was *Fusarium solani* at 25 °C (mesophilic phase), while at both 45 °C and 50 °C (thermophilic phase) *Candida ethanolica* was the dominant species. The diversity in the fungal community recovered from polyester PU coupons buried at the surface of compost pile was dependent on the incubation temperature (Zafar et al. 2014). At 37 °C, *Acremonium flavum* and

Candida rugosa are consistent mesophilic species with dominant *Arthrographis kalrae* on day 28. At 45 °C on day 2, the biomass obtained from the surface of buried polyester PU coupons are dominated by *Aspergillus* spp. and on day 28 a mixed community of *Lichtheimia* sp. and *Aspergillus fumigatus* with occasional isolates of *Malbranchea cinnamomea* and *Emericella nidulans* are found. *A. fumigatus* and *E. nidulans* have previously been isolated as potential polyester PU degraders (Barratt et al. 2003). *M. cinnamomea* and *A. fumigatus* have also been recovered in the compost at 50 °C. The major population at 50 and 55 °C is *Thermomyces lanuginosus*, a PU degrader (Zafar et al. 2014).

29.4.3 Remediation of Metals and Radionuclides

The use of biological materials for metal removal and recovery technologies has gained important credibility during the past decade, because of the good performance and low cost of this complexing material (Wu et al. 2005; Cho et al. 2012; Lakherwal 2014; Bowman et al. 2018). The natural affinity of biological compounds for metallic elements could contribute to economically purifying heavily metal-loaded wastewater. Among the various resources in biological wastes, dead biomass of microorganisms (bacteria, yeasts, fungi, algae) exhibits particularly interesting metal-binding capacities (Cho et al. 2010). For instance, *Rhizopus arrhizus*, a Mucorale filamentous fungus, can accumulate lead or uranium, up to I (1% and 16% of its own dry mass, respectively) (Tobin et al. 1984). These properties are attributed to the high content of complexing functional groups in their cellular wall (e.g., amino, amide, hydroxyl, carboxyl, sulfhydryl, phosphate radicals) (Tiquia-Arashiro 2018). Residual biomass, produced by the thermophilic fungus, *Talaromyces emersonii* CBS 814.70, following growth on glucose-containing media, was examined for its ability to take up uranium from aqueous solution (Bengtsson et al. 1995). It was found that the biomass had a relatively high observed biosorption capacity for the uranium (280 mg/g dry weight biomass). The calculated maximum biosorption capacity obtained by fitting the data to a Langmuir model was calculated to be 323 mg uranium/g dry weight biomass. Some of the critical biosorption parameters have already been identified, and pH was shown to influence to a large extent the formation of metal-biosorbent complexes. pH variation can modify the speciation and the availability of the metallic elements in solution and also the chemical state of the chemical functional groups responsible for metal binding in the biomass.

29.4.4 Cancer Treatment

Aspergillus terreus, a thermophilic fungus abundant in composts (Aydi Ben Abdallah et al. 2015), produces asperjinone, a nor-neolignan, and terrein, a suppressor of ABCG2-expressing breast cancer cells, which can restore drug sensitivity and

could be the key to improve breast cancer therapeutics. Terrein displayed strong cytotoxicity against breast cancer MCF-7 cells. Treatment with terrein significantly suppressed the growth of ABCG2-expressing breast cancer cells. This suppressive effect was achieved by inducing apoptosis via activating the caspase-7 pathway and inhibiting the Akt signaling pathway, which led to a decrease in ABCG2-expressing cells and a reduction in the side-population phenotype (Liao et al. 2012).

29.4.5 Nanoparticle Synthesis

Some microorganisms have developed the ability to resort to specific defense mechanisms to quell stresses like toxicity of heavy metal ions or metals (Tiquia-Arashiro 2018; Bowman et al. 2018; Tiquia-Arashiro and Rodrigues 2016a). The microorganisms can survive and grow even at high metal ion concentrations and are capable of binding large quantities of metallic cations (Tiquia-Arashiro and Rodrigues 2016a, b). The remarkable ability of these group of microbes to reduce heavy metal ions makes them one of the best candidates for nanoparticle synthesis (Tiquia-Arashiro and Rodrigues 2016b, c, d, e, f). Syed et al. (2013) elucidated the biosynthesis of silver nanoparticles (AgNPs) by the thermophilic fungus *Humicola* sp., a dominant fungus in compost ecosystems. The fungus when reacted with Ag^+ ions reduces the precursor solution and leads to the formation of extracellular nanoparticles. The uniqueness of this study is that the investigators achieved superior control over the size of these nanoparticles, focusing upon them to be in the size range of 5–25 nm, so that these AgNPs when employed in biomedical applications will not block the glomerulus of the kidneys and will easily pass through urine within a short period of time. The AgNPs synthesized are nontoxic to cancer and normal cells up to concentrations of 50 μg/mL and thus will find various applications in drug and targeted drug delivery systems (Syed et al. 2013).

Gadolinium oxide nanoparticles are very important as nuclear, electronic, laser, optical, catalyst, and phosphor materials (Tiquia-Arashiro and Rodrigues 2016a, b). Many organic compounds use Gd_2O_3 for their dimerization (Gündüz and Uslu 1996). It is also used in imaging plate neutron detectors, as neutron reactors (Gündüz and Uslu 1996), and as an additive in ZnO_2 to enhance its toughness. Gd_2O_3 has several potential applications in biomedicine, too. For example, it is used in magnetic resonance imaging, since it exhibits superparamagnetism and involves T1 relaxation, and can be useful as a multimodal contrast agent for in vivo imaging (Bridot et al. 2007). It can also be easily doped with other lanthanides and exploited as a fluorescent tag, thus replacing other fluorescent organic mrolecules. Khan et al. (2014) showed that the thermophilic fungus *Humicola* sp. can be used for the synthesis of Gd_2O_3 nanoparticles at 50 °C. $AsGdCl_3$ is dissolved in water along with fungal biomass, and $GdCl_3$ ionizes to Gd^{3+} and $3Cl^-$. The Gd^{3+} ions are then attracted towards anionic proteins, which are secreted by *Humicola* sp. in solution. Reductase enzymes present in the anionic protein fraction act on Gd^{3+} and convert it to Gd^{2+}. Oxidase enzymes, which are also secreted by the fungus in the solution mixture, act

on these Gd^{2+} ions resulting in the formation of Gd_2O_3 nanoparticles. The $GdCl_3$ NPs are irregular in shape, presenting an overall quasi-spherical morphology. Particle size distribution analysis of Gd_2O_3 nanoparticles confirmed that the nanoparticles are in the range of 3–8 nm with an average size of 6 nm. Since Gd_2O_3 nanoparticles have proved their value in site-specific drug delivery systems for cancer therapy, Khan et al. (2014) extended the work of biosynthesis of Gd_2O_3 nanoparticles to bioconjugation with taxol. Bioconjugation of taxol with gold and iron oxide nanoparticles has also been reported (Gibson et al. 2007; Hwu et al. 2009). Taxol is one of the most important anticancer drugs used for breast, ovarian, and lung cancers. The potent anticancer effect of taxol is mainly attributed to its mechanism of action. It stabilizes microtubules by preventing their depolymerization Khan et al. (2014). However, taxol is a hydrophobic drug and less specific to certain tumors due to its low solubility in water. To counter these problems, we carried out the bioconjugation of chemically modified taxol with biocompatible Gd_2O_3 nanoparticles, which may result in an enhancement of the hydrophilicity of taxol and may render it more potent in killing tumor/cancer cells (Khan et al. (2014).

29.5 Conclusions

Thermophilic fungi occur widely in composts, manures, and decomposing plant materials. They play an important role in the decomposition of organic matter due to their avidity for degrading various components of organic matter such as starch, pectin, hemicellulose, cellulose, and, to a lesser extent, lignin. While thermophilic fungi have long been known to be involved in composting and humification, the mechanisms involved in the accelerated decomposition of biomass are not well understood. This literature survey shows that although several thermophilic fungi have been isolated and identified, little knowledge about the physiology of this group is available. The role of thermophilic fungi in decomposition during composting suggests that thermophilic fungi may be good sources of thermostability of enzymes that can be applied in many industrial processes.
