(Received 6 June 1979; accepted in revised form 9 January 1980)

**Abstract**—The heat capacities of synthetic pyrope (Mg<sub>3</sub>Al<sub>2</sub>Si<sub>2</sub>O<sub>12</sub>), grossular (Ca<sub>3</sub>Al<sub>2</sub>Si<sub>3</sub>O<sub>12</sub>), and a solid solution pyrope<sub>60</sub>grossular<sub>40</sub> (Mg<sub>1.8</sub>Ca<sub>1.2</sub>Al<sub>2</sub>Si<sub>3</sub>O<sub>12</sub>) have been measured by adiabatic calorimetry in the temperature range 10–350 K. The samples were crystallized from glasses in a conventional piston-cylinder apparatus.

The molar thermophysical properties at 298.15 K (J mol<sup>-1</sup> K<sup>-1</sup>) are:

	C <sub>p</sub> <sup>o</sup>	S <sub>298</sub> <sup>o</sup> - S <sub>0</sub> <sup>o</sup>	H <sub>298</sub> <sup>o</sup> - H <sub>0</sub> <sup>o</sup> /T
Pyrope	325.31	266.27	47852
Grossular	333.17	260.12	47660
Py <sub>60</sub> Gr <sub>40</sub>	328.03	268.32	47990

The values for the end members are significantly greater than those presented previously for natural samples of pyrope and grossular. The pyrope<sub>60</sub>grossular<sub>40</sub> exhibits an excess heat capacity below 120 K; the maximum occurs at 45–50 K. The anomalously high heat capacity of pyrope at low temperatures and the excess heat capacity of the solid solution are apparently caused by the unusually large, eight-fold coordination of Mg<sup>2+</sup> in the garnet structure.

### INTRODUCTION

GARNETS occur in a wide variety of geological environments and participate in reactions that can serve as pressure and temperature indicators, thus the thermodynamics of garnet solid solutions are of considerable petrologic interest. Thermophysical data for the pure end members are needed to evaluate the mixing relations in natural garnets. Unfortunately, with the exception of data on two natural samples, there are no measurements of low-temperature heat capacities for geologically important compositions. Kolesnik *et al.* (1977) report data for a pyrope-rich garnet

but only the heat capacity at 298 K was adjusted to the end-member composition. WESTRUM *et al.* (1979) measured heat capacities from 5–600 K on a natural, gem-quality grossular of composition

\* U.S. Geological Survey, 959 National Center, Reston, VA 22092, U.S.A.

In both of the above studies, compositional corrections were necessary for impurities whose thermodynamic properties had to be estimated.

Enthalpies of solution ( $\Delta H_{\text{soln}}$ ) measured recently for synthetic garnets on the pyrope–grossular join by NEWTON *et al.* (1977a) at 970 K in a 2PbO·B<sub>2</sub>O<sub>3</sub> melt show a positive deviation from ideality for the enthalpy of mixing ( $\Delta H_{\text{mix}}$ ), with a maximum of ~9 kJ mol<sup>-1</sup> displaced slightly toward pyrope-rich compositions. Heat capacities in the range 350–1000 K have been measured by differential scanning calorimetry for synthetic pyrope (NEWTON *et al.*, 1977b), and synthetic and natural grossular (KRUPKA *et al.*, 1979). Relative enthalpy measurements using a Tian–Calvet microcalorimeter have been reported over a similar temperature range for natural samples of pyrope and grossular (TOPOR *et al.*, 1972; KISELEVA *et al.*, 1972).

Garnets of rocks in much of the lower crust and upper mantle are rich in pyrope and grossular components, thus the thermophysical properties of these end members are of particular importance. The apparent anomalously high entropy of pyrope (NEWTON *et al.*, 1977a) and a postulated excess entropy of mixing for solid solutions on the pyrope–grossular join (HENSEN *et al.*, 1975), inferred from phase equilibrium calculations, are additional reasons for the direct measurement of low-temperature heat capacities.

Table 1. Cell edges of synthetic garnets. Uncertainties are least squares standard errors ( $1\sigma$ )

Sample	$a_0$ (nm)	Peaks	Int. Std.
Pyrope	1.14540(5)	15	silicon
Grossular	1.18507(3)	20	spinel
Pyrope <sub>60</sub> grossular <sub>40</sub>	1.1628(1)	17	spinel

Heat capacities for synthetic pyrope ( $Mg_3Al_2Si_3O_{12}$ ), grossular ( $Ca_3Al_2Si_3O_{12}$ ), and pyrope<sub>60</sub>grossular<sub>40</sub> ( $Mg_{1.8}Ca_{1.2}Al_2Si_3O_{12}$ ) have been measured to examine the possibility of excess heat capacity in solid solutions as well as to provide low-temperature thermophysical data on the end-members.

### SAMPLE PREPARATION

#### Pyrope

An oxide mix was prepared from MgO (single crystal periclase, Muscle Shoals Electrochemical Corp.), Al(OH)<sub>3</sub> (Fisher, reagent grade), and SiO<sub>2</sub>·nH<sub>2</sub>O (Baker, reagent grade). All reagents were initially fired at 1675 K for 4–6 hr and cooled in a desiccator containing Drierite immediately prior to weighing. All mixing, here and below, was done with a corundum mortar and pestle. The oxide mix was fused at 1875 K for 10 min in 325–350 mg portions. The melt was quenched to a glass in a Hg bath and was subsequently homogenized by crushing and regrinding, again, with a corundum mortar and pestle. The glass was crystallized in graphite containers (1623–1673 K, 30 kbar, 1 hr, 215 mg per run) in a conventional piston-cylinder apparatus.

#### Grossular

The oxide mix was prepared from CaCO<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub> (Baker, Ultrex grade) and SiO<sub>2</sub> (acid-leached, natural quartz, Lisbon, Maryland). The CaCO<sub>3</sub> was dried at 383 K for at least 48 hr. The firing of the oxides was the same as for the pyrope sample. The mix was decarbonated at 1023 K and fused at 1673 K for 1 hr. The glass was homogenized by crushing and regrinding and was crystallized (1523 K, 25 kbar, 3 hr, 500–600 mg/batch in graphite containers).

#### Pyrope<sub>60</sub>grossular<sub>40</sub>

The oxide mix was prepared from CaCO<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub> (Baker, Ultrex grade), MgO (single crystal periclase, Muscle Shoals Electrochemical Corp.), and SiO<sub>2</sub> (acid-leached, natural quartz, Lisbon, Maryland). The drying procedure and decarbonation were the same as above. The mix was fused at 1773 K for 1.5 hr. Approximately one-

third of the crushed and remixed glass was crystallized at 1573 K and 40 kbar for 1 hr in graphite containers. The balance was surrounded by a matrix of graphite and invar and was crystallized at 1623 and 46 kbar in Professor George C. Kennedy's laboratory at the University of California at Los Angeles. After the removal of the matrix, electron microprobe analyses of the garnet at the edges of several chips gave FeO concentrations of less than 0.03%.

Many of the early runs made on the pyrope<sub>60</sub>grossular<sub>40</sub> were contaminated with aluminous clinopyroxene, apparently stabilized by the small amounts of Na<sub>2</sub>O in ordinary reagent grade chemicals. This problem was resolved by using high purity reagents and 20% seeding.

Graphite was removed from the samples by oxidation in air at 1023 K. The graphite-invar matrix was removed by alternating treatments with KNO<sub>3</sub> + H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub> + HCl. No sign of gelatinization could be detected in garnet chips subjected to this treatment.

The crystallized garnet used for the heat capacity determinations was in the form of translucent discs (6–8 mm dia) and chips composed of aggregated crystals 5–10 μm in dimension. Microscopic examination showed very small amounts of an unidentified birefringent material in some of the chips, but when present the concentration was estimated to be much less than 1%. All peaks in the X-ray diffraction scans were attributable to garnet.

The cell parameters, presented in Table 1, were refined from powder diffraction data (BURNHAM, 1962). The data were obtained using Cu K<sub>α</sub> radiation at a scan rate of 1/8° 2θ min<sup>-1</sup>. U.S. National Bureau of Standards (NBS) silicon and spinel [ $a_0 = 0.80839(3)$  nm, refined with NBS silicon] were used as internal standards. The positive deviation [0.0015(1) nm] of the pyrope<sub>60</sub>grossular<sub>40</sub> unit cell edge from a linear combination of the end member values is in excellent agreement with that found by NEWTON *et al.* (1977a).

Chemical analyses of the garnets were obtained with the ARL electron microprobe equipped with a solid state detector at the University of Chicago. It is our experience (also R. C. NEWTON, personal communication, 1979) that good analyses of synthetic, fine-grained aggregates, such as the present materials, are difficult due to the problem of distinguishing grain boundaries with the electron microprobe optics. With this cautionary note, averaged analyses of at least 10 spots for each sample are listed in Table 2.

Table 2. Electron microprobe analyses of synthetic garnets

Composition		CaO	MgO	Al <sub>2</sub> O <sub>3</sub>	SiO <sub>2</sub>	Sum
Pyrope	Probe		30.05	25.49	45.06	100.60
	Theoretical		30.00	25.29	44.71	100.00
Grossular	Probe	36.79		22.40	39.51	98.70
	Theoretical	37.35		22.64	40.01	100.00
Py <sub>60</sub> Gr <sub>40</sub>	Probe	15.85	17.22	24.75	42.69	100.51
	Theoretical	15.94	17.19	24.16	42.71	100.00

The compositional range of the pyrope<sub>60</sub>grossular<sub>40</sub> was estimated to be  $\pm 1-2$  mol% by visual examination of the shape and width of high-angle diffractions. The limited number of electron microprobe analyses are compatible with this conclusion.

The sample masses *in vacuo* were 9.7596, 10.1420, and 9.7926 g for pyrope, grossular, and pyrope<sub>60</sub>grossular<sub>40</sub>, respectively. The formula weights used in the calculations were 403.127, 450.452, and 422.057 g mol<sup>-1</sup> for pyrope, grossular, and pyrope<sub>60</sub>grossular<sub>40</sub>, respectively and are based on the 1975 values for the atomic weights (Commission on Atomic Weights, 1976).

### CALORIMETRY

The same calorimeter (laboratory designation W-34) with a mass of 10.61 g was used for all heat capacity measurements. After loading and evacuation, a small measured amount of purified helium was added to promote thermal equilibration. The amounts of Apiezon-T grease, helium, and solder used for the measurements of the garnet samples closely match those used during the measurement of the heat capacity of the empty calorimeter, which was redetermined as a part of the present investigation. Corrections for differences in the masses of the above materials were small in comparison with the accuracy of the final results. When the end-member samples were measured, the fraction of the total heat capacity (calorimeter + sample) attributed to the samples increased from approximately 0.03 at 10 K, to 0.3 at 100 K, and to 0.5 at 350 K. The values for the pyrope<sub>60</sub>grossular<sub>40</sub> sample were similar except at 10 K where the fraction was 0.14.

The heat capacity measurements were made in the Mark II adiabatic cryostat described elsewhere (WESTRUM *et al.*, 1968). A capsule-type platinum resistance thermometer (laboratory designation A-5) was used for temperature determinations. All determinations of mass, current, voltage, time, and temperature were referred to calibrations or standardizations performed by the U.S. National Bureau of Standards.

### RESULTS

The experimental heat capacity values for pyrope, grossular, and pyrope<sub>60</sub>grossular<sub>40</sub> are presented in Tables 3-5 in chronological sequence at the mean temperatures of the determinations. Temperature increments employed in the measurements can be inferred from the differences in the adjacent mean temperatures. The heat capacities have been adjusted for curvature to correct for the finite temperature increment of each measurement. The standard deviations of the heat capacities from polynomials, fitted by least squares, are <5% below 50 K, <1% from 50-100 K, and <0.1% above 100 K except for grossular for which the percentage is 0.15 above 100 K. The data for pyrope<sub>60</sub>grossular<sub>40</sub> are plotted in Fig. 1. For clarity only the fitted polynomials are shown for the end-member compositions. In addition, the smoothed values of KOLESNIK *et al.* (1977) for a natural pyrope sample are plotted below 50 K for comparison.

At the lowest temperatures the heat capacities were fitted to an equation of the form  $C_p = \alpha T^3$  to permit extrapolation of the measured data to zero Kelvin. This extrapolation accounts for less than 0.01% of the entropy function at 298.15 K. The results for each

sample were again fitted to polynomials in temperature by a least-squares method. The derived thermodynamic functions are given in Tables 6–8. These values are considered to have a probable error of less than 0.1% above 100 K.

### DISCUSSION

Figure 2 is a deviation plot comparing the heat capacity measurements on natural and synthetic samples of pyrope and grossular. In calculating the deviations between the natural and synthetic pyrope, the heat capacity of the natural sample was based on the formula weight of pure pyrope (403.127 g mol<sup>-1</sup>). The natural grossular values were treated similarly by WESTRUM *et al.* (1979). Neither data set for the natural samples has been corrected for deviations from end-member composition. In both cases the values for the synthetic samples are significantly greater over most of the measured range than those of the uncorrected natural samples, although an adjustment to end-member composition would be expected to account for much of the discrepancies.

#### Pyrope

The heat capacity values measured on the natural pyrope garnet in the lowest temperature region require a comment. Figures 1 and 2 show that the heat capacity does not smoothly approach zero as  $T \rightarrow 0$  K. The 18.8 mol% almandine content of

the garnet may be partly responsible. Almandine is known to undergo paramagnetic to antiferromagnetic ordering at 7.5 K (Prandl, 1971) for which the theoretical entropy contribution is  $3R \ln(2S + 1) = 40.14 \text{ J mol}^{-1} \text{ K}^{-1}$  (KITTEL, 1976; ULBRICH and WALDBAUM, 1976). The apparent anomaly may represent the high-temperature tail of this transition. At higher temperatures, the adjustment to end-member composition will be dominated by the almandine contribution. Because the correction will be large and because various methods of estimating the almandine heat capacity vary widely in results, no attempt was made to correct the heat capacity of the natural pyrope sample for additional components. Much of the discrepancy may be removed, however, by such a correction. KOLESNIK *et al.* (1977) give a corrected value for  $C_{p,298} = 320.24 \text{ J mol}^{-1} \text{ K}^{-1}$  which is 1.5% low in comparison to our measurements on synthetic pyrope.

A value of  $S_{298}^0 = 268 \text{ J mol}^{-1} \text{ K}^{-1}$  based on the univariant reaction enstatite + spinel = pyrope + forsterite was calculated by NEWTON *et al.* (1977b). The absence of a heat capacity anomaly and the relatively good agreement between the observed  $S_{298}^0$  and the value calculated from phase equilibrium studies is strong evidence against Mg<sup>2+</sup> positional disorder as proposed by ZEMANN and ZEMANN (1961) and KLEBER *et al.* (1969) from X-ray studies.

#### Grossular

In the natural grossular FeO and H<sub>2</sub>O are the major additional oxides attributed by WESTRUM *et al.* (1979) to almandine and hydrogrossular components, respectively. The  $C_p$  values, adjusted to end-member composition at temperatures > 100 K by WESTRUM *et al.* (1979), are shown by solid triangles in Fig. 2. Unfortunately, the corrections increase the deviation with regard to the synthetic sample, KRUPKA *et al.* (1979), in a differential scanning calorimetry study on synthetic grossular and a natural grossular of similar composition to that used by WESTRUM *et al.* (1979), also observed lower heat capacities for the natural sample in the temperature range 350–700 K. The synthetic grossular in their study was crystallized hydrothermally from a gel at 923 K and 517 bar, a synthesis procedure quite different from the one in the present work. They did not detect a significant difference in the heat capacities of their natural and synthetic samples in the higher temperature (700–1000 K) section of their study. At least part of the difference in behavior of the corrected natural grossular and the synthetic shown in Fig. 2, could relate to the heat capacity approximation for hydrogrossular used by WESTRUM *et al.* (1979). It is probable from structural considerations that the use of brucite to model hydroxyls in a hydrogarnet, as was done by these authors, over-estimates their contribution to the heat capacity (A. B. THOMPSON, personal communication, 1979). A differential scanning calorimetry study might readily resolve this point.

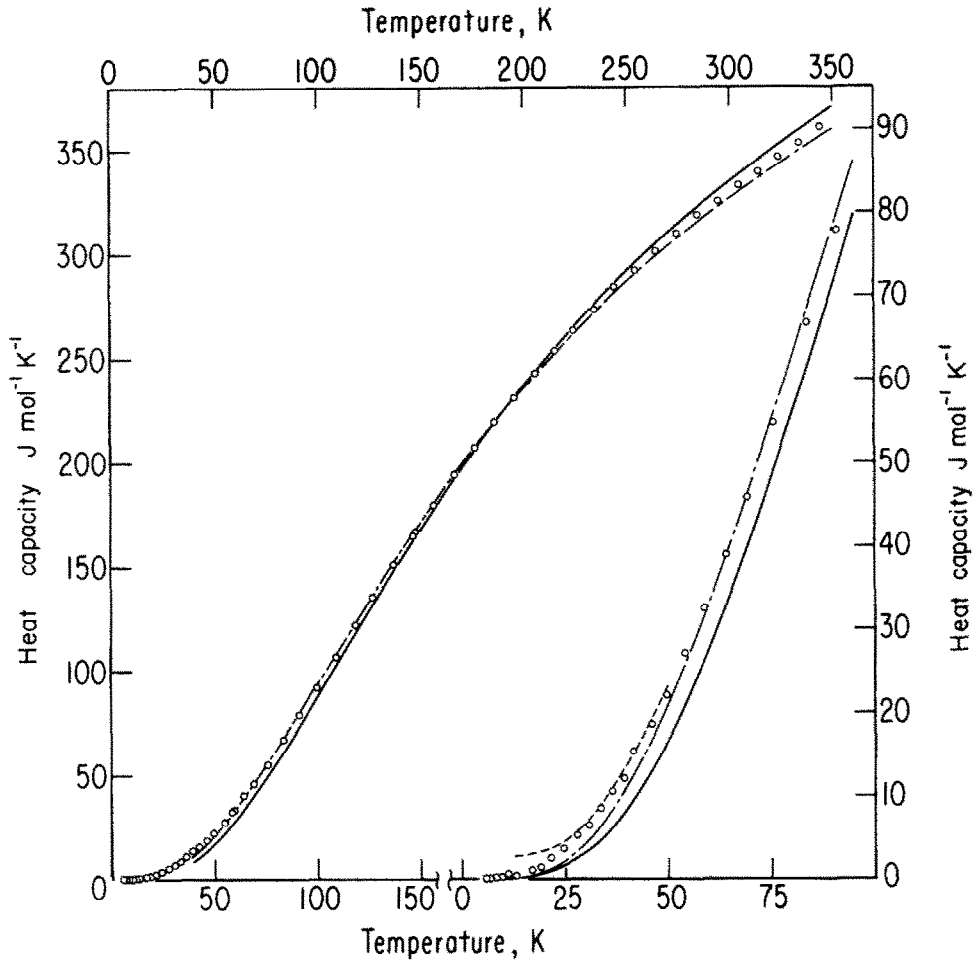

Fig. 1. Molar heat capacities of synthetic pyrope, grossular, and pyrope<sub>60</sub>grossular<sub>40</sub>. Circles are the data points for the mix crystal. Smoothed values are given for grossular— and pyrope—, Smoothed values for natural pyrope, adjusted to the formula weight of pyrope, are given by a dashed line at  $T < 50$  K. The lower temperature region has been expanded at the right.

Fig. 2. Deviation plot. Differences between natural and synthetic samples of pyrope and grossular are given by

$$\Delta C_p = C_p(\text{synthetic}) - C_p(\text{natural}).$$

Open circles are for pyrope; solid circles are for grossular. Natural grossular values, adjusted to end-member composition, are indicated at three temperatures by solid triangles.

Fig. 3. Excess heat capacity of pyrope<sub>60</sub>grossular<sub>40</sub> compared to a linear combination of the end member heat capacities. Percentages are based on the linear combination.

$$C_p(\text{excess}) = C_p(\text{pyrope}_{60}\text{grossular}_{40}) - [0.6C_p(\text{pyrope}) + 0.4C_p(\text{grossular})].$$

*Pyrope<sub>60</sub>grossular<sub>40</sub>*

The excess heat capacity of the pyrope<sub>60</sub>grossular<sub>40</sub> composition shown in Fig. 3 is based on a linear combination of the end-member heat capacities. Though the greatest excess heat capacity, 25% of the linear combination, occurs at 40–45 K, the relative contribution is greater at lower temperatures. Above 115–120 K the excess heat capacity is within the experimental error. The accumulated  $S_{298.15}^{\circ} - S_0$  is  $4.5(3) \text{ J mol}^{-1} \text{ K}^{-1}$ . This value can be compared to an excess of  $13.0 \text{ J mol}^{-1} \text{ K}^{-1}$  estimated by HENSEN *et al.* (1975) from phase equilibrium experiments which were limited to pyrope-rich compositions. By analogy with the excess entropy of mixing calculated by THOMPSON and HOVIS (1979) in the analbite–sanidine series, the maximum excess may be displaced to grossular-rich compositions. Without additional information, however, any asymmetry cannot be assessed.

The excess heat capacity of the pyrope<sub>60</sub>grossular<sub>40</sub> composition and the apparently high heat capacity of pyrope may be related to the coordination of magnesium in garnets. GIBBS and SMITH (1965) reported a larger than expected thermal ellipsoid for  $\text{Mg}^{2+}$  which was attributed to its unusually large, eight-fold coordination. In the solid solution, the occupation of this structural position in part by calcium might expand it, increasing the vibrational amplitude of the magnesium ions and their contribution to the heat capacity. This trend can be observed in the low-temperature in Fig. 1.

*Note added in proof*

Very recently KOLESNIK *et al.* (*Geokhimiya*, 1979, 713–721) have published heat capacity data (13–300 K) for a natural grossular sample. At 298 K,  $C_p = 334.26 \text{ J mol}^{-1} \text{ K}^{-1}$  and  $S^{\circ} = 259.78 \text{ J mol}^{-1} \text{ K}^{-1}$ . The composition of the sample is very close to end-member grossular, and the thermophysical functions at 298 K agree within error with those of the synthetic grossular in the present study.

*Acknowledgements*—It is a pleasure to acknowledge the advice and support of R. C. NEWTON. We are also indebted to J. BOERIO-GOATES and R. D. CHIRICO for their assistance with the calorimetry. We thank J. R. GOLDSMITH and T. J. B. HOLLAND for reading the manuscript and A. NAVROTSKY and G. L. HOVIS for their constructive reviews. The project was supported by NSF grant EAR74-22851 (R. C. NEWTON) and by the Structural Chemistry and Chemical Thermodynamics Program, Chemistry Section, National Science Foundation under contract GP-42525 (EFW). Additional support was provided by the Materials Research Laboratory Program of the National Science Foundation at the University of Chicago.
