Nitric oxide: biosynthesis and biological significance

Michael A. Marletta

The recent discovery that mammalian cells can synthesize nitric oxide coincided with the identification of this simple gas as a factor involved in cellular communication. Nitric oxide has now been shown to be derived from $\text{l}$-arginine in macrophages, endothelial cells and possibly other cell types. Its physiological role in macrophages may be as a cytotoxic agent. However, nitric oxide produced by endothelial cells is thought to trigger vascular smooth muscle relaxation through activation of the enzyme guanylate cyclase.

The study of what appeared to be quite diverse physiological reactions led to the discovery of nitric oxide ($N=O$) as a mammalian metabolite that plays a critical role in cellular communication as well as other important functions. The investigation of the apparent synthesis of nitrate ($\text{NO}_3^-$) by mammalian cells revealed that, in macrophages, $N=O$ was an intermediate in the production of both $\text{NO}_2^-$ and nitrite ($\text{NO}_2^-$) from $\text{l}$-arginine. In quite unrelated experiments, a factor produced by endothelial cells was shown to be required for the acetylcholine-induced relaxation of vascular smooth muscle. This factor has now been identified as $N=O$, also derived from $\text{l}$-arginine. This review will summarize these initial studies that led to the identification of $N=O$ as a metabolite and examine its biochemical synthesis and possible biological function. Another recent review by Moncada and colleagues emphasizes the regulation of cell function and communication.

It is rare to find such a reactive molecule as a free intermediate in mammalian biochemistry. The chemistry of $N=O$ has been studied in great detail although not typically under biological conditions. Nitric oxide reacts readily with molecular oxygen in the gas phase and in aqueous solution to yield nitrogen dioxide ($\text{NO}_2$) which is also reactive and ultimately reacts to form $\text{NO}_2^-$ and $\text{NO}_3^-$. The role of $N=O$ as an enzyme-bound intermediate in the reduction of $\text{NO}_2^-$ by anaerobic denitrifying bacteria has been demonstrated by Hollocher and co-workers over the last several years, however, as will be described below, the mammalian pathway for $N=O$ is quite distinct from the bacterial reductive pathway.

Macrophage synthesis of $\text{NO}_2^-$ and $\text{NO}_3^-$

The first metabolic balance studies consistent with mammalian synthesis of $\text{NO}_2^-$ were carried out at the turn of the century (see Ref. 3 and references therein). Renewed interest in $\text{NO}_3^-$ synthesis in humans stemmed from the potential for the formation of carcinogenic $N$-nitrosamines using this metabolically-derived $\text{NO}_2^-$ as a reactant. The endogenous formation of $N$-nitrosamines has been under investigation for about the last 20 years and the conditions that could lead to the reaction of secondary amines with $\text{NO}_2^-$ have been well studied. Previously, exposure to $\text{NO}_3^-$ was always presumed to be that from environmental sources. Tannenbaum and co-workers first showed that $\text{NO}_3^-$ synthesis was indeed a mammalian process. They found that humans and rats, when maintained on a low $\text{NO}_2^-$ diet ($\sim 180 \text{ mol day}^{-1}$ for humans), excreted levels well above the ingested amount. Similar results were obtained with germ-free rats, thus ruling out the participation of gut microflora in the reaction. During the course of the human experiments, one of the subjects coincidentally became ill and showed a large increase in urinary $\text{NO}_3^-$ excretion. Subsequent experiments in rats showed that the urinary $\text{NO}_3^-$ levels could be elevated about tenfold when fever was induced by an intraperitoneal injection of $E. \text{coli}$ lipopolysaccharide (LPS). These findings suggested that this elevated synthesis might be related to the immunostimulation known to be brought about by LPS.

The studies above suggested a poten-
tial origin of NO3 synthesis and, perhaps more importantly, an experimental approach to the problem. Studies carried out with inbred strains of mice which had been characterized with defects in either T cells, B cells or macrophages suggested that after immunostimulation, the macrophage was responsible for this increase in NO3 synthesis. This LPS-induced synthesis in vivo was then reproduced by treatment of murine peritoneal macrophages in culture. LPS-treated macrophages typically synthesized about 150 nanomoles per 10^6 cells per 24 hours.

Further in vivo studies showed that strong immunostimulants such as *Bacillus Calmette-Guerin* increased urinary NO3 excretion in mice up to 50-fold, suggesting that endogenous lymphokines could also stimulate macrophages to carry out this synthesis. Subsequent experiments showed that a major lymphokine involved in this response was interferon-γ (IFN-γ). The stimulatory effects of LPS and IFN-γ were synergistic and a number of murine macrophage cell lines were found to respond in a similar fashion to LPS and IFN-γγ.

Further studies with the RAW 264.7 macrophage cell line showed that the chemical precursor to NO2 and NO3 was exclusively the amino acid L-arginine which was converted to citrulline. Experiments carried out with L-[guanidino-15N2]-arginine unequivocally showed that the nitrogen atoms of both NO2 and NO3 were derived solely from one of the two chemically equivalent 15N-labeled nitr-2. Initially it was assumed that the NO3 resulted from the oxidation of NO2 but experiments suggested that both anions were derived from a common intermediate. Experiments with 1-[guanidino-15N2]-arginine unequivocally showed that N=O was labeled in both NO2 and NO3. The formation of NO2 and NO3 was specific for the L (S) stereochemistry at the α-carbon of arginine. Hibbs and co-workers had been studying the cytostasis in certain tumor target cells induced by co-culture with activated macrophages. They found that this cytostatic-inducing property required L-arginine in the cell culture medium and they showed, using unlabeled L-arginine, that activated macrophages synthesized NO2 and citrulline from L-arginine.

**Endothelium-derived relaxing factor (EDRF)**

In 1980, Furchgott and Zawadzki showed that endothelial cells were required for the acetylcholine-induced relaxation of vascular smooth muscle. A number of substances are now known to lead to the release of endothelium-derived relaxing factor (EDRF), including adenosine nucleotides, calcium ionophores and bradykinin.

The major pharmacological properties of EDRF are smooth muscle relaxation in a number of different vascular preparations and the inhibition of platelet aggregation. Speculation about the structure of EDRF continued until 1986 when Furchgott and Ignarro suggested that it might in fact be N=O. Experiments carried out by Moncada and colleagues showed that EDRF was indeed N=O. Using a bioassay consisting of a strip of smooth muscle superfused by effluent from a column containing porcine aortic endothelial cells immobilized on microcarriers, they showed that release of EDRF from bradykinin-stimulated cells led to relaxation in the strip of smooth muscle. A number of indirect experiments showed the structure of EDRF was consistent with the chemical properties of N=O. Then, using chemiluminescence detection, they directly observed the formation of N=O.

This finding has been reproduced by several laboratories. Moncada and colleagues next showed that the precursor to N=O was L-arginine, suggesting an identical pathway to that characterized in macrophages. There is some evidence that polybasic polypeptides containing L-arginine can serve as substrates for EDRF generation but it is not clear if these alternate substrates serve simply as metabolic precursors to L-arginine. The identification of N=O as EDRF suggests a mechanism of action for the vasodilatory drugs such as amyl nitrite and nitroglycerin. Used since the 19th century, these compounds will produce N=O in the presence of thiols such as glutathione thereby circumventing the generation of N=O from L-arginine.

**Biochemistry of N=O**

**General characteristics**

Although the pathway itself appears to be identical in macrophages and endothelial cells, its regulation in the two cell types is quite different. In macrophages no enzymatic activity is observed in either freshly isolated, thioglycollate-elicited peritoneal cells or in any of the macrophage cell lines examined without activation by LPS and/or IFN-γ. A lag phase that is dependent on the concentration of the activating agent(s) is observed during which time protein synthesis required for the expression of the pathway takes place. After the lag phase that is typically about eight hours, the synthesis of NO2 and NO3 begins and continues linearly for about 48 hours after which time cell death leads to a decreased rate of synthesis. The similarity of freshly isolated cells and cell lines has been demonstrated and we have made use of cell lines extensively, in particular the RAW 264.7 line that is both quantitatively and qualitatively identical to freshly isolated cells.

In the cell-free system described below the synthesis of N=O, and consequently NO2 and NO3, continues as long as the substrates are available.

The situation in endothelial cells is very different. Protein synthesis is apparently not required. Stimulation by, for example, bradykinin, leads to an immediate burst in N=O synthesis which decays rapidly. When 1-2×10^7 cells were stimulated with bradykinin at 10 min intervals, the amounts produced (<1 nmol) are small relative to those produced in the macrophage but nonetheless significant. The rapid decay is due to reaction with O2, leading to production of NO3 and NO2, typically in amounts below the limit of detection. When stimulated with bradykinin at 10 minute intervals, N=O was released with each treatment, the amount released (between 70 pmol and approximately 0.7 nmol) being dependent on the concentration of bradykinin used.

The calcium ionophore A23187 is the only stimulant that leads to an extended release of N=O (Ref. 15); an immediate increase in N=O decays slowly over the next 30 minutes. This is presumably due to an extended but decreasing rate of synthesis along with a continual decomposition reaction.

A recent report is consistent with the generation of N=O in the rat cerebellum after stimulation of N-methyl-D-aspartate receptors. Nitric oxide was not measured directly, but the indirect experiments are all consistent with the chemical properties of N=O. The burst of N=O formation is similar to that observed in endothelial cells.

**Substrate, products and inhibitors**

When activated macrophages were placed in media that lacked all free amino acids, synthesis of NO2 and NO3 was 25-30% of that obtained in the normal media. The only amino acid
that restored the synthesis of NO_2 and NO_3 was l-arginine. In fact, l-arginine at 2 mM gave 120% the value obtained with the amino acid complete media that contains 0.6 mM L-arginine. No other naturally occurring amino acid was shown to be a substrate. The background synthesis obtained in the amino acid free medium is probably derived from endogenous arginine, and results with varying concentrations of [^{15}N]-arginine are consistent with this conclusion. Studies with ^14C-labeled l-arginine showed that citrulline was the other product of the reaction and although the stereochemistry at the α-carbon was never determined, it has been assumed not to change. No intermediates involving the amino acid backbone were observed. In addition, NH_3 and NH_2OH were not substrates, ruling out the speculation that the pathway involved hydrolysis of l-arginine to citrulline and NH_3 followed by the oxidation of NH_3 to NO_2 and NO_3 (Ref. 11). The enzyme catalysing this hydrolysis reaction, arginine deiminase, has never been reported in mammalian tissues. The reaction seems to be quite specific for l-arginine. Equimolar concentrations of l-homoarginine (Fig. 1) are about 80% as efficient for NO_2 and NO_3 synthesis. d-Arginine is not a substrate nor does it inhibit the reaction either in vivo or in a cell-free system, thus ruling out the possibility of the inability of d-arginine to enter the cell. Moncada and colleagues have shown that the N=O produced from endothelial cells is derived from the same guanidino nitrogens of L-arginine. These experiments again utilized l-[guanidino-^{15}N]-arginine with bradykinin stimulation.

A limited number of compounds have been studied as potential inhibitors of this reaction. Hibbs and coworkers were the first to show that a monomethylated arginine analogue, N^6-monomethyl-l-arginine (Fig. 1) inhibited NO_2 formation in macrophages. The inhibition in the cell free activity from macrophages was 50% at 130 μM (Ref. 8). This compound was shown to have a similar inhibitory effect in endothelial cells. In contrast, l-canavanine, a fairly broad inhibitor of arginine-utilizing reactions, inhibits NO_2 and NO_3 synthesis in macrophages but has no effect on the reaction in endothelial cell cultures or homogenates. Thus, although the pathway of N=O formation in the two cell types seems to be identical there may be subtle differences in the enzymes involved. The major difference between the two cell types seems to be in the regulation of the biosynthetic pathway, which may be related to physiological function.

Current status of the enzymology

Although some progress has been made, the molecular mechanisms of this unusual oxidation of arginine remain largely unknown. The enzyme activity in macrophages and endothelial cells is found in the cytosol and NO_2 synthesis in macrophages but NO_3 synthesis synthesis in macrophages but has no effect on the reaction in endothelial cell cultures or homogenates. Thus, although the pathway of N=O formation in the two cell types seems to be identical there may be subtle differences in the enzymes involved. The major difference between the two cell types seems to be in the regulation of the biosynthetic pathway, which may be related to physiological function.

Biological function of nitric oxide generation

The proposals regarding the biological role for N=O have mainly centered around the enzyme guanylate cyclase. This enzyme catalyses the conversion of
of GTP to cyclic GMP (cGMP). It had been known for some time that \( \cdot \text{N}=\text{O} \) was capable of activating guanylate cyclase leading to a substantial increase in cGMP levels\(^\text{19}\). Other compounds that activate guanylate cyclase include NaN\(_3\), NH\(_2\)OH, NaNO\(_2\), nitroglycerin and sodium nitroprusside. Under biological conditions all these agents are capable of generating \( \cdot \text{N}=\text{O} \). The enzyme is ubiquitous and exists in both soluble and particulate (membrane bound) forms. Both forms are generally found in the same cell, although the amounts and subcellular localization vary from cell to cell and are influenced by the particular physiological state of the cell. The soluble enzyme has been purified to homogeneity from a number of sources and, consequently, has received more attention than the particulate form. The purified soluble enzyme will bind a heme prosthetic group and the reaction of \( \cdot \text{N}=\text{O} \) with iron proteins, particularly hemo-proteins, is well known\(^\text{20}\). Evidence suggests that binding of \( \cdot \text{N}=\text{O} \) to the heme plays a direct role in the activation of the enzyme. The key experiments supporting the \( \cdot \text{N}=\text{O} \)--heme interaction model have come from a number of laboratories and show that some purification procedures can lead to the loss of the prosthetic heme with resulting loss in the ability to be activated by \( \cdot \text{N}=\text{O} \) and related agents. However, reconstitution of the heme-depleted enzyme with hematin and reducing agents, typically thiols, leads to enzyme that can once again be stimulated by \( \cdot \text{N}=\text{O} \) generating compounds\(^\text{19}\). The amount of activation is dependent on the source of the enzyme and ranges from 10- to 50-fold. It is also clear that activation of guanylate cyclase involves thiols on the enzyme and the evidence taken together suggests oxidation/reduction processes that are linked to the basal and activated activity of the enzyme. Guanylate cyclase shows high-affinity binding for heme\(^\text{21}\), and studies concerning the physiological importance of this are continuing.

The role of cGMP as a second messenger is not as well developed as that for another cyclic nucleotide, cAMP. However, over the last 5–10 years cGMP has assumed a more prominent role as second messenger, in particular, increases in cGMP have been associated with smooth muscle relaxation. Alterations in Ca\(^{2+} \) levels induced by cGMP ultimately control smooth muscle tension. Several laboratories showed that the nitrovasodilators, such as nitroglycerin, produce an increase in cGMP levels in smooth muscle tissue and, as mentioned above, these nitrovasodilators can activate the enzyme guanylate cyclase through the generation of \( \cdot \text{N}=\text{O} \). Thus, nitrovasodilators might simply circumvent the generation of \( \cdot \text{N}=\text{O} \) from arginine and produce \( \cdot \text{N}=\text{O} \) directly. Taken together, these findings suggest that at least one physiological role of the arginine pathway is to activate guanylate cyclase leading to an increase in the second messenger cGMP. Other recent results support this proposed role including those of Garthwaite and colleagues\(^\text{16} \), who showed that glutamate induced the release of a diffusible messenger that had chemical properties very similar to \( \cdot \text{N}=\text{O} \). This appears to be another example of intercellular communication where the intracellular signal is cGMP whose level is increased via the activation by \( \cdot \text{N}=\text{O} \). It has long been known that in the central nervous system, and especially in the cerebellum, the excitatory neurotransmitter glutamate can elicit large increases in cGMP levels.

What, then, is the role of \( \cdot \text{N}=\text{O} \) production in the macrophage? There are two major possibilities. The killing and cytostasis-inducing functions of activated macrophages might suggest that, through its chemical properties, \( \cdot \text{N}=\text{O} \) is acting as a cytotoxic agent. Hibbs and colleagues have reported that \( \cdot \text{arginine} \) is required for activated macrophages to induce cytostasis in target tumor cell lines\(^\text{10} \). Furthermore, they have recently reported\(^\text{9} \) that the same pattern of metabolic inhibition induced by macrophages in the tumor cell line can be reproduced directly by \( \cdot \text{N}=\text{O} \). On the other hand, it is known that cyclic nucleotides are involved in the regulation of several macrophage functions including phagocytosis, motility, response to lymphokines and DNA synthesis and it has been reported that macrophages treated with \( \cdot \text{N}=\text{O} \) generating agents show a large increase in cGMP levels\(^\text{2} \). This would suggest that macrophage killing/cytostatic properties might be cGMP dependent and that the \( \cdot \text{N}=\text{O} \) synthesized is used to elevate intracellular cGMP levels.

The involvement of \( \cdot \text{N}=\text{O} \) as a key metabolite in the activation of the enzyme guanylate cyclase represents a novel control mechanism. The biochemistry of the pathway of \( \cdot \text{N}=\text{O} \) production including the oxidation of \( \cdot \text{arginine} \) at the guanidino nitrogen will no doubt involve some novel enzymology that has already begun to unfold. The understanding of this enzymology and regulation of this pathway will ultimately lead to agents specifically designed for the rational control of \( \cdot \text{N}=\text{O} \) formation. The pharmacological potential for these new agents is promising.

Haem as a multifunctional regulator
G. Padmanaban, V. Venkateswar and P. N. Rangarajan

Haem has long been known as the prosthetic group of haemoproteins such as haemoglobin, catalase and the cytochromes. Its biosynthesis is regulated by feedback mechanisms that ensure its adequate production but prevent its overaccumulation, which is highly deleterious as diseases such as porphyrias attest. However, recent years have seen rapid strides in our understanding of how haem (or more accurately haemin, its oxidized form) itself acts as an intracellular regulator of a variety of other metabolic pathways for systems that utilize oxygen.

Haem dynamics in the cell
The haem biosynthetic pathway has been demonstrated in a wide variety of living systems. However, most information on haem dynamics has been obtained with liver cells. It is estimated that 1 ml of marrow erythroblasts can make 6100 nmol δ-aminolevulinate (ALA) h⁻¹. (ALA is the first committed precursor of the haem biosynthetic pathway, see Fig. 1.) In liver, ALA is made at a rate of 20–25 nmol (g liver)⁻¹ h⁻¹, about 15% of that of whole bone marrow. In liver ALA is quantitatively converted to haem. The total haem content of liver is estimated to be 2.6 nmol g⁻¹ and nearly 65% of it is used to replenish cytochrome P-450 haem. The ‘free and exchangeable’ haem pool is replenished cytochrome P-450 haem. The free and exchangeable haem pool is replenished cytochrome P-450 haem.

levels of haem biosynthetic and degradative enzymes².
Haem is synthesized in the mitochondrial and is then distributed to the different haemoproteins located in mitochondria, microsomes, peroxisomes and cytosol. The mechanism of intracellular transport of haem is not very clear. There is some evidence supporting the concept of cytoplasmic haem carriers transporting haem from mitochondria to other locations. Ultrastructural studies have revealed the presence of rough endoplasmic reticulum–mitochondrion (RERM) complexes in the liver cell, and it has been suggested that these complexes would facilitate the integration of haem made in mitochondria with the apo-cytochrome that haem in liver are ALA synthetase (ALAS) and haem oxygenase¹. ALAS is induced by a wide variety of chemicals and suppressed by the administration of haem. There is good evidence that haem negatively regulates the synthesis of ALAS. With the use of cloned cDNA, it has been shown that ALAS mRNA, pre-induced by 2-allylisopropylacetamide. Since there is no change in the half-life of ALAS mRNA under these conditions, haemin most likely represses the transcription of the gene. Earlier, this laboratory had proposed a positive regulatory model, where ALAS induction could be positively modulated by apo-cytochrome P-450, the effect ceasing with the formation of the holoprotein⁶. Haem

Haem regulates its own biosynthesis
The two crucial enzymes involved in regulating the levels of intracellular haem in liver are ALA synthetase (ALAS) and haem oxygenase¹. ALAS is induced by a wide variety of chemicals and suppressed by the administration of haem. There is good evidence that haem negatively regulates the synthesis of ALAS. With the use of cloned cDNA, it has been shown that ALAS mRNA, pre-induced by 2-allylisopropylacetamide. Since there is no change in the half-life of ALAS mRNA under these conditions, haemin most likely represses the transcription of the gene. Earlier, this laboratory had proposed a positive regulatory model, where ALAS induction could be positively modulated by apo-cytochrome P-450, the effect ceasing with the formation of the holoprotein⁶.
