Introduction

In February 1975, the Detroit metropolitan area unemployment rate stood at 16.4 percent while the nation experienced 8.2 percent unemployment. Obviously, unemployment rates will not be identical in every state of the union, however, it is legitimate to ask why Michigan unemployment is so much higher than the national average. Furthermore, it is quite a legitimate goal for having the highest unemployment rate.

An examination of unemployment data¹ reveals that demography is very important in explaining varying unemployment rates. Historically, teenagers, females, and racial minorities have experienced greater-than-average rates of unemployment. This is no reason, however, to believe that Michigan is endowed with an overwhelming proportion of teenagers, females, or racial minorities. We must therefore look at the industrial composition of the Michigan economy as a source of explanation.

The industrial structure of Michigan has been the subject of numerous studies² and will not be discussed here. The wealth of data and experience of state development agents indicate that heavy manufacturing industries in Michigan have contributed to the hypersensitivity

of Michigan employment to national business cycles. Development agents are well aware of this problem, and, whenever possible, they try to balance the Michigan labor force by encouraging the growth of service and office jobs.

Cyclicality of employment in manufacturing industries, even though recognized, has not received a detailed, quantitative treatment in the literature. The purpose of the present paper is to (1) develop a quantitative measure of sensitivity of industry employment to business cycles; (2) compute such a measure for selected industries; and (3) use the above measures in conjunction with criteria developed by the Economic Development Administration (EDA) to identify certain industries or industry groups as ideal candidates for further industrial development in the state.

The paper is organized into three sections. The first section will deal with the methodological details of measuring sensitivity to business cycles. The second section will be devoted to reporting the computed measures of cyclicality for specific industries. The final section will be devoted to reporting industries which constitute ideal candidates for the less developed areas of Michigan.

SECTION 1

Measuring Cyclical Sensitivity

This section will relate the employment movements within particular industries to employment movements in total nonagricultural employment in the United States. The main methodology is simple linear regression. The measure of cyclical sensitivity developed here is hoped to be of some practical use to state development agents and the Michigan Department of Commerce in their future efforts at selecting specific industries for promotion in the state.

A look at some data

Figure 1 shows total nonagricultural employment in the United States for every month from January 1947 to June 1972. The data is seasonally adjusted and is taken from Employment and Earnings: United States, 1909-1972 published by the Bureau of Labor Statistics (BLS). The shaded months are periods of recession as defined by the National Bureau of Economic Research. Figure 2 and Figure 3 show two components of total employment--manufacturing and services.

The three graphs exhibit pronounced differences in volatility. Manufacturing shows the most volatility while services seem to be unaffected by business cycles. Table 1 summarizes the behavior of the three time series in the officially recognized postwar recessions.

The data in Table 1 indicate that the loss of jobs during recessions is more than twice as severe in manufacturing as it is in total non-agricultural employment. The service sector seems to escape the influence of recessions and even scores some gains during such periods.

In present form, the average annual decline figures could be construed as a measure of sensitivity. There are some drawbacks to such a measure, however. First, the overall positive trend in all components of employment is not taken into account. A real decline of 2.69 percent in total employment is really more serious than the simple percentage would have us believe. The long-run trend in employment is near 3 percent, so the real annual loss of 2.69 percent between August 1957 and April 1958 represents a 5.7 percent annual rate of decline from the expected level of total employment. The second drawback is that the measures constructed in Table 1 depend only on the peaks and troughs of employment; they disregard the variations in employment within the intervening months. Even though this may not be too serious in recessionary periods (which are usually of shorter duration than expansionary periods), fluctuations within expansionary periods will prove this particular measure ineffective.

The problem of long-run trends can be dealt with effectively if we transform the three time series to monthly percentage changes. The reader can satisfy himself by reviewing the plot of the three transformed time series in Figure 4. Due to the nature of the plot routine used, Figure 4 continues for several pages, which somewhat limits its usefulness. Nevertheless visual inspection should satisfy most readers that each one of the three transformed series lacks any long-term trend.

?

Fig. 4. (Concluded)

Before proceeding with further analysis, we should look at some interesting aspects of the data presented in Figure 4. [Symbols 1, 2, 3 are used for manufacturing, total, and services, respectively.]

- (1) Manufacturing employment seems to be more volatile than the other two, confirming our earlier suspicions.
- (2) Services employment seems to be less volatile than the total employment.
- (3) Volatility of all three series seems to be greater during recessions than during expansionary periods.

The above hypotheses will be tested later. Tables 2 - 4 present some descriptive measures for the three series in Figure 4.

Table 2

DESCRIPTIVE MEASURES FOR MONTHLY PERCENTAGE CHANGES IN
MANUFACTURING, SERVICES, AND TOTAL EMPLOYMENT FOR RECESSION
(NBER DEFINITION) MONTHS, 1947-1972; N = 54

	<u>Manufacturing</u>	<u>Services</u>	<u>Total</u>
Mean percentage change in employment	-.81	.15	-.29
Standard deviation of percentage changes	.79	.23	.35
Coefficient of variation	-.77	1.53	-1.21
Minimum	-2.94	-0.86	-1.97
Maximum	0.53	.62	.38

Table 3

DESCRIPTIVE STATISTICS FOR MONTHLY PERCENTAGE CHANGES IN
MANUFACTURING, SERVICES, AND TOTAL EMPLOYMENT FOR EXPANSIONARY
PERIODS IN 1947-1972; N = 251

	<u>Manufacturing</u>	<u>Services</u>	<u>Total</u>
Mean	.25	.33	.27
Standard deviation	.67	.20	.33
Coefficient of variation	2.68	.61	1.22
Minimum	-2.61	-.46	-1.28
Maximum	3.55	.91	1.57

The coefficient of variation normally serves as an adequate measure of variability. Unfortunately the month-to-month percentage changes (especially in services) are so close to zero that the coefficient of variation cannot serve our purpose.

Correlation analysis

So far we have looked at possible absolute measures of volatility. We now turn attention to measurement of volatility in relation to the general volatility of total employment. Figure 5 is a scatter diagram of monthly percentage changes in manufacturing versus those in total nonagricultural employment in recession months. A strong positive relationship is indicated. One word of explanation must be injected here, lest the reader attributes the above relationship to the fact that manufacturing employment is a part of total employment and summarily dis-

Fig. 5. Monthly percentage changes in manufacturing vs. total nonagricultural employment in postwar recession months.

misses the methodology being used as improper. Manufacturing is a sizable proportion of the total employment, and thus part of the criticism is well founded; however, manufacturing and services together account for less than 50 percent of total employment so that all of the association between manufacturing and total employment cannot be attributed to lack of freedom of the series to move independently. Moreover, we have chosen manufacturing and services as extreme illustrative examples. The prescribed methodology will be applied to specific industries, which will constitute minute fractions of the total nonagricultural sector, and hence the lack of freedom of movement will not be a problem.

The degree of linear association between two random variables is commonly described by the correlation coefficient. This measure is a real number between -1 and 1 and, in a sense, signals the existence or lack of a straight line around which a sizeable proportion of probability mass is concentrated. A coefficient equal to 1 would indicate that the entire probability mass of the joint distribution of two random variables is concentrated on a straight line. The sign of the coefficient signifies whether the two variables on the average move in the same direction (+) or in the opposite direction (-). A zero coefficient indicates the lack of linear association between the two variables. Table 4 is a matrix of sample coefficients of correlation for the three variables under consideration within 54 recession months.

Table 4

SIMPLE CORRELATION COEFFICIENTS

	Manufacturing	Services	Total
Manufacturing	1.00		
Services	.2429	1.00	
Total	.8353	.4421	1.00

The Table 4 coefficients are sample values computed on the basis of 54 observations. Because of sampling errors, they may not exactly equal the real correlation among the variables. It is not necessary, however, to know the real magnitude of the coefficient of correlation to statistically reject or accept the hypothesis that there is no linear association between any two of the variables and that the observed relation is strictly due to chance. In the above example, if we were to take repeated independent samples of size 54, we would expect to find computed correlation coefficients with magnitudes larger than 0.2681 in only five out of every 100 sampled.¹ So, at the 5 percent significance level we reject the hypothesis of no linear association for all variables except services versus manufacturing employment.

¹0.2681 is obtained by solving the equation $t = \sqrt{\frac{n-2}{1-r^2}}$ for r , setting $n = 54$ and $t = t_{52}^{.025}$.

It is very unlikely we will find (even at a specific industry level) many industries that bear no association or negative association with the total economy. If we did find such industries we could very well stop and choose the industry as a candidate for state industrial development. Our task does not end when some positive correlation is indicated, however. The existence of the positive correlation coefficient indicates only that there is some straight line with positive slope around which sizable probability of the joint distribution of the two variables is concentrated. The coefficient does not tell us where the line is located. Naturally, if we find out that the slope of the line is less than 1, we will want to consider such industry for future industrial development in the state because, even though the employment in such industry moves up and down with the business cycles, its movements are, on the average, smaller than those of the aggregate employment and thus could lend relative stability to the regional employment. On the other hand, if the slope of such line is greater than 1, we would want to reject the industry on the basis that its cyclical movements amplify the national cycles and hence would have a destabilizing effect on regional employment.

The following section employs regression to discover the slope of the line which was not revealed by the correlation coefficient. Since the slope is intimately related to the coefficient of correlation, we could compute it by appropriately scaling the coefficient of correlation. The use of a regression routine, however, does provide useful statistics for testing hypotheses related to the slope.

Regression Analysis

A regression line is estimated for the data shown in Figure 5 with the following results:

$$Y_m = -0.00401 + 1.392 Y_T$$

where Y_m and Y_T are the monthly percentage changes in manufacturing and total employment, respectively. Both coefficients are significantly different from zero at the .0001 level. Coefficient of determination is .70. Standard error of estimate equals .0033. Standard error of $\hat{\beta}$ equals 0.12704.

Interpretation of the regression equation

During recessions, whenever total nonagricultural employment experiences a monthly percentage change equal to k we expect manufacturing employment to change by a percentage equal to $-0.00401 + 1.392 k$. If $k = +.5$ percent, our expectation of the percentage change in manufacturing employment will be $+.69$ percent. Notice that in this example a positive change is considered. This is not impossible, even in recessionary periods. It is important to remember that even though our sample is restricted to recession periods, there were no restrictions on the direction of change within such periods.

Even though the estimated regression equation provides us with the expected percentage change in manufacturing employment as a function of percentage change in general employment, it does not provide any information about the degree of error possible using the regression equation. Given that total employment during some recession changes by .5 percent, is it likely that manufacturing employment will change by 2 percent?

Is it likely that it will not change at all, or possibly decrease by .75 percent? Naturally the answers to these questions lie in the manner in which the data points in Figure 5 are scattered around the regression line. If the points are located tightly around the line, we intuitively know it would be unlikely that future observations would deviate from the line to a great extent. On the other hand, if wide deviations from the line are numerous in the scatter diagram, we have reason to believe that such deviations will be commonplace in the future. The standard error of estimate is the measure that quantifies the above reasoning. The greater the standard error of estimate, the wider will be the deviations from the expected using the regression equation. In fact we can go further and state the probability is $(1 - \alpha)$ that a single future observation on monthly change in manufacturing will fall within $\pm k \hat{\sigma}$ of the value given by the regression equation where $\hat{\sigma}$ is the standard error of estimate and k is a quantity that can be calculated using only sample information and α once they are known.

Testing hypothesis

If the regression coefficient of the total employment is to be used as a screening device to discriminate between cyclical and non-cyclical industries, we need to have a decision rule based on the $\hat{\beta}$ value and the $\hat{\sigma}$ value of a particular industry. The particular $\hat{\beta}$ value may be estimated using data on recession months (if sensitivity in such periods is considered more undesirable than sensitivity in other periods). For example, we need a rule which would classify an industry as "sensitive" or "cyclical" if $t > 1.1$ and "unsensitive" otherwise, where t (or z for cases where $n > 30$) is a statistic to be calculated from sample data.

In applications of simple linear regression, the usual hypothesis tested is a hypothesis of the equality of $\hat{\beta}$ to zero. In our application the situation is a little different. If we started on a search of industries with $\hat{\beta}$ coefficients of zero, our search would turn up very few industries, if any at all. We must recognize that what we are after is not industries having absolutely no sensitivity to overall business cycles, but rather industries whose cycles have smaller magnitudes than the national cycles. So our null hypothesis then becomes $H_0: \hat{\beta} < 1$ and the alternate hypothesis $H_1: \hat{\beta} \geq 1$. Note that standard regression routines compute a t statistic only for $H_0: \hat{\beta} = 0$. Recalculation of the t statistic appropriate for our null hypothesis is quite simple and involves reducing the estimated $\hat{\beta}$ by one and dividing the result by the standard error of $\hat{\beta}$.

Before picking a decision rule we must evaluate what kind of risk of error we are willing to accept. In the present situation we can make an error and classify a stable industry as cyclical (type I error) or classify a cyclical industry as stable (type II). Conversation with development agents quickly reveals where their sentiments lie. They invariably favor a lower risk of type I error at the expense of increased type 2 error. The reasoning is usually based on the judgment that we should not let any stable industry slip through our fingers. If this means that once in a while we encourage industries that are not really stable, the effect will not be all that bad since even an unstable industry will provide jobs in the short run. It is my opinion that the above reasoning will only invite more severe unemployment in the next recession; thus more attention should be given to type II error and exceedingly smaller α levels.

should be avoided. With a given sample size, obviously we cannot lessen both types of risk; for illustration purposes 0.05 is chosen here as the tolerable maximum risk of type I error. From the table of z distribution, 1.645 is chosen as the cutoff point.

Let us now test to see whether we would reject or accept an industry having the variation characteristic of the manufacturing employment data shown in Figure 5.

$$H_0: < 1$$

$$H_1: \geq 1$$

$$\alpha = 0.05$$

decision rule: reject H_0 if $z > 1.645$

$$z = \frac{1.392 - 1.0}{0.12704} = 3.09 \Rightarrow \text{reject } H_0.$$

Obviously, this rejection should not come as a surprise. We have known all along that cyclical employment is much more pronounced within manufacturing than in total employment. We have just used this data for convenience of illustration. Imagine, however, if the industry under consideration would have been "men's knit shirts." It is not immediately obvious (even to development experts) whether this particular industry is more or less cyclical than the aggregate economy. The hypothesis testing methodology described will make this an effortless task.

Figure 6 is the scatter diagram of services employment versus total employment. At first glance the scatter seems to be of greater slope and wider deviation than Figure 5. The readers should consider the difference in the y axis scale. The regression equation is:

$$Y_s = 0.00233 + .291Y_T$$

SVCS

.61780 -2+

54 CASES FOR THIS GRAPH

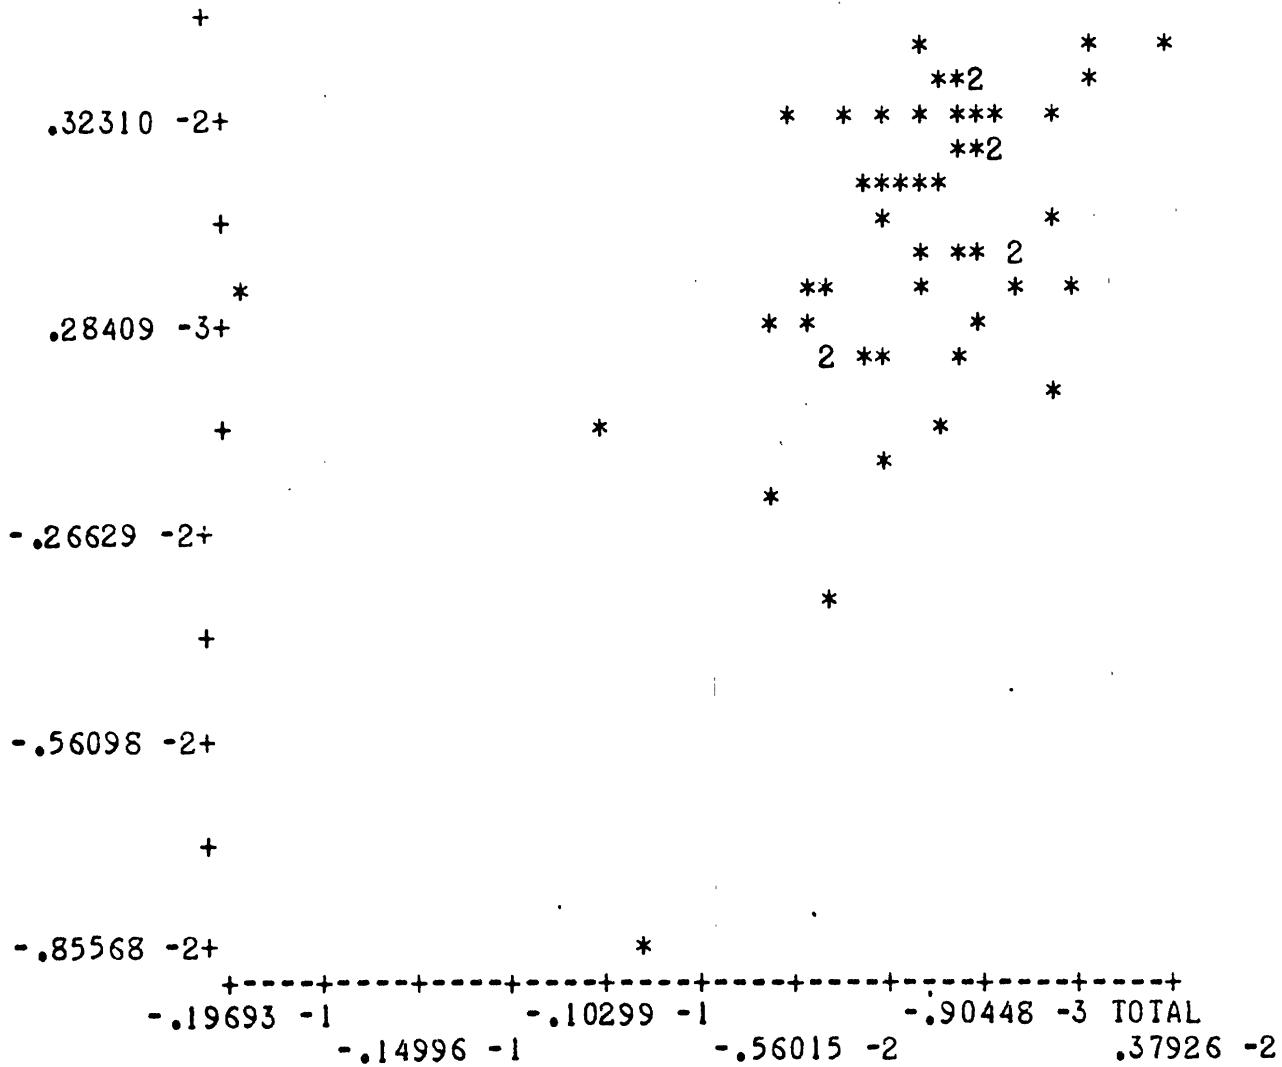

Fig. 6. Monthly percentage changes in service vs. total nonagricultural employment in postwar recession months.

where Y_s and Y_T are the percentage monthly changes in services and total employment in the 54 postwar recession months. Both coefficients are significantly different from zero at .001. Coefficient of determination (r^2) is equal to 19.5 percent and the standard error of estimate is .002. Standard error of $\hat{\beta}$ is equal to 0.082.

$$H_0: \beta < 1$$

$$H_1: \beta \geq 1$$

$$\alpha = 0.05$$

decision rule: reject H_0 if $z > 1.645$

$$z = \frac{0.291 - 1}{0.082} = -8.65 \Rightarrow \text{do not reject } H_0.$$

Employment changes in recessions vs. expansions

So far this analysis has been confined to only 54 months of recession in the U.S. postwar history. The reason for this should be obvious. It is precisely during such recessionary periods when industrial states suffer unemployment far surpassing the national average. Our aim in screening for stable industries is to help bring Michigan closer to the nation during recessions as opposed to its current state which is twice as cyclical as the nation.

But what about expansions? Ideally we would like to find industries with high peaks and very small valleys to promote in the state. This accomplishment would still cause high cyclical, but it all would be concentrated in the boom periods. Michigan would grow much faster than the rest of the nation during expansions and suffer no disproportionate unemployment during recessions.

Unfortunately this seems to be the impossible dream. Volatile industries are volatile during recessions as well as expansions. Figures 7 and 8 show the scatter diagrams for the manufacturing and service sectors during all the months that are not within the recessionary period. The regression results for the two scatter diagrams are given in Tables 5 and 6, respectively. In the study of specific industries, we will not stratify recession vs. nonrecession for two reasons. First, as the analysis indicates, the likely outcome is going to be that the β coefficient for a given industry will be higher or lower than one in both recessions and expansions. Second, at specific industry levels, some series start with 1958 or even 1964, affording only the eleven month recessionary observation in 1970 which would not be an adequate sample size.

Discussion of type II error

Earlier in this paper we suggested that in screening industries on the basis of their employment sensitivity to the national business cycles, it would be necessary to keep type II errors (as well as type I errors) at reasonable levels. It should be obvious that the smaller α level we choose, the larger the cutoff point will be for the computed z statistic. With $\alpha = .05$ and a sample size of 54, the cutoff was 1.645. Reducing α is like using a wider net to catch more and more stable industries for state development. Unfortunately, smaller values of α would end up classifying virtually every industry as a stable one. Another way of saying the same thing is that indexes of cyclicality could be used as a screening device as long as some industries pass and some fail the screening test. Setting the α level so small that every industry passes is having no screening at all.

Let us now consider the probability of a type II error. If indeed $\beta = 1.2$, what is the probability that our test for the data in Figure 5 will fail and classify such an industry as stable? The answer is given by

$$N \left(\frac{1.645 - 1.2}{0.12704} \right) = N(3.5) = 0.9998.$$

Even if $\beta = 1.5$, we still run a $N(1.14) = 0.8729$ risk of misclassifying a $\beta = 1.5$ industry as a stable industry. Obviously, given the number of observations, with $\alpha = 0.05$ we face the possibility of serious type II errors. If we choose $\alpha = 0.10$ in the above example, the cutoff point would have been 1.28. Then, the probability of incorrectly classifying $\beta = 1.2$ as stable would be 53 percent and probability of incorrectly classifying $\beta = 1.50$ as stable would be $N(-1.73) = 4.18$ percent. In section II $\alpha = .10$ will be applied to specific industries.

Seasonal adjustments in industry employment data

In this study, there is a question as to whether we should use seasonally adjusted or unadjusted data. The answer to this question lies in the objective of the screening. If the objective is the selection of industries which are seasonally less volatile than the national economy, then we should not forget seasonal variations and should work with unadjusted data. Our aim, however, is screening of industries in search of those which are not very sensitive to national business cycles; hence we should work with seasonally adjusted data. In other words, if an industry has a very seasonal pattern of employment, yet does not exhibit much sensitivity to business cycles, we would want to include it among the list of stable industries.

Some industry employment data provided by the Bureau of Labor Statistics is already seasonally adjusted. Those series which are provided without such adjustment will be adjusted using the X-11 program originally published by the Bureau of the Census.²

In the next section, a list of stable and unstable ($\beta < 1$ vs. $\beta > 1$) industries are given. Testing of the hypothesis was carried out at $\alpha = .10$. Data for each series covered the period January 1958-June 1972. The list of SIC codes are from 1967. Since an SIC title tape was not available for matching with the SIC numbers, only the numbers are given in the next section.

²The author extends his thanks to Professor W.A. Spivey for making the MTS version of the program available and to Craig Ansley for making the necessary adjustments in the program and putting it in subroutine form.

SECTION 2

List of Cyclical and Noncyclical SIC Industries

The hypothesis-testing methodology of Section 1 was applied to every SIC industry for which the Employment and Earnings: United States, 1909-1972 provided total employee data for the period January 1958 to June 1972. The risk of type I error, i.e., classifying a stable industry as unstable, was held at .10.

The tables provided here suggest that our search has not been in vain. The popular notion that manufacturing is unstable and services are stable is challenged by our noncyclical list which contains many manufacturing industries. Represented among the noncyclical are industries from SIC 26, 28, 33, 34, 35, 37 ---all long accepted as cyclical. Supporting documents (computer outputs) accompany this report.

S.I.C. classification

SECTION 3

Specific Industries for Michigan

In 1973 the Office of Economic Development Administration, U.S. Department of Commerce, published the grouped results of a survey entitled "Industrial Location Determinants." Manufacturing establishments were surveyed to determine the critical and noncritical requirements of each industry (five-digit product class level) for locating in a geographical area.

Since the publication of the report, the EDA has matched various industries to the profiles of certain less-developed regions of the nation with the hope that such matching may be used by development agents to zero in on target industries. The matching was done by an ad hoc scoring rule.¹ For a geographical area to be matched with an industry, the area would have to satisfy all the critical requirements of the industry. The noncritical requirements were used to determine various degrees of perfection of the match. Specifically, industries with scoring values of 90-100 were considered grade A, 80-90 grade B, etc.

Whether the EDA used cyclical stability as a criterion in selecting industries for certain areas is not known. (Even if we assumed such a criterion was used, the weight given to it would still be unknown.) In this section, the industries chosen as

¹The EDA's methodology for matching the survey results to various locations is not documented and not published. Information included here is from informal telephone conversations with EDA officials.

grade A industries for upper and upper lower Michigan are subjected to further screening based on the cyclical sensitivity described earlier in this paper.

First, it should be mentioned that all EDA selections are at the five-digit SIC level, for which published employment data do not exist. Our screening was, of necessity, conducted at the four-, three-, and in certain cases the two-digit levels. For example, one of the grade A industries for the community of Iron Mountain was 22561-warp knit fabrics. Our employment data did not provide five-digit breakdowns, hence we looked among the list of cyclical and noncyclical industries from the previous section. The aim was to exclude the industry from the list of potential Michigan industries if 2256 showed up among the cyclical industries, and to include the industry if it showed up among the noncyclical industries. Unfortunately 2256 does not appear in either list. As a result we look for 225 which is listed as a noncyclical industry in the tables of Section 2, and hence we accept the industry. On page 1 of the EDA selection report we placed a 3 to the left-hand side of SIC 22561 as a reminder that this industry was accepted by virtue of SIC 225 being declared noncyclical in the tables. The same problem arose with industries being rejected as cyclical. For example SIC 35672 is marked as 3★ where the 3 again signifies that the closest SIC code in our Section 2 tables was SIC 356, and where the ★ signifies that 356 appeared among our list of unstable industries.

The illustrative screening was done only for grade A industries; however the complete EDA report² accompanies this paper. Documents supporting the Section 2 tables are also enclosed.

²The author extends his thanks to Leonard Bronder of the Michigan Department of Commerce for making this report available.
