May 1980

## Introduction

This report summarizes work performed by the Highway Safety Research Institute of the University of Michigan on the project entitled "Side-Impact Dummy Calibration Testing Program." This work was performed for the Alderson Research Laboratories on Purchase Order #31353 under the National Highway Traffic Safety Administration contract #DOT-HS-9-02225.

The primary project objective was to subject several Part 572 Dummies to a series of side-impact calibration tests. The resulting data base should allow clarification of the expected dummy response corridors, with the ultimate goal of setting performance standards. A secondary objective was to recommend modifications in both the test procedures and dummy design to achieve consistent results. This secondary objective proved to be of major importance, as dummy-to-dummy response variations were large.

## Test Procedures

The head and pelvis tests are conducted with the test probe device developed for dummy chest and knee frontal impact calibration. The probe consists of a 51.5 lb. cylindrical impact mass which has a 6-inch diameter impact face and is guided during impact to produce a linear motion with no significant lateral, vertical, or rotational movement. The acceleration of the probe along its axis is transduced by an axially positioned accelerometer.

A magnetic pick-up is incorporated into the impact probe design to allow velocity measurement. A serrated metal strip which is part of the probe shaft passes under the pick-up and produces a sawtooth voltage output which can be recorded as a function of time. The velocity of the probe can be calculated from the frequency of the sawtooth waveform and the known spacing of the serrations.

In conducting the head impact test, the dummy is seated in a stable upright position and the seat height is adjusted to allow the probe centerline to pass through the head center of gravity. The probe then impacts the dummy head at a test velocity of 7 feet per second. The responses obtained are comparable in magnitude to the Part 572 frontal head impact specifications.

For the pelvis test, the dummy is positioned such that the probe centerline passes through the dummy H-point (3.9 inches above the seat surface and 4.8 inches forward of the back line). A test velocity of 14 feet per second is used.

The neck test procedure represents a modification of the existing Part 572 test procedure for frontal neck response. The modifications

involve mounting the head/neck system at 90 degrees to the impact direction, using a pendulum velocity of 13 fps and increasing the weight of the pendulum to 136.8 lbs. (as opposed to 65.2 lbs.), which changes the moment of inertia about the pivot axis to 185 lb.ft.sec.<sup>2</sup> (as opposed to 24.5 lb.ft.sec.<sup>2</sup>). The same deceleration material (Hexcel 1.8 lb./cu.ft. aluminum honeycomb) is used. The head/neck angle and the head chordal displacement are determined from photometric analysis of high-speed movies taken at 1000 frames/second.

A more detailed description of the above testing procedure may be found in DOT-HS-803-253, "Calibration Procedures of Test Dummies for Side Impact Testing," J.W. Melvin and J.B. Benson.

## Discussion of Program Results

While the tests produced fairly repeatable results, considerable response variation is evident. Tables 1 through 7 contain summaries of the peak acceleration responses of the tested dummies. Also, time history traces from all tests are presented in the appendix to this report.

A major cause of the response variations appears to be non-uniformity of the vinyl skin covering. An attempt was made to evaluate the influence of this factor on head impact response. By coating the impactor surface with chalk prior to impact, it was discovered that the major area of contact approximated a two-inch diameter circle. This circle is centered on a point 1.25 inches above and .15 inches forward of the point determined by the intersection of the skin surface with a transverse line through the head center of gravity.

The results of measuring the skin thickness in this region appear in Table 8. Measurements were taken at the center point, as well as 5/8" below (Bottom), 5/8" forward (Front), and 5/8" behind (Rear) the center point of the region. The last two columns of this table, the reciprocal of average skin thickness and average impact response, are compared in Figure 1.

It is clear from this data that consistent differences exist between the sides of each dummy head. In each case, the left side shows both a greater skin thickness and a lower impact response. This suggests that skin thickness is a major determining factor in impact response. However, it also appears that this factor alone does not account for the entire response variation, as there are several cases of large differ-

ences in peak acceleration with no significant differences in skin thickness.

A possible explanation of this is suggested by examination of the contact area. The placement of the skin mold sutures creates a ridge of material along the side of the head. This ridge varies in size and shape from dummy to dummy, as well as from side to side on the same dummy. Furthermore, significant differences in skin thickness are often present on opposite sides of the suture ridge. This surface irregularity could well affect the size of the impactor contact area, and thus greatly influence the response magnitude.

Although the results are more consistent, the pelvis impact tests also exhibit some dummy-to-dummy variations. Examination of the dummies again raises suspicion of non-uniformities in the skin covering as a causal factor. While there are no obvious irregularities, the various bolt access holes provide evidence of asymmetry; the flesh appears in most cases to be rotated with respect to the pelvis structure.

In the case of the head/neck tests it is apparent that random factors account for the majority of the observed variance. Average values for several measured parameters for each dummy appear in Table 9. The appendix contains test-by-test results of film analysis.

#### Recommendations

During the course of conducting these tests, several opportunities for improving dummy design and test procedures became evident. First, the placement of the skin mold sutures prevents the accurate control of skin thickness and uniformity on the side of the head. Moving these suture ridges seems prerequisite to consistent side-impact response.

Secondly, the accelerometer mounting holes in the pelvis seem

inadequate. A modification to allow the use of two 1/4-20 screws instead of the present small #2 screws should rectify this situation. Convenient placement of these holes would allow the use of interchangeable accelerometer mounting blocks in both the head and pelvis.

Also, the accelerometer cover plates do not at present provide for convenient wire routing. To allow impacts on either side of the head without endangering accelerometer cables, wire slots should be machined in both sides of the head plate. Also, the pelvis backing plate should be slotted to allow space for wiring to pass.

Finally, examination of the data reveals that the initial impact response levels are consistently lower than the subsequent test responses. This is apparently due to a conditioning of the skin material. It seems, therefore, that the repeatability of the testing procedure might be improved by the inclusion of break-in impacts prior to data collection.
