ABSTRACT

STUDY OF LIQUID FILMS FINGERS AND DROPLET MOTION
FOR STEAM TURBINE BLADING EROSION PROBLEM

by

Wontaik Kim

Chairman: Frederick G. Hammitt

Some phenomena leading to large steam turbine blading erosion have been investigated experimentally. Primarily these are the behavior of thin liquid films, and their subsequent break-up into droplets and fingers at the trailing edge of a stationary blade in the University of Michigan low-pressure wet-steam tunnel.

Both high-speed (5000 Hz) cinematography and still photography have been used to visualize the pertinent phenomena and measure the important parameters. Also electrical conductivity microgages were used to measure liquid film thickness.

A film "Transition Map" for various flow regimes has been constructed, based on the author's results. Three film flow regimes were delineated: rivulet, wavy-film and an entrainment regime.

Critical conditions for rivulet flow were obtained experimentally. Comparison with existing theoretical models shows that the wetting contact angles required in these models are much smaller than those measured here and elsewhere for static conditions. "Bulges" at the film-rivulet stagnation point, and waviness in the film, have been

observed and may be responsible for discrepancies between the author's observations and earlier theoretical models.

Film wave characteristics have been measured, showing some waviness always. These wavelets are either two-dimensional or three-dimensional depending on the flow conditions. A shear perturbation instability mechanism for wave generation seems pertinent for the present thin film case, while pressure perturbation is pertinent for thick-film cases. The author's wave propagation speed measurements show that for two-dimensional waves, the classical capillary-gravity wave propagation model is suitable, while for the high-subsonic waves Wurz's model[W14] correlates the results well.

For the entrainment regime, a correlation has been found based on the author's film thickness measurements. This correlation explains horizontal film flow data well (including the author's), but not vertical passage data.

At the trailing edge, time-dependent liquid finger behavior has been observed. It is found that Karman vortex shedding in the steam is not a controlling factor, rather surface tension and other dynamic forces of the steam play more important roles for finger formation.

The author's measured wake droplet trajectories show two important phenomena which were not reported previously in the literature. These are periodic deceleration of wake droplets and break-up time-dependence upon droplet Weber number. The primary cause of periodic deceleration of drops

may be steam vortex-shedding from the blade into the wake. Direct measurements of such vortices were not attempted in this study.

Droplet break-up time dependence on inverse Weber number is explained well by classical wave growth theory.

Doctoral Committee;

Professor Frederick G. Hammitt, Chairman
Professor Vedat S. Arpaci
Professor James W. Daily
Professor Jerzy R. Moszynski, University of Delaware
Professor Charles M. Vest

ACKNOWLEDGEMENTS

The author is very grateful for the support and assistance of many individuals towards the completion of this work. In particular, he would like to express his appreciation to Professor Frederick G. Hammitt for his careful and consistent advice during this thesis work; Dr. S. Krzeczkowski for his useful suggestions and assistance while he was here as a Visiting Scientist; Professor Vedat S. Arpaci for his many discussions and encouragement during the author's most difficult time in the graduate work; to Professors James W. Daily, Jerzy R. Moszynski and Charles M. Vest for their serving as a doctoral committee members.

Thanks are also due to large number of student assistants for their time and effort in the test operation and data reduction.

The assistance of Ms. Ruth Howard in the preparation of the thesis manuscript is most greatly appreciated.

The author also gratefully acknowledges the financial support by the National Science Foundation, Grant ENG 75-2315, internal University of Michigan Funds (SEP) and University Fellowship.

And finally the author extends his appreciation to his wife, Songmin, and daughter, Christina, who provided shelter and comfort throughout the entire graduate work.

Dedicated to my father

Mr. Kyung-Suk Ma

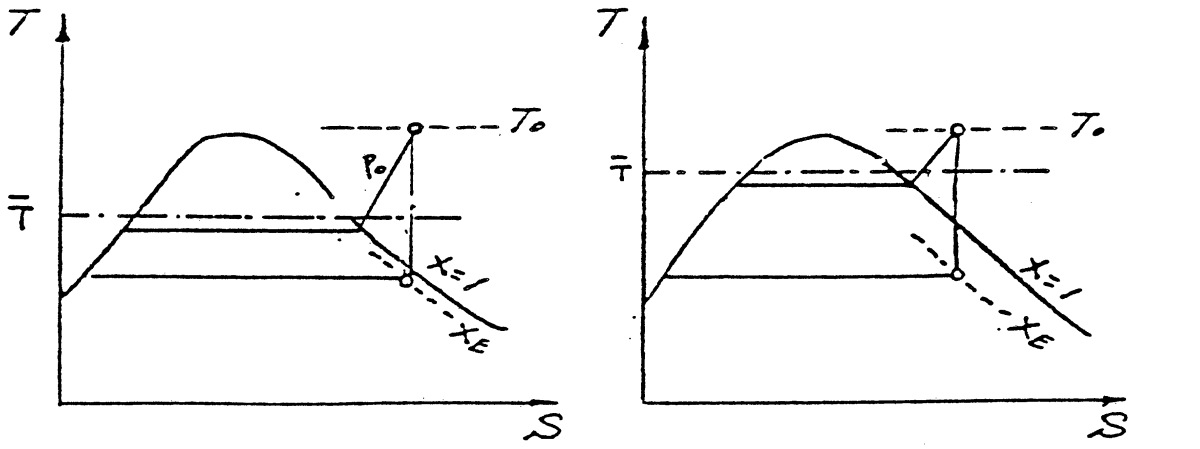
CHAPTER I

GENERAL PROBLEMS ASSOCIATED WITH STEAM WETNESS

One might ask the question, "Now that steam turbines have been used and improved since the late 17th century, why do we still need further research thereon?" That may seem a plausible question because the first substance discussed in elementary thermodynamics courses is steam, and all power engineers must have thoroughly studied the properties and behavior of steam, concepts of steam turbine efficiencies, etc. Nevertheless, there continue to be many on-going research programs, particularly relating to wet steam flow in steam turbines which, being multiphase flow, is itself a very complex subject. Therefore, it is of benefit to review the history of the various problems concerning steam turbines, specifically in the area of the author's research.

From the early days of steam turbines, designers have made substantial efforts to improve the efficiency of the steam cycle. The most promising way of accomplishing this was to raise the temperature and pressure of steam to as high a value as would be compatible with the best construction materials available at an acceptable price. It became apparent soon that the limits set to the temperature of highly stressed parts were rather strict, while the limits concerning the pressure in the boiler and turbine inlet could be raised more easily by improved design.

As seen in Fig. 1.1 an increase of steam pressure P_o,

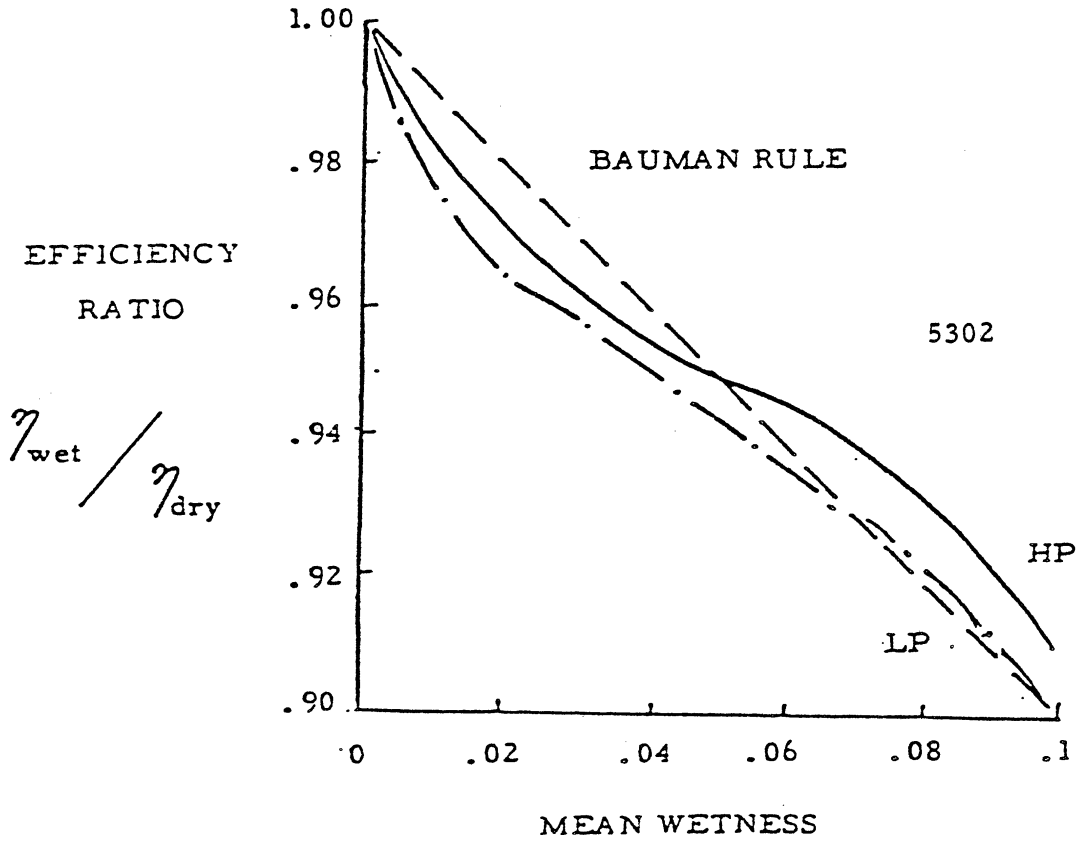


(a) Low P_o ;
Low Carnot efficiency
Low exit wetness $(1 - X_E)$

(b) High P_o ;
High Carnot efficiency
Higher exit wetness $(1 - X_E)$

Fig 1.1 : Steam Cycle Characteristics (Temperature and Entropy Diagram)

Fig 1.2: Wetness Loss Data From Tests on Laboratory Turbines (Miller, 1972)



at constant steam temperature, T_o, raises the mean temperature, $\bar{T}$, of heat addition to the cycle, which means an improved Carnot efficiency. However, it was also necessary to limit pressure. Practical pressure limits were set both by stress considerations and limitations on wetness fraction at turbine exit.

For increased exit wetness, two problems are noted. First, severe erosion damage to the low-pressure blading occurs. After a few months or years of service, poorly designed low-pressure rotor blades can be significantly damaged, i.e., seriously roughened, pitted or even broken. To prevent grave erosion damage as well as substantial loss of efficiency, limitation of exit wetness to $\sim$ 12% (by mass) was found necessary. Thus wetness became as severe a limiting factor to the attainable efficiency of steam turbine plants as the temperature and pressure resistance of materials.

Second, it was found that the aerodynamic efficiency of turbine stages operating in the wet steam region was considerably lower than that of dry stages. One of the earliest empirical correlations of turbine efficiency to account for wetness loss was that of Baumann[B1]. He concluded that 1% of mean wetness reduces efficiency by 1%. It was also experimentally verified[M1] that supersaturation produces a significant part of the total loss in efficiency (Fig. 1.2).

Sources for this efficiency loss include the thin wavy film of deposited droplets on the casing wall and blades which results in higher friction loss than would a dry wall.[C1]

Also a part of the vapor energy is spent in accelerating the liquid droplets. This energy term does not add to turbine power output.

The fact that present day large water-cooled nuclear reactors produce only saturated high pressure steam forces the study of moisture effects in steam flow. For typical plants (such as PWR) the high pressure (45-65 bar) saturated or near-saturated steam enters and expands in the high-pressure turbine with ~15% or more of wetness developing at a pressure of ~5 bar. Continued expansion would give ~25% wetness at turbine exit which is clearly not acceptable. Figures 1.3 and 1.4 show the events leading to steam turbine erosion in such plants.

A. CONDENSATION OF STEAM

In many technical processes, such as expansion, compression or heating and cooling, the wet steam is subjected to rapid changes of state. In such processes, time is not sufficient for full phase equilibrium. The necessary evaporation and condensation is limited by many factors. Therefore, non-equilibrium processes take place, which are characterized by finite temperature differences between and within phases. Equality of pressure between vapor and liquid phase is usually maintained, because pressure disturbances propagate at acoustic speed. Thus supersaturated (or subcooled) steam and superheated liquid may coexist. However, these states are very unstable. They occur only

EROSION PROCESS

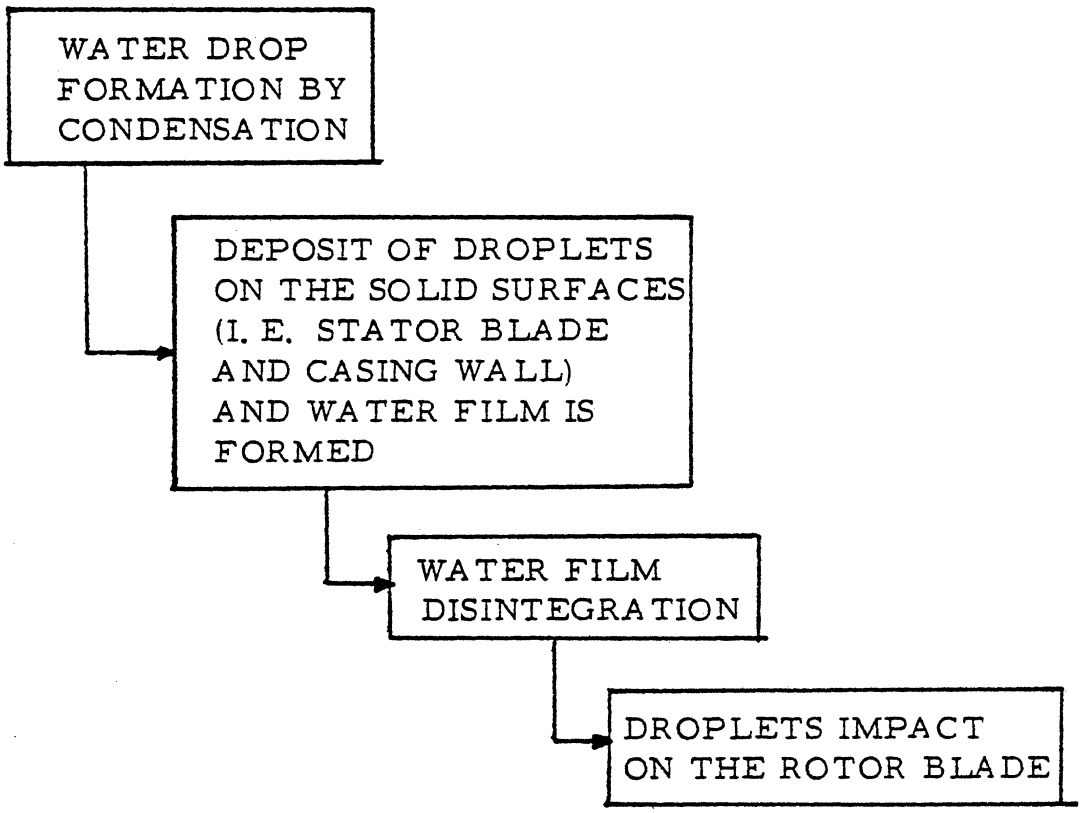


Figure 1.3 : Summary of Erosion Process.

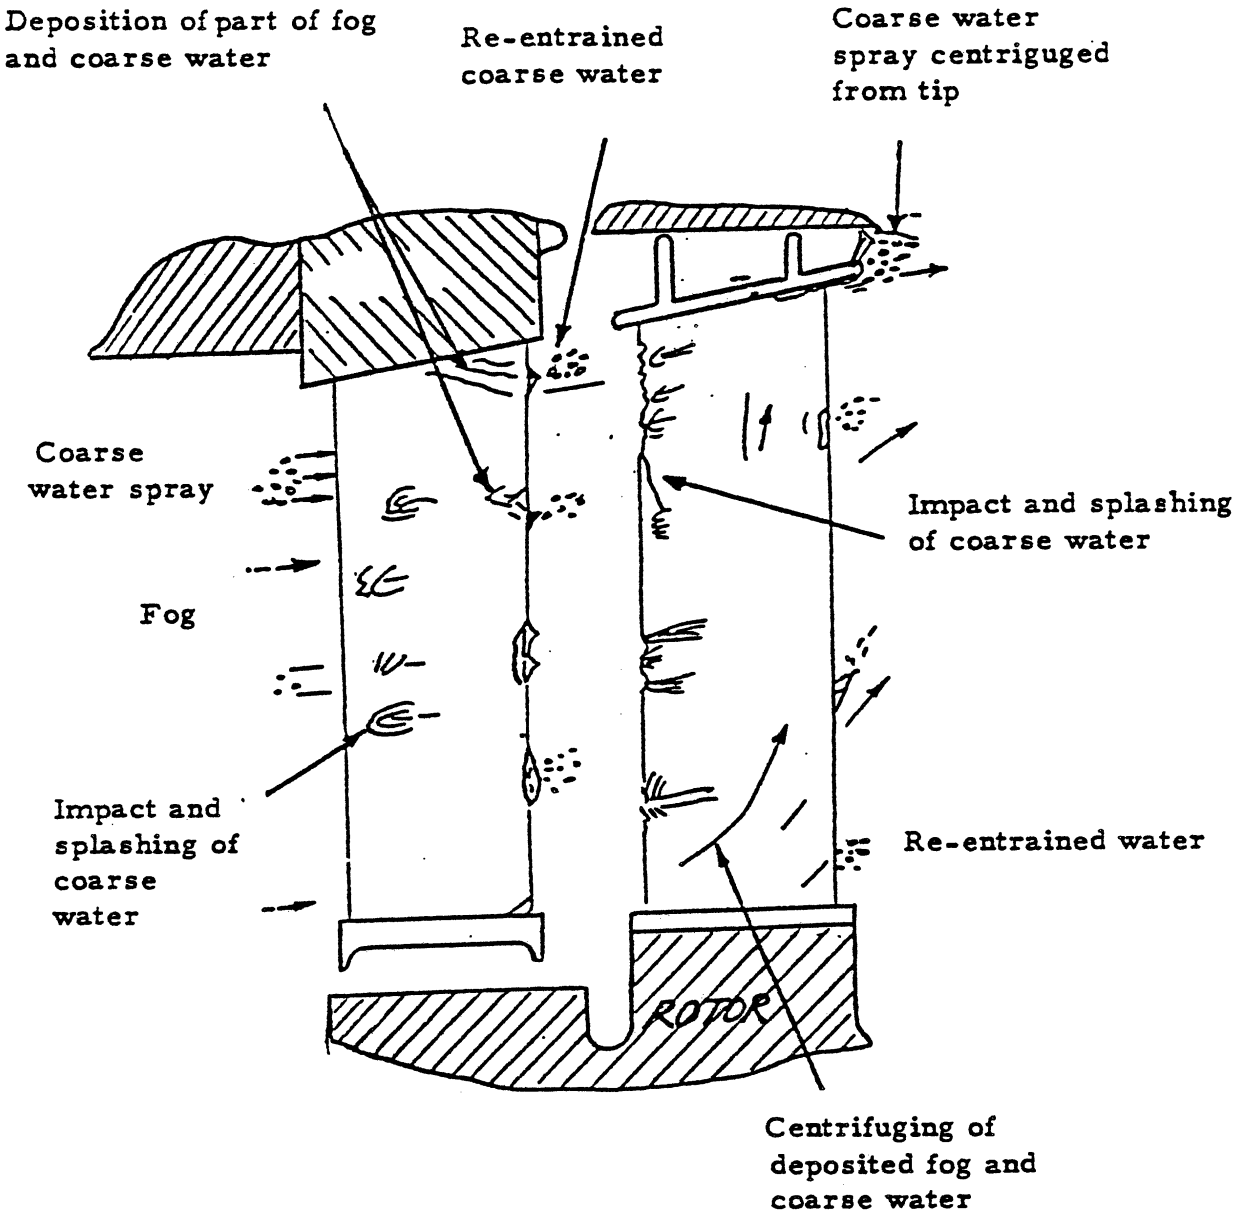

Fig 1.4 : Diagram of the Forms of Water in a Wet-Steam Turbine Stage.

during dynamic processes, and disappear when equilibrium is recovered. Thus in the fast steam expansion in a turbine, steam condenses in the so-called "Wilson zone"[W6]. Numerous investigators such as Yellot[Y1,Y2] Gyarmathy[G1,G2] and Ryley[R1] found that the "Wilson zone" lies at ~5 % equilibrium wetness.

The size of droplets in spontaneous condensation is known to be in the range of 0.01~ 0.1 μm.[G1,P1,V1] Also the number density of droplets per unit volume has been estimated to be $\sim 10^{15}/m^3$, assuming a uniform size of 0.1 μm [G2]. Droplets formed at the Wilson zone will grow in the following downstream expansion region. The growth rate of droplets has attracted the attention of many researchers. Hill[H1] developed a growth law from kinetic theory considering the droplet growth rate to be the difference between the molecular impingement rate of the vapor at the droplet surface and the evaporation rate of the droplet.

Gyarmathy[G2] used Fick's diffusion law and Fourier's law of heat conduction to develop a growth rate for spherical droplets in a continuum environment of arbitrary supersaturation and moisture fraction. Moses and Stein[M2] compared their experiment with several growth laws and concluded that Gyarmathy's model is more accurate than the others. Whether the vapor behaves with regard to a droplet as a continuum or as a free-molecular gas depends on the value of the Knudsen Number,

$$K_n = \frac{\text{mean free path of vapor molecule}}{\text{diameter of droplet}}$$

i.e., Kn $\leq$ 0.01; continuum flow

Kn $\geq$ 4.45; free molecular condition prevals.

Most primary droplets studied in steam turbines fall between these extremes.

B. DEPOSITION OF PRIMARY DROPLETS ON THE BLADE SURFACES

Primary steam droplets are not in general large enough to cause erosion damage by direct impact. Rather water from deposition of primary drops is collected on blade surfaces, and then torn from the stationary blades in larger "droplets" which then cause erosion of the next rotating row. Traupel[T1] has shown that the thermal boundary layer will maintain blading surfaces in a superheated condition. Thus evaporation rather than condensation is expected, so that direct condensation on the blade is unlikely.

Gardner[G4] proposed two possible mechanisms of collection, "Brownian Diffusion" for drops smaller than 0.1 μm and "Eddy Impaction" for those larger than 0.1 μm. For the Brownian diffusion model, molecular diffusion controls near the surface and eddy diffusion at a distance. The efficiency of collection decreases as drop size increases. On the other hand, for the eddy impaction mechanism, particles approach the wall by eddy diffusion, and proceed the remaining distance by already gathered inertia, dissipated by viscous resistance. Contrary to Brownian diffusion, the

collection efficiency increases as drop size increases.

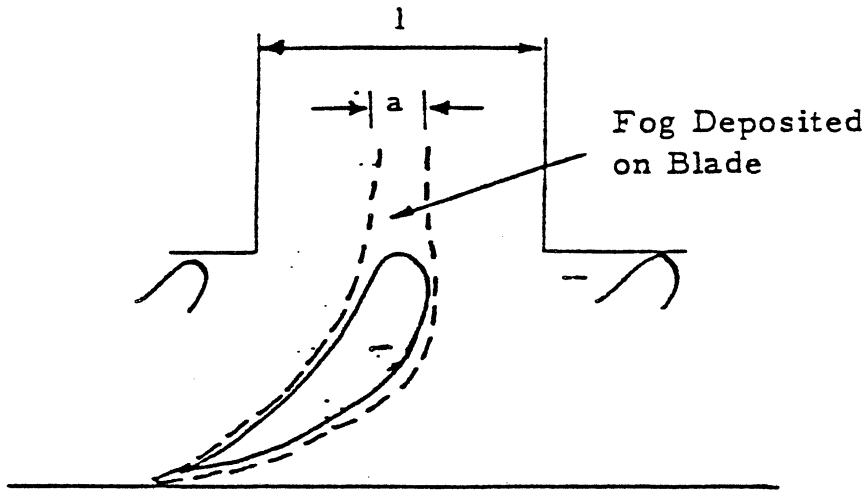
Crane[C2] carried out experiments for the "collection efficiency" of the eddy impaction mechanism. Some typical results for HP and LP turbine blades are shown in Fig. (1.5).

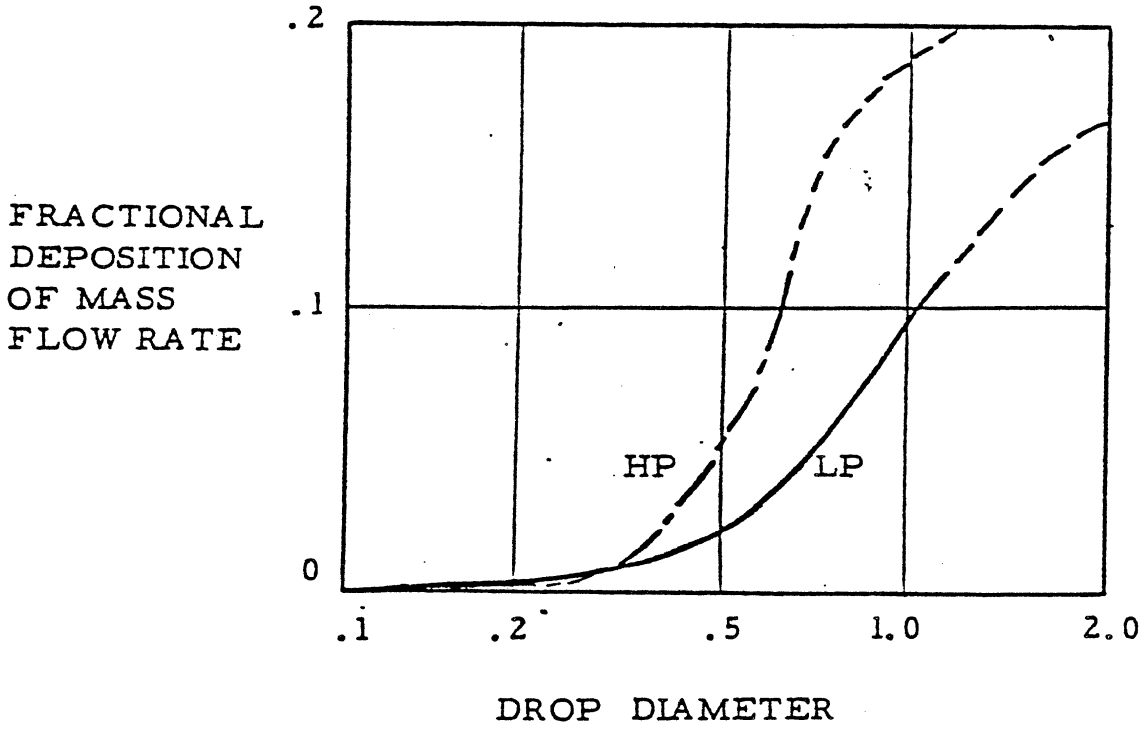
Recently Ganic and Rohsenow[G5] proposed a modified deposition mechanism, considering lift forces, due to drop rotation within the laminar sublayer caused by high vapor velocity gradients, and reaction forces due to asymmetrical drop evaporation inside the laminar sublayer. In addition inertia, drag, bouyancy, and gravitational forces were included.

C. FILM FLOW AND SECONDARY DROP FORMATION

The deposited drops form a very thin water film, or sometimes separate rivulets on the stator blades. This water will flow along the blades under the influence of steam "drag" (interfacial shear). Finally the film is torn away at the trailing edge or at the wave crests of a wavy film upstream of this edge, depending on the prevailing conditions. Droplets detached from such films are in fact much larger than the primary droplets, and cause the observed erosion damage to downstream rotating blades. Thus the behavior of these thin films, and the size of the secondary drops, their acceleration and their break-up and time of break-up into smaller though still large droplets, must provide the design bases to avoid steam turbine blade erosion. This is the major subjects of author's present research.

Information about the droplet acceleration is very





5305

Fig 1.5 : Approximate Fractional Deposition of Fog Drops on Blading. (C2)

important,since the closer the velocity of the droplets approaches the main steam velocity,the less will be the normal impact velocity between the droplet and the blade surface,thus causing less damage.(see Fig.1.6). It is generally agreed that only the normal component of droplet velocity contributes to the erosion damage. Example of damaged blade is shown in Fig. 1.7.

D. VELOCITY OF SOUND IN WET STEAM

Mach number is an important design parameter in steam turbines, and the steam flow is generally in a compressible flow regime. For this reason,steam velocities are here usually presented in terms of Mach number.

Theoretical and experimental studies of acoustic velocity are due to many researchers[D1,C3,P2,G6]. Petr's results[P2] are summarized graphically. The speed of sound(Fig.1.8) was expressed in terms of the "frozen" speed of sound, which is defined as : $a_F^2 = \frac{K_i P}{\rho_g}$

where K_i is isentropic expansion index, a_F is the gas phase speed of sound, inferring that there is no interaction with the liquid phase(which is frozen). Petr considered the effect of frequency on the sound wave speed. As seen in Fig.1.8, acoustic velocity approaches a_F as frequency is increased. For reduced wetness fraction and increased density of the gas phase, the mixture tends towards the single-phase acoustic speed a_F. This is used in this thesis.

CHAPTER II

INTRODUCTION

The behavior of a horizontal thin liquid film driven by interfacial shear from a cocurrent high-velocity subsonic, low-pressure wet steam flow and its subsequent break-up in the wake of a simulated turbine blade into relatively large droplets have been researched in detail. Conditions are nominally adiabatic.

The results include the identification of several wavy film regimes under various flow conditions, and the construction of a flow-regime transition "map". Important parameters governing the different map regimes, such as film thickness and the detailed wave characteristics like amplitude, form, and propagation celerity, have been measured using electrical conductivity microgages and high speed photography including both still and motion picture. Author's experimental results concerning the critical parameters controlling the transitions between regimes, and the wave characteristics have been compared to other studies in the literature. Where important discrepancies exist between analytical and experimental results of other investigators and author's data, new theoretical analyses or plausible sources of the discrepancies have been suggested.

Liquid phase behavior in the blade wake is highly important, having obvious direct application to the steam

turbine blade erosion problem. Measurements of the "liquid finger" characteristics and the observed periodic decelerations of large droplets are "firsts" from this study, as are the detailed high-speed motion pictures. Due to the overall complexity of the problem and non-existence of previous comparable experimental or analytical results in many cases, much of the experimental data have been reduced using dimensional analysis, rather than direct solution of the required differential equations.

The following sections are descriptions of author's overall results, including pertinent literature surveys. They consider primarily two subjects: 1) the behavior of the liquid film flow and 2) the formation of "liquid fingers" and secondary "droplets", and their subsequent trajectories. These phenomena are of major importance for the erosion-resistant design of the subsequent rotating turbine rows. Some results are also pertinent to the "loss of coolant accident" of liquid-cooled nuclear powerplants such as PWR.

A. FILM FLOW

As explained in previous chapter, understanding of the thin liquid film behavior on turbine stator blades, and its subsequent break-up into liquid droplets, are essential to improved steam turbine blade design, concerning particularly erosion. However, besides the steam turbine application, the study of such liquid film flows has many other important applications. Conveying of liquids by co-current gas

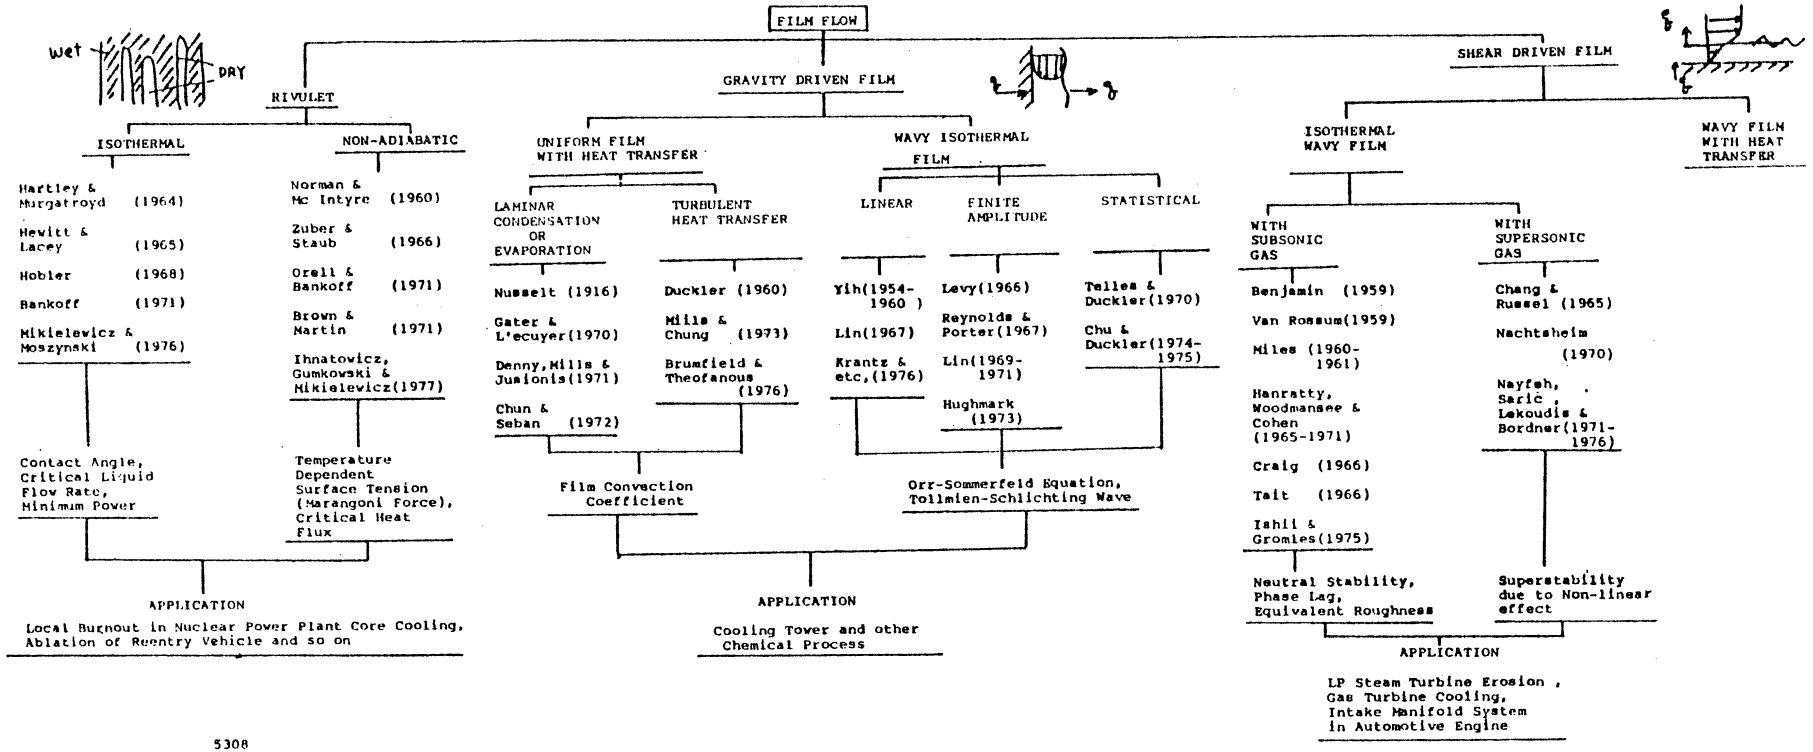
streams in oil pipelines, "loss of coolant accident" and emergency core cooling in liquid-cooled nuclear reactors, internal boiler tube flow, transpiration cooling systems for re-entry vehicle nose cones are pertinent examples. The family of liquid film flows is categorized in Fig. 2.1 .

To allow a study of this range of phenomena and applications, a high-velocity, low-pressure, wet steam tunnel had been designed here and constructed. A simulated turbine blade (in this study, a thin flat plate, Fig. 3.3) is inserted parallel to the flow direction along the axis of a transparent rectangular test section. For film thickness measurement, electrical conductivity microgages were developed,[M10] calibrated and installed at various suitable locations flush with the blade surface. The various attainable film flow regimes, together with wavelet characteristics, were observed using both high-speed cinematography and a still polaroid camera with a 1.2 μs flash and flood lights.

Most previous investigations involving film thickness measurements were for relatively large film Reynolds numbers, because of their interest in relatively thick liquid films occurring in pipe flow applications,(Fig. 2.2). Author's film Reynolds number (pertinent to the steam turbine case) is very low ($Re_f < 56$).*

As injected liquid film flow rate is increased from zero at fixed steam velocity, various film-flow regimes have been observed here. A film-flow "map" from this study is thus

*Based on surface film velocity and mean film thickness.



5308

Fig. 2.1 Categorization of Liquid Film Flow Study

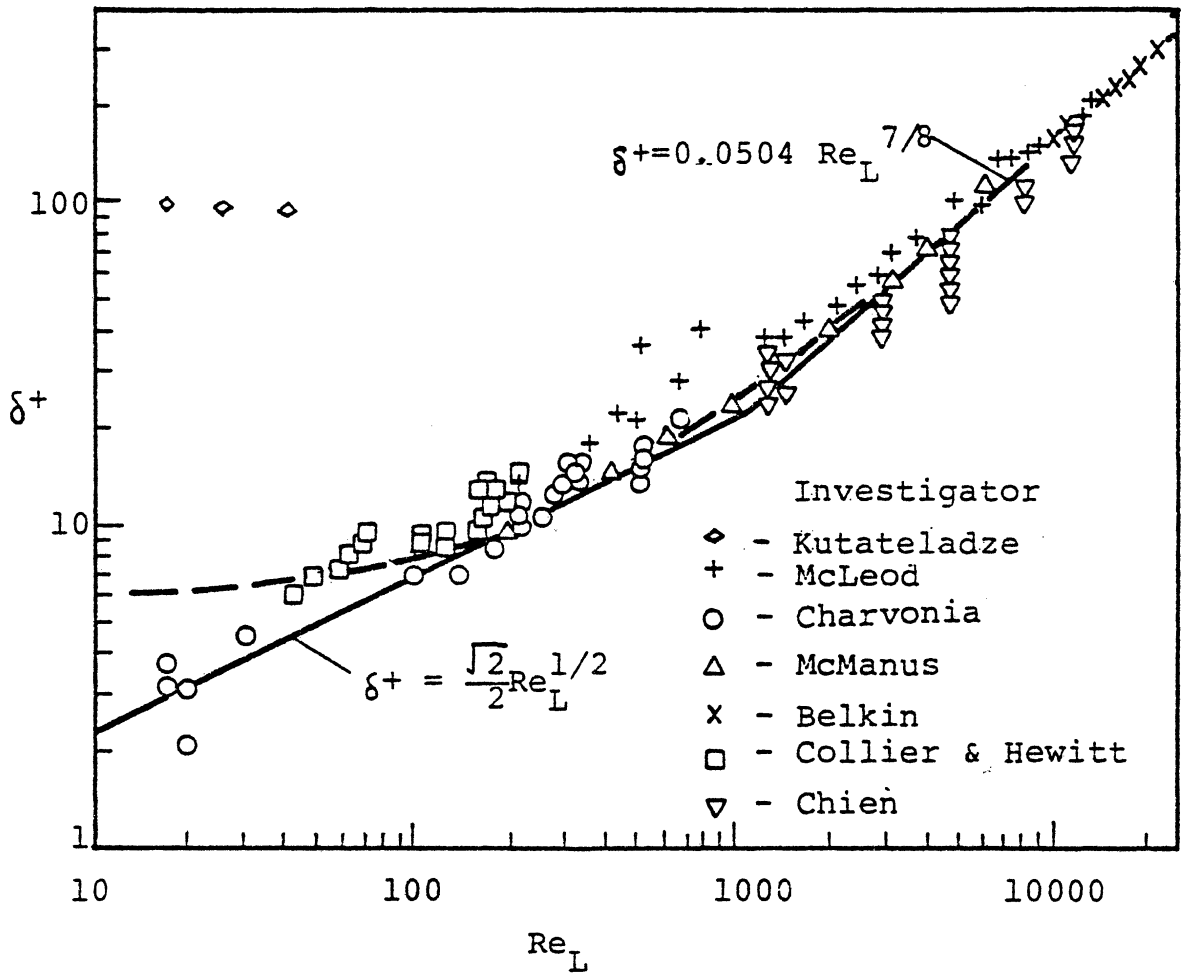


Fig. 2.2 Liquid Film Thickness Measurement Data
(Kosky, 1971 (K 10))

presented here. The film flow regimes are;

i. Rivulet flow (partly dry and partly wet)

ii. Two-dimensional wavy film (small wave)

iii. Three-dimensional wavy film (large wave)

iv. Entrainment regime (droplet formation at the crest of waves)

1. Rivulet Flow Regimes

The transition between regimes (i) and (ii) is of particular interest for safety considerations of nuclear powerplant core cooling (dry-spot formation) as well as to turbine stator blades at the low pressure end.

Hartley and Murgatroyd's analysis[H2] in 1964 was the first attempt to predict a critical liquid flow rate and thickness corresponding to continuous film break-down into rivulets. The mechanism initiating such dry patches was not discussed. The study was concerned rather with whether once a dry patch is formed, will it remain dry or become rewetted. They suggested two criteria. One was based on a force balance at the upstream stagnation point of a dry patch; the other on a minimum total power criterion based on kinetic and interfacial energy in a transversely unrestrained stream. Their minimum power criterion did not include any influence of the contact angle, which since has appeared to be very important in this regard.

Based on Hobler's analysis[H3], where a minimum power criterion allowed for the effect of contact angle, Mikielewicz and Moszynski[M3] suggested an improved criterion.

Both Hartley-Murgatroyd's force balance (H-M) and the Mikielewicz-Moszynski models (M-M) included contact angle criteria. Comparing with author's experimental minimum flow rate criterion, contact angle, θ, needs be $\sim 6°$ and $\sim 10°$ respectively for these models to be compatible with author's data. The static contact angle between a stainless-steel plate and a water droplet (in air) is believed to be $49 \pm 4°$. (H4) However for a single curvature such as in the case of a rivulet, the measured angle (M15) was found approximately half of that static angle. Anyway the wetting angles necessary to make the H-M and M-M models realistic are too small to be exactly valid. Of course contact angle is dependent on surface conditions, i.e., roughness, cleanliness, etc. and also on gas phase. Such aspects were not considered in the theoretical analyses.

Author's photographic studies (Fig. 4.1), show an abrupt liquid bulge just upstream of the stagnation point for a dry-patch. Some analyses (M12,I1) mentioned this particular geometry. This may be partially responsible for the large discrepancies in contact angle between observation (M15) and requirement to match the H-M and M-M criticality models.

Non-Adiabatic Dry Patch Formation

For cases with strong heat flux, Zuber and Staub (Z1) considered surface tension variation with temperature. Orell and Bankoff (O1) added the liquid pressure due to the thrust of evaporating molecules. Both these analyses are based on the Hartley-Murgatroyd model. (H2) These studies are not direct-

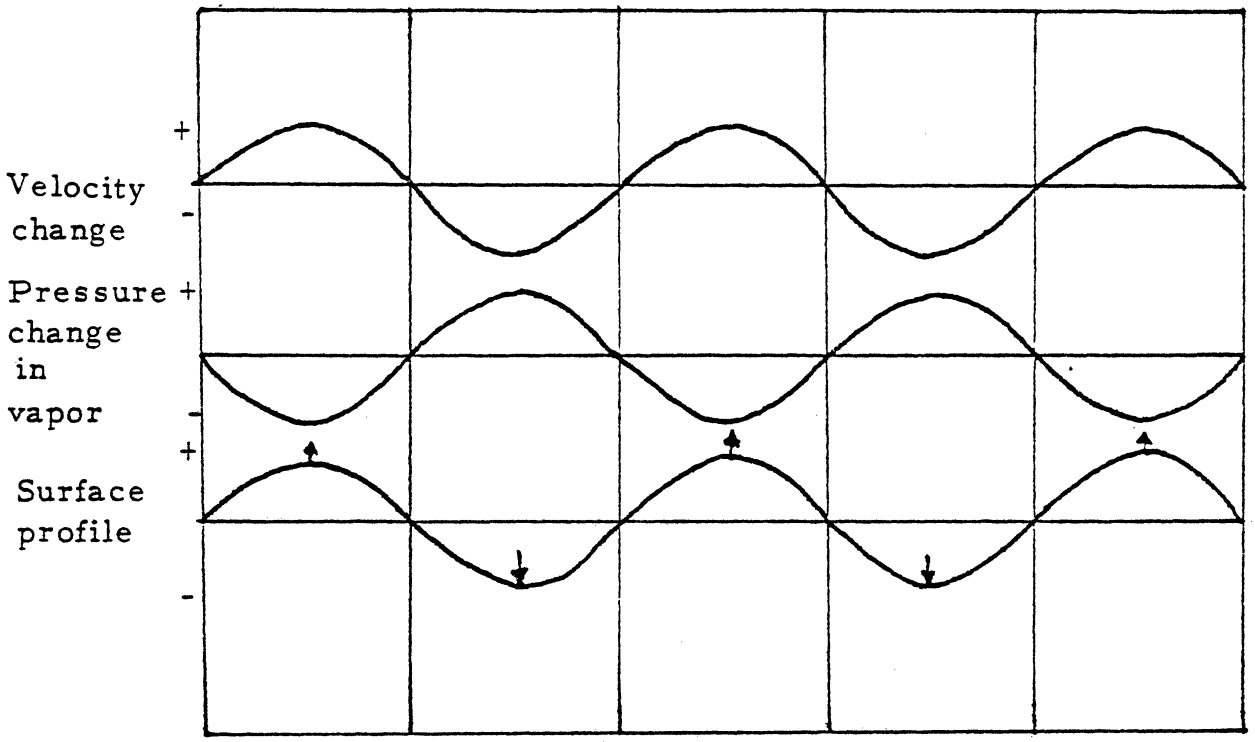
ly applicable to author's case which was nominally adiabatic.

2. Wavy Film Regime

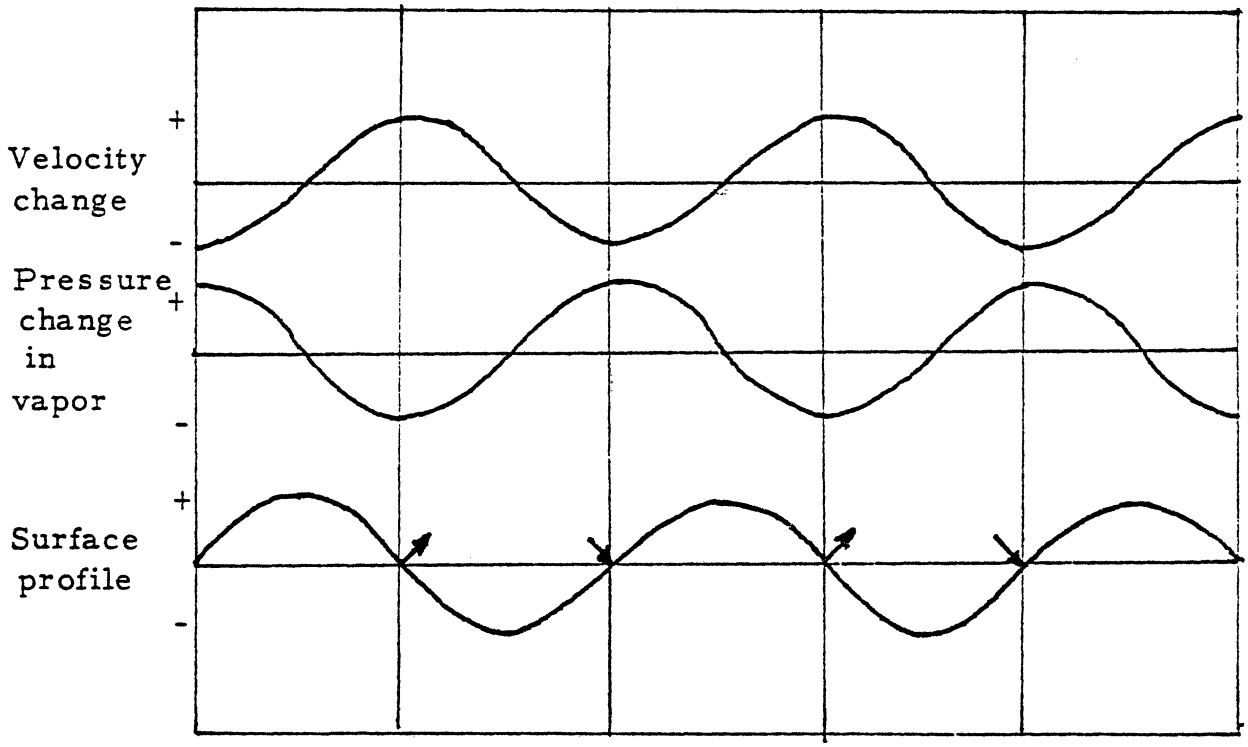
If liquid flow rate is further increased at fixed steam velocity, the blade surface is completely wetted and the dry patch or rivulet regime no longer exists; rather a wavy film regime appears. This is shown from author's photographic results confirmed by film thickness gage output. The interaction of the external driving vapor flow with the liquid interface produces two important effects. The first is the establishment of a velocity profile in the liquid due to the shear stress at the liquid-vapor interface. The second is the action of perturbations in the normal and tangential stresses exerted by the vapor due to the appearance of waves.

The main steam flow may be considered inviscid because of the high Re ($>10^5$). In our case it is also subsonic ($M < 0.8$). The pressure perturbations in the liquid are then in phase with the amplitude of the surface waves. In fact the pressure perturbation from the vapor would be 180° out of phase with the wave amplitude due to the resultant vapor streamline curvature. Thus there is an energy transfer from the vapor flow to and from the wavelets in the liquid layer (Fig. 2-3a). This is the classical Kelvin-Helmholtz instability mechanism for wave formation. In real cases, however, the pressure distribution in the liquid is not, in general, precisely in phase with the surface wave amplitude.

As seen in Fig. (2-3b) the perturbation distribution upon the profile slopes leads to a resultant stress in the



a) Kelvin-Helmholtz Mechanism
pressure changes lag surface profile by π



b) Pressure changes lag surface profile by $\pi/2$

Fig 2-3: Velocity and pressure changes in flow over wavy surface.

flow direction, and does work on the waves. This interfacial stress, derived from the normal pressure distribution near the boundary, is sometimes called "form drag".

Since the behavior of the liquid film is largely governed by stresses exerted upon its surface by the vapor flow, good estimates of these stresses are obviously desirable. In general, the vapor stream is turbulent, and consequently random fluctuations of stresses exist at the liquid interface. Although the resonant response of a liquid surface to random pressure fluctuations is important in the generation of ocean waves[P5], such a resonance mechanism is not important in the author's present problem, since the convected velocities of the vapor flow fluctuation are always much greater than the wave velocities in the liquid film. Thus only a very weak response of the surface is possible.

The surface stresses produced by interaction of the mean steam flow with small periodic perturbations of the boundary surface have been evaluated by Miles[M4,M5,M6] and Benjamin[B4] for mean vapor-velocity profiles of the boundary-layer type. However, their approaches lead to great mathematical complexity.

Miles[M4] proposed the "Tollmien-Schlichting" instability mechanism for large film Reynolds number. In this mechanism, the unstable disturbances receive their energy from the mean flow of the liquid layer, rather than from the vapor, by way of the Reynolds stresses in the liquid near the wall. The disturbances receive their energy either from the mean flow

of liquid or vapor depending on whether the wave speed is less than or greater than the interface velocity. Miles concluded that a necessary condition for instability, assuming a Tollmien-Schlichting mechanism, is $Re_f > 203$. Saric and Marshall[S2] verified this mechanism experimentally for supersonic gas flow, and concluded Re_f must be >100 for this mechanism to occur.

The analysis and experiments of Craik[C10] with an incompressible air flow showed that thinner films may be more unstable than thickner ones. His expression for shear perturbation in phase with wave slope is inversely proportional to film thickness; the thinner the film the larger the shear perturbation. Because of this thin film consideration, author's experimental results can best be compared to Craik's model.

The analysis of Nayfeh and Saric[N3] extended Craik's work to include an arbitrary body force. External flow was supersonic and a long-wave analysis was used. A simple relation between the wave speed and growth rate was derived. This author's vapor velocity is subsonic. However an interesting result was reported for the supersonic vapor flow case. Nayfeh and Saric's non-linear analysis[N4,N5] showed that stable linear disturbances die faster whereas unstable disturbances achieve steady-state amplitude instead of growing indefinitely if disturbance boundary layer is larger than subsonic boundary layer. This was verified experimentally[S3] by observing no liquid removal even for supersonic gas flow.

3. Entrainment Regime

From author's photographic study, for higher steam velocities, as liquid flow rate is further increased, the waves grow and crests are broken, much like ocean "breakers". Droplets are then shed from the wave crests into the vapor flow. From the viewpoint of turbine blade erosion, this entrainment mechanism, at least the parameters controlling its inception, is important. Since the entrainment takes place along the stator blading or casing wall, the flight time of such entrained droplets is different from those generated at the trailing edge.

Experimental inception criteria for droplet entrainment in horizontal two-phase film flow have been measured by many (V2,W2,W4) and numerous inception criteria for vertical pipe flow have also been proposed by others.(C16,S4,G7,G8) All of these used air-water, relatively high film Reynolds number ($Re_f > 100$) and low gas velocity. The tests were generally performed in low velocity wind tunnels.

Attempts(W5,H6) have been made to correlate the various data available. However, these were empirical and fit only the limited range of data used. In general these do not fit the high-velocity, thin-film data of present interest. Results are conflicting due to effects of flow orientation, i.e., horizontal, or vertically up or down. Zhivaikin's data(Z2) shows that the inception of droplet entrainment depends on flow direction at low liquid Reynolds number, while Wallis(W7) indicates that onset is independent of flow

direction.

An extensive entrainment inception model was proposed by Ishii and Grolmes.[I2] Based on Zuber's analysis,[Z1] they considered the wave amplitude and flow within the wave crest. They assumed that the interfacial shear force at the top of the wave induces an internal velocity of same order as film velocity, and that the velocity of the wave crest with respect to the film is proportional to film velocity. Using Hughmark's correlation[H6] for the effective interfacial friction factor, they concluded that critical non-dimensional vapor velocity for entrainment inception is proportional to $(-\frac{1}{3})$ power of film Reynolds number for relatively thick films ($Re_f > 160$). For low film Reynolds number flow they speculated upon the similarity between Hinze's critical droplet disintegration mechanism[H8] and their entrainment inception. They concluded that non-dimensional vapor velocity for entrainment is proportional to $(-\frac{1}{2})$ power of the film Reynolds number. Compared to author's experimental results, their correlation for low film Reynolds number criterion is high.

B. LIQUID FINGERS AT BLADE TRAILING EDGE AND SECONDARY DROPLET FORMATION

Liquid films formed on the stator blade can be partially removed by suitable separators or by the entrainment mechanisms already discussed. However, the remaining film is entrained by shear force of the driving vapor from the blade trailing edge, forming into "secondary droplets" in the steam wake.

The liquid droplet motion in the wake near the trailing edge is very important to the erosion problem, controlling the upper size limit for drops reaching the rotor blade. Since the erosion potential of droplet impact increases strongly with droplet size [P6,S9], this is an extremely important question for blading erosion.

1. Formation of Liquid Fingers

In author's experiment, liquid film detachment from the trailing edge is never continuous, but appears as discrete "fingers". An extensive study of the time-averaged shape of such fingers, together with the time parameters involved in the frequency of finger formation has been made. It is important to secondary droplet formation, directly pertinent to blade erosion potential. Surface tension, together with shear, inertial forces and film flow conditions at the trailing edge are governing parameters for finger behavior.

Axial finger length and finger wave length (distance between fingers) as function of time have been measured from numerous high-speed motion pictures for the various steam and liquid flow conditions. The frequency for the formation of longer fingers was especially studied, since these are of particular importance from the erosion viewpoint, transporting large slugs of liquid into the path of the next rotating row.

Dimensional analyses were used to study the effects of surface tension, inertial and viscous forces of the vapor

and liquid flow on the frequency of formation of the longer fingers and wave lengths of fingers. It is shown that Strouhal number based on formation frequency, finger length and liquid film velocity decreases with increasing steam Reynolds number.

2. Acceleration of Secondary Droplets

When droplets are detached from the fingers, they are accelerated by drag forces due to vapor flow in the wake region. Information concerning droplet acceleration is most important, since the closer the droplet velocity appoaches steam velocity, the less their erosion potential, since impact damage is a strong function of normal velocity alone.(P6)

Many studies of liquid droplet acceleration have been motivated by aircraft and missile rain erosion problems. In such cases the velocity is supersonic, so that droplet desintegration is influenced by shock-wave patterns. Thus the trajectories and acceleration of droplets just after passing through a shock wave is of interest.(L7,S5,S6) Nevertheless, an important, partially unknown parameter is the drag coefficient for droplets as a function of Mach number and shape. This of course is also a function of drop Reynolds number. Empirical or theoretical drop or bubble drag coefficients have been reported because of their importance in heat and mass transfer.(A1,C14) All of these drag coefficient correlations considered single droplets with external gas or vapor flow. Also of interest is the drag coefficient for a drop in the presence of other drops

of varying sizes. Tam[T2] derived a formula for the drag exerted on a cloud of spherical particles of a given particle size distribution at low Reynolds number. Based on the statistical concept of distributed particles, he concluded that the drag experienced for a particle depends only on the first three moments of the distribution function.

None of these correlations can be directly applied to author's particular case, because author's flow regime is the wake region of a tapered flat blade. Author's experimental droplet accelerations, when plotted as a function of time, show periodic abrupt changes, i.e., an accelerating droplet suddenly decelerates, sometimes reverses direction, and then accelerates again. This observed phenomenon can best be explained by the trailing vortices shed from the blade, similar to a Karman vortex street. The presence of a discrete vortex near a droplet would produce an induced velocity field which may be responsile for the observed changes in droplet acceleration. The periodic vortices shed from the droplets themselves may also be important. A very similar observation is reported by Tyler and Salt[T4] for solid spheres in free-flight. The periodic behavior is assumed due to Karman vortices shed from the spheres.

3. Break-Up of Droplets

In the higher steam velocity ranges, the disintegration of the droplets was found to occur more rapidly. Author defined the break-up time, t_b, as the duration from the time when discrete droplet forms from fingers, to the time when

the droplet becomes amorphous or disintegrates. Non-dimensional break-up time based on initial drop diameter and vapor flow conditions was found to be approximately inversely proportional to the droplet Weber number.

CHAPTER III

EXPERIMENTAL FACILITY AND MEASUREMENT CONDITIONS

A. STEAM TUNNEL GENERAL

Figures 3.1 and 3.2 are a schematic and a photograph of the low pressure wet-steam tunnel facility, "Wet Steam Tunnel," at the University of Michigan. This wet steam tunnel was designed[K5,H9,H10] to produce flow parameters in the test section which would generally match the average steam parameters in the last stages of large steam turbines.

Mean static steam conditions in the test section are near saturation, probably never superheated, showing varying degrees of moisture depending primarily upon test section velocity,(Table 3.1).* Of course, wetness increases with velocity head for fixed supply conditions. Actually in many cases, upstream of the throttle valve has rather low quality (almost hot water according to pressure and temperature measurements at the upstream orifice under low flow conditions). However, after traversing the valve, water is trapped in the "stilling tank" so that the quality of steam reaching the test section is still nearly dry. This is confirmed by the fact that water build-up is not observed on the blade or in the test section. The test section temperature (which is almost stagnation temperature) does cover a certain temperature range (usually decreasing as steam flow rate is reduced). It is assumed for present purposes that supply conditions are constant, though this is not precisely true.

*These are "typical" conditions, not entirely accurate.

Fig.3.1 Facility Schematic

Table 3.1 Thermodynamic Operating Conditions of Steam Tunnel

The supply is from the building heating boiler. No actual measurements of steam quality in the test section have been made, but only conventional thermodynamic calculations. However, precise knowledge of test section steam wetness is not of great importance for present purpose, where liquid film is injected and conditions are nominally adiabatic.

Test section steam velocity can be measured either by a Pitot tube installed in the test section or by the upstream orifice. Once agreement between these devices was established, only the flow orifice was used, to avoid the flow perturbations caused by the presence of the Pitot tube. The relationship used for measurement of steam velocity is as follows:

$$U_s = \frac{W_w \, v}{3600 \, A_c} \qquad (3.1)$$

where:

U_s = bulk average steam velocity, in the test section (ft/sec)

W_w = mass flow rate of steam (lbm/hr)

v = specific volume of the steam (ft^3/lbm)

A_c = cross-sectional area of the test section (ft^2). For the present geometry $A_c = 0.069$ ft^2. And from the handbook, "Principles of Flow Meter Engineering" (S10).

$$w_w = 2781.72 \left(H_{hg} \left(\frac{P_2}{T_2} \right) \right)^{1/2}$$

where

H_{hg} = manometer head, inches of mercury

T_2 = steam line temperature (°R)

P_2 = saturation pressure at the steam line temperature (lb/in^2-abs.)

More details of the steam flow measurement and related data reductions are available in reference.[M9]

Static pressure was measured along the side wall of the test section. Three pressure taps were installed; the first opposite the leading edge of the blade, the second 11.5 cm downstream with respect to the leading edge, and the third 25.5 cm downstream from the leading edge (5.5 cm downstream of the trailing edge). These static pressures were read using a precision Heise gage as negative gage pressures. Ann Arbor atmospheric pressure of course varies from day to day. The average pressure, however, is 14.3 psia (9.86×10^4 N/m^2). Thus the average absolute test section static pressure ranged between 1.2 and 1.3 psia (0.83×10^4 and 0.89×10^4 N/m^2). One thermocouple was embedded flush with the side wall of the test section. The temperature reading obtained there was always higher than the saturation temperature corresponding to the test section pressure. This positive temperature differential is of course due to the boundary layer recovery of part of the kinetic temperature in this high velocity steam flow near the wall.[S8]

Average parameters in the test section, i.e. position #4 of Fig. 3.1 are:

P_4 = 0.09 bar	(1.25 psia)	test section pressure
T_4 = 43°C	(109.4°F)	saturation temprature at P_4
X_4 = 0.95		estimated steam quality
v_4 = 16 m^3/Kg	(256.47 ft^3/lbm)	steam specific volume

$U_{s\ max}$ = 335 m/s (1100 ft/s), maximum obtainable steam velocity

The test section (8 cm x 8 cm x 100 cm) is constructed of clear transparent plastic (Lexan) which allows the necessary photographic studies. A simulated turbine blade, i.e., essentially a thin flat plate with tapered ends (Fig. 3.3), with electrical conductance microgages on the blade to measure liquid film thickness, including time variations, is inserted along the centerline and parallel to the flow axis.

The design and calibration of these gages is discussed in Appendix A. The "stilling tank" (Fig. 3.1) provides a honeycomb flow straightener to produce uniform flow in the test section. The condenser is of the jet type (rather than conventional shell-and-tube design). Jets of tap water are used to condense the steam in a counterflow vertical tank. The bottom of the tank serves as a "hot-well" from which a centrifugal condensate pump takes suction. The pump then exhausts the combined flow into the laboratory drain system. To improve condensing, and hence obtain increased vacuum and steam velocity, perforated trays were installed in the condenser to produce more efficient mixing. In addition, a mechanical vacuum pump (Kinney Hi-Vacuum pump, Model KC-15) was used to increase the test section-condenser vacuum still further.

B. BLADING PROFILE AND ELECTRICAL CONDUCTANCE MICROGAGES

As shown in Fig. 3.3, a thin flat plate used to simulate the steam turbine blade was designed, fabricated

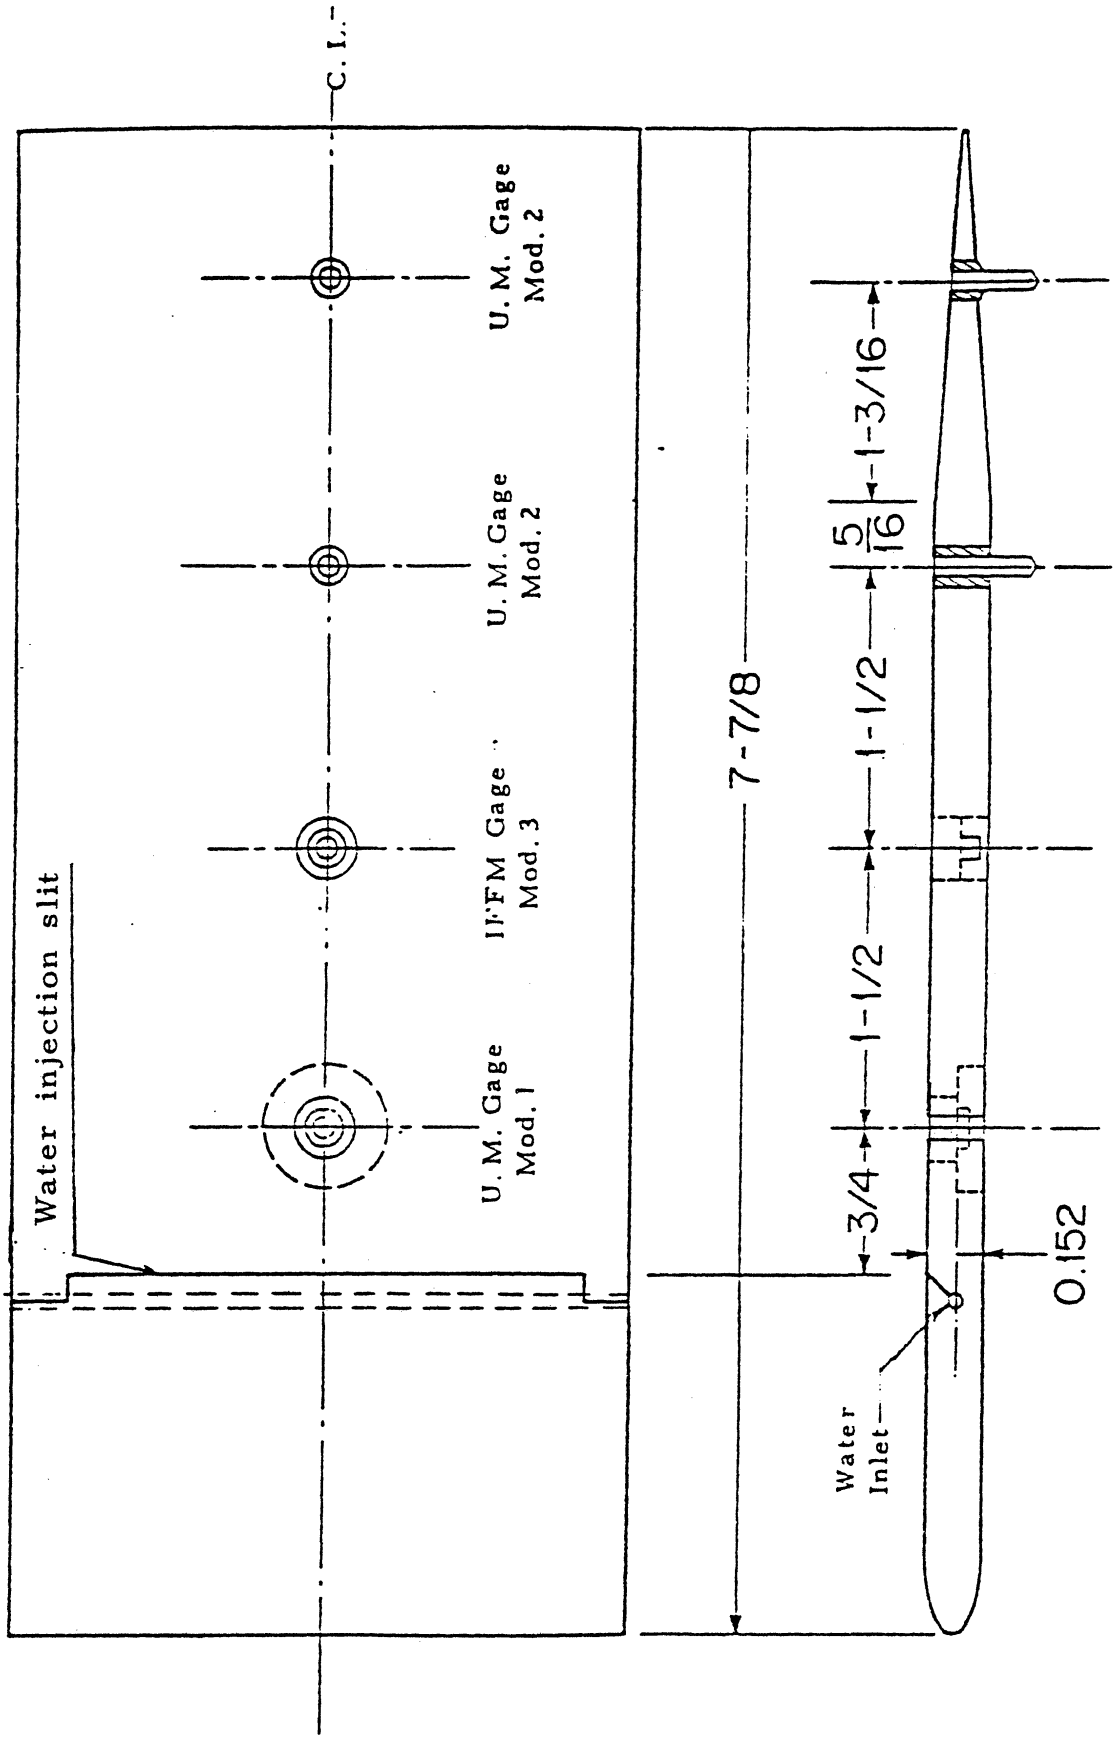

Fig. 3.3 Test Section Blade

and installed in the test section for these tests. In one version, a liquid film is injected through a small slit normal to the tunnel axis, to simulate the liquid film flow condition encountered naturally in the turbine stator blades.

Minimum film injection rate depends upon the measuring and throttling capability of the flow meter, and is 5 cm^3/min (0.625 cm^3/min-cm, "specific" liquid flow rate per unit blade width). The maximum rate used was 100 cm^3/min (12.5 cm^3/min-cm). The pressure differential for film injection from the open reservoir used is due to the vacuum in the test section (~1.25 psia) plus an elevation head between liquid reservoir and the test section.

Electrical conductance microgages were installed flush with the blade surface to measure the liquid film thickness variation with respect to time. Since detailed decriptions of gage design and calibration are given in Appendix A, only a few important aspects are discussed here. Essentially, the electrical conductance of a thin liquid film connecting the central pole of the gages with an external annulus (separated by an electrical insulator), all installed flush with the blade surface (Fig. 3.3), is measured by an a.c. circuit including a Wheatstone bridge. The output is connected to a dual-beam oscilloscope, so that the simultaneous output of two gages can be compared at a given instant of time. An a.c. circuit is used to avoid problems of electrostatic charge. While results depend somewhat on circuit frequency,(C15,H19) it was found that the response is flat

with a frequency in the range of 1 kHz (H10,F1), which was thereafter utilized. The output in terms of circuit conductivity was found to be approximately linear for small film thickness, but gage output becomes "saturated" at higher thickness (>300 μm). (M10,F1,H10,H11,H18)

Thus the useful operating range of the gages is limited to $\lesssim$ 300 μm. (See Appendix A and references F1, M10). This is sufficient for present purposes.

C. PHOTOGRAPHIC FACILITIES

Photographs were made using both a still polaroid camera (4x5 Busch precision camera, Model D) and a modified high speed Wollensac Fastax camera (WF-1) for the investigation of wavy films, finger formation, and droplet trajectories.

In the Fastax WF-1 camera, film is transported continuously past the aperture while a rotating prism, geared to film motion, produces an image which is stationary with respect to time. Individual frames (16 mm x 8 mm) constitute the 100 ft. rolls of film used. (Kodak Tri-X reversal 7278 film).

A "Wollensac-Goose" control regulates the camera motor speed. The motor continuously accelerates the film, which is initially at rest. The maximum acceleration, and hence framing rate, is determined by the film strength. Since the film is initially at rest, the framing rate changes continuously, so that the maximum framing rate occurs only near the end. The exact framing rate at a given point is determined from timing marks placed along the edge of the film using a 60 Hz timing light.

For present work, the framing mechanism was removed and a magnetic coil installed near the drive sprocket. Framing was achieved using the magnetic pickup coil, which is triggered by the drive sprocket. Pulses are then delivered to a strobo-trigger circuit (EG&G high-speed stroboscope Type 501), which fires the flash lamp (EG&G-FX2). Synchronization of camera and strobe is thus ensured at all film speeds. An EG&G stroboscopic light source which produces high intensity 1.2 μs light pulses at a maximum rate of 6,000 flashes/sec was used to reduce the exposure time per frame. Since the Fastax camera has a rated top speed of ~ 14,000 frames per sec., framing rate was limited in the present case by the flash rate of the light source, which was in fact sufficient.

The Fastax cinematography was sufficient to "freeze" all droplet and wave motions, as was the still photography used. By using the timing marks on the film, the time increment between frames could be determined accurately for the purpose of establishing wave propagation speed and droplet accelerations and break-up times.

For the still photography, two sets of flood lights were employed (Color Trans Quartz-King dual 650, Model no. 160-011). The lens settings were selected as required. Film used was Polaroid 4x5 land-film/Type 57. Typical exposure time was 5 ms with two flood lights. This relatively long exposure time was sufficient, even though much shorter exposure times were used for the Fastax. These different exposure time requirements are due to the combined effects

of light intensities and film speeds used.

D. EXPERIMENTAL MEASUREMENT CONDITIONS

The range of experimental parameters and measurements is listed in Table 3.2 below:

TABLE 3.2 - Experimental Parameters

Independent Variables	
Steam Velocity, U_s,	- 20 to 335 m/s (Mach No. = 0.05 to 0.81)
Specific Liquid Flow Rate, q	- 0.010 to 0.208 $cm^3/cm\text{-}sec$ (Re_f = 1.4 to 56.2)
Dependent Variables	
Wavy Films	(see Fig. 3.4)
Film Thickness, h,	- 1 to 10 mils (25.4 to 254 um)
Film Wave Length, λ	- 5 to 12 mm (small waves)
	10 to 20 mm (large waves)
Wave Propagation Speed, C,	-20 to 200 cm/s (small waves)
	100 to 1500 cm/s (large waves)
Finger Formation and Droplet Motion (see Fig. 3.5)	
Finger Length, L,	- 3 - 30 mm
Finger Wave Length, λ_f, (average distance between fingers)	- 2 to 10 mm
Frequency of Large Finger Formation, f,	- 8 to 16 $sec.^{-1}$
Initial Size of Largest Drop in Wake, D_o,	- 0.5 to 2.0 mm
Droplet Acceleration, A_m,	- 300 to 400 $m.sec.^{-2}$ ($\cong$ 30 to 40 g)
Duration of Large Droplets, t_b,	- 0.001 to 0.02 sec.

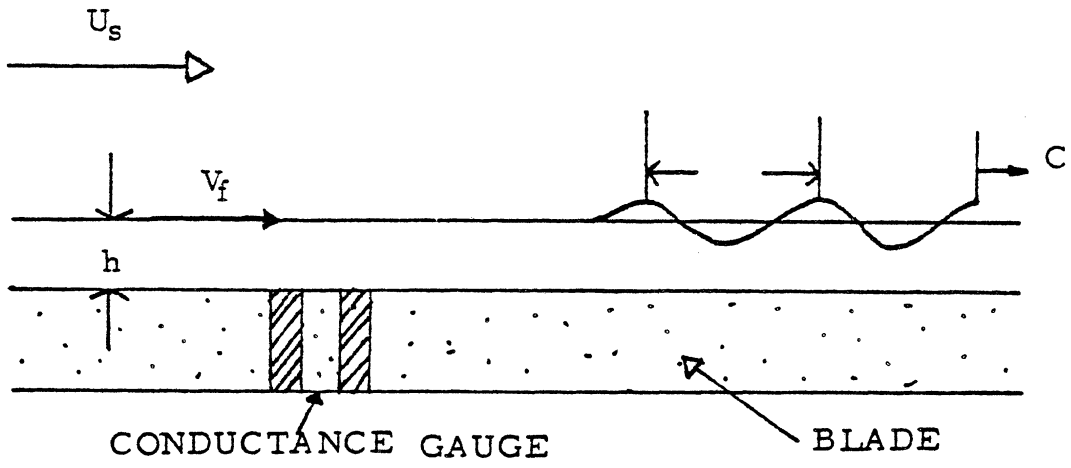

Fig 3.4 : Schematic of Wavy Film Characteristics

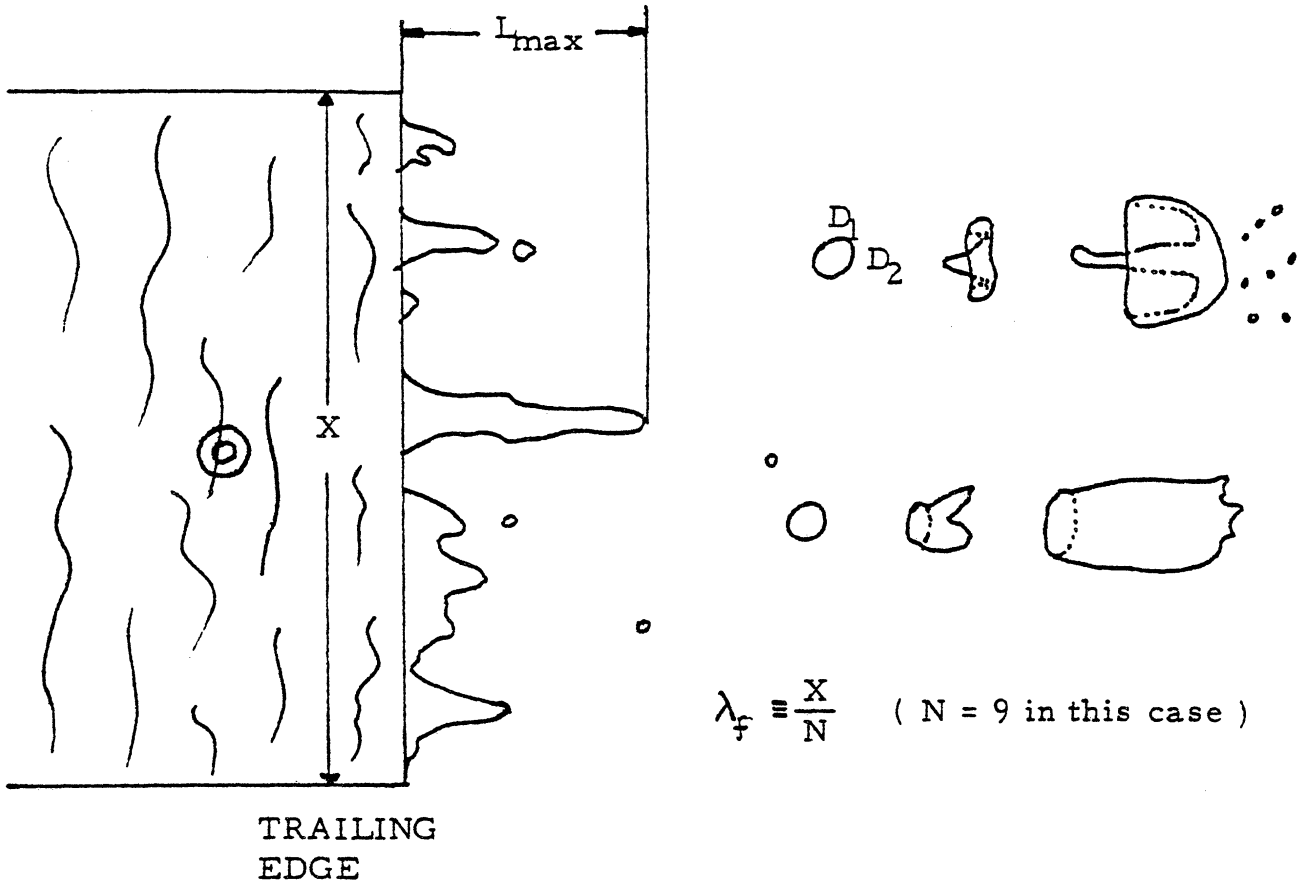

Fig 3.5 : Schematic of Finger Formation and Secondary Droplet Motion

CHAPTER IV

BEHAVIOR OF LIQUID FILM

A. VISUAL OBSERVATION OF WAVY FILM

One of the most important features of film flow are the wave patterns which appear at the free surface or interface between the liquid and vapor phases. Such wavy film flows are highly complex. Thus no satisfactory general theory has yet been evolved; rather only specialized and simplified models are available. Further, the complete experimental determination of the parameters characterizing very thin wavy film patterns, as in the present case, is extremely difficult.

To study the wavelet patterns in detail, about one thousand still photographs have been taken at various steam and liquid flow conditions, as well as $\sim$100 rolls of 100 feet length of Fastax high speed motion pictures. Oscilloscope photos of film thickness conductivity gage voltage output were taken, simultaneously with the wavelent pattern photos. The photographs of Fig. 4.1 show the various wavy film patterns for different flow conditions. For different steam velocities, the transition points between various wavy pattern regimes, as the liquid flow rate is increased, have been observed. Plate Series #1 of Fig. 4.1 show the various wavy patterns for steam velocity, U_s=30 m/s, which is the minimum steam velocity used for this investigation. Instrumentation limitations prevent the use of still lower steam velocities. As can be seen in plate 1.1 for minimum

5396

film flow ($q = 0.01$ $cm^3/cm.sec$), the liquid film on the blade is not continuous but contains "dry spots", i.e., one region is dry, and contiguous regions are covered with a thin liquid film.

To be consistent with existing literature,[M3,M8] this flow pattern is called "rivulet flow". The existence of rivulet flow requires a balance of the various applicable forces at the junction of wet and dry regions. These are due to surface tension, shear, inertia and gravity. Surface tension and shear(viscosity)are strong functions of temperature. Thus for strong heat flux (not present case) temperature dependence of these properties need be considered. The films are never waveless in author's experiments (Plate 1.1). Thus a fully realistic analysis is very difficult.

If the liquid flow rate is further increased, as in plates 1.2 and 1.3 ($q = 0.02$ $cm^3/cm.sec$), the blade surface becomes completely covered with a thin liquid film which remains relatively smooth. Plate 1.3 includes portions of both wavy and relatively smooth films.

Further increasing liquid flow rate, q, one finds more complicated wave patterns of the liquid on the blade. Plate 1.5 ($q = 0.125$ $cm^3/cm.sec$) shows relatively symmetrical wave patterns about a plane parallel to the axis, while plates 1.6 and 1.7 show patterns which are non-symmetrical about this axis. These symmetrical waves will be called "two dimensional waves", and the non-symmetrical waves "three-dimensional waves". The important differences

between these wave forms will be discussed later.

Plates of series #2 of Fig. 4.1 for a somewhat higher steam velocity (U_s = 50 m/s) are quite similar to Series #1 in showing the wavy film pattern transitions. There are, however, a few peculiar features not found in the plate #1 series. In plate #2.1, a more irregularly shaped rivulet forms than that of plate #1.1. Also, at the junction of dry and wet regions, a bulge in film thickness is observed. The bulge geometry is of interest, because of its possible influence on vapor flow patterns near the stagnation point. Hartley and Murgatroyd[H2] assumed the liquid film thickness to decrease smoothly from the up-stream value to zero at the stagnation point. The forces acting on the stagnation point due to changes in vapor flow pattern could then be relatively easily estimated. However, with an abrupt liquid bulge at the stagnation point as in author's case, the vapor flow pattern around the stagnation point becomes more complicated and difficult to estimate. Some[M12,I1] considered this geometry but did not get fully acceptable results. The significance of this particular flow geometry will be discussed in more detail in section C of this chapter.

Plate #2.2 ($q = 0.021$ $cm^3/cm.sec$) shows a relatively unique rivulet formation. There are only two dry spots, one at the center, and the other a little further down-stream near blade axis. In most "rivulet" photos, there are many rivulets along with parallel dry strips. Here also

a film thickness bulge is seen at the stagnation point. Again, there are waves in the liquid film ahead of the stagnation point bulge.

Plates #2.3 (q = 0.043 cm^3/cm) and #2.4 (q = 0.083 cm^3/cm sec) show typical "two-dimensional waves" formed on the blade. In plate #2.3 only relatively faint wave outlines are observed, while those in plate #2.4 are more clearly defined. In both photos, the wave fronts are nearly straight, and most are perpendicular to the flow direction. Since the wave length in plate #2.3 is greater than in plate #2.4, it appears that wave length decreases as liquid flow rate is increased.

As liquid flow rate is further increased, the shape of waves becomes less regular and their cross-sections attain a relatively steep front with long tail (see plates #2.5, q= 0.125 cm^3/cm sec) , #2.6 (q = 0.157) and #2.7 (q = 0.208)). Usually each such three-dimensional wave is preceded by a number of small satellite wavelets. The wave lengths from plate #2.7 are smaller than those from plate #2.6 or 2.5. Also the transverse length of the three-dimensional wave front is reduced, and consequently a more "pebbly" shape appears, as the film flow rate is further increased.

From inspection of the oscilloscope photos, the wave heights can be estimated. In a particular case (plate #2.4) the wave amplitude is ~20% of the average film thickness. It is ~100% of average film thickness in plate #2.7. The amplitude of the "three dimensional" waves is typically as

large as the mean film thickness itself.

Plates #3 are photos of wavy films for a larger steam velocity (U_s = 80 m/s). These show the same transition of wavy films as do the #1 and #2 series. Plates #3.4, 3.5 and 3.6 indicate very typical "three-dimensional" waves, with pebbly wave fronts.

Plates #4 are for steam velocity, U_s = 144 m/s. In plate #4.1 (q = 0.01 cm^3/cm sec), wavy liquid filaments are in good contrast with the adjacent dry strips. Plate #4.2 (q = 0.021 cm^3/cm sec) shows two-dimensional waves, parallel to each other and with wave fronts perpendicular to the flow direction. Further, the wave lengths are relatively uniform. Plate #4.3 (q = 0.043 cm^3/cm sec) shows three-dimensional and two-dimensional waves at the same time with relatively irregular wave lengths; i.e., waves with longer wave lengths are accompained by three or four small satellite waves.

Plate #4.4 (q = 0.083 cm^3/cm sec) also shows three-dimensional waves (with steep fronts) as well as a dry spot at the upper right of the picture. Dry spots in the vicinity of three-dimensional waves are not common. Plate #4.4 is one of a very few pictures obtained showing such dry spots near three-dimensional waves in author's entire experiment. Such a complicated wave shape in front of the stagnation point associated with the dry spot makes the analysis of this particular film breakdown phenomenon difficult.

A different phenomenon can be observed in plate #4.5

($q = 0.125$ cm^3/cm sec), i.e., a white blur apparently above the film appears in the picture. The blurred portion, though somewhat out of focus appears to be a spray of liquid. It can thus be presumed that the crest of the three-dimensional wave has been entrained into the main stream flow. This type of liquid entrainment also is observed in plates #4.6 ($q = 0.167$ cm^3/cm sec) and #4.7 ($q = 0.208$ cm^3/cm sec).

This entrainment mechanism is of considerable interest having application to many mass transfer problems in various chemical and aerospace processes, besides that of steam turbine erosion. If relatively large slugs of liquid, formed on the stator blade, are removed by this entrainment mechanism, the probability of forming large droplets at the trailing edge of the blade may be less than without entrainment beforehand. The largest droplets from the trailing edge of the blade are of order 2 mm[K4]. However droplets entrained from the wave crest are much smaller, and thus have much less erosion potential. Also they are formed further from the next rotating row. Thus they have more time for acceleration to main steam velocity, losing some erosive potential (Fig. 1.6).

Plates #5 are for steam velocity of 227 m/s. Even for very small film flow rates, (plate #5.1, $q = 0.010$ cm^3/cm sec) no rivulet flow regime was observed. Because of the limitations of the instrumentation, liquid flow rates less than $q = 0.010$ cm^3/cm sec were not investigated, but presumably a rivulet regimes would have been found there.

Plates #5.1 and 5.2 (q = 0.02) show two-dimensional waves with relatively small wave lengths. Plate #5.3 shows three-dimensional waves, while all the plates between #5.4 (q = 0.083) and #5.7 (q = 0.208) show the entrainment regimes.

Plate #6 series is for the steam velocity of 305 m/s. Trends concerning wavy film transition are the same as found in the plates #5. Plate #6.1 (q = 0.01 cm^3/cm sec) shows two-dimensional waves. Plates #6.2 (q = 0.021 cm^3 cm sec) and 6.3 (q = 0.043 cm^3/cm sec) show three-dimensional waves, and all the plates between #6.4 (q = 0.083 cm^3/cm-sec) and #6.7 (q = 0.208 cm^3 cm sec) show the entrainment regimes.

The entrainment regime pictures do not show any peculiar differences for the various steam and liquid flow conditions. Rate of entrainment is of considerable interest in light of mass transfer, but no measurements of entrainment rate were possible. Flow conditions and oscillogram scales are listed in Table 4.1.

Based on all the above, a liquid film "Transition Map" (Fig. 4.2) for the experimentally attainable steam and liquid flow conditions was made.[K6] From this map (Fig. 4.2) the wavy film regimes can be identified for given steam and liquid flow conditions. Physical interpretation of the transition zone will be discussed next in as simple a manner as possible, without losing the basic physics.

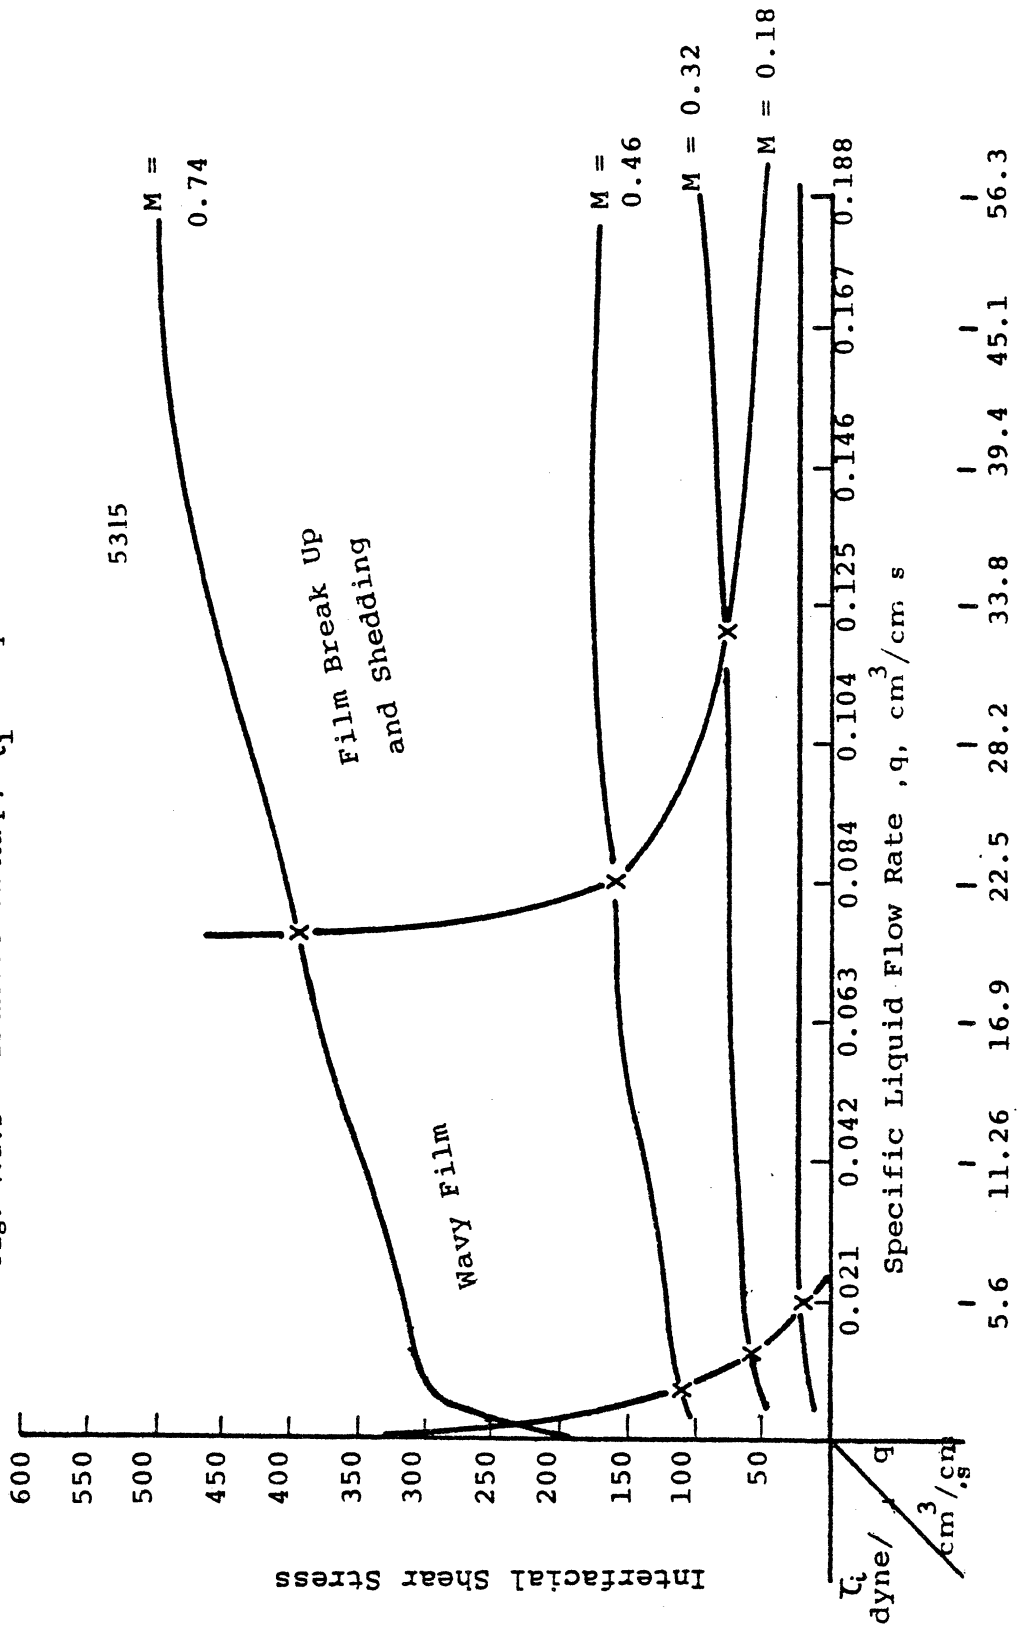

Fig. 4.2.b Transition Map, τ_i vs q

B. MEASUREMENT OF FILM THICKNESS AND ESTIMATE OF INTERFACIAL SHEAR STRESS

Liquid film thickness measurements have been made using electrical conductance microgages previously discussed. The use of a "generalized characteristic curve" to reduce the data is explained in Appendix A. Some initial film thickness measurements were already reported.[H10,H11,K7] Among the most important parameters determining the thin-film flow regime are the film thickness itself, since it is necessary to compute the interfacial shear caused by the high velocity steam flow.

The vapor flow establishes an approximate Couette-type velocity profile in the liquid, i.e. constant shear imposed at the interface. Wavelets are also initiated due to perturbations in the normal and tangential stresses exerted by the vapor. Increased flow resistance (axial pressure drop) is found when waves are present, due to their effect on "roughness". Consequently, the velocity profiles in both phases may be affected according to the different interfacial wave structures.

It is convenient to describe the effect of the interface structure by comparing the drag on the liquid surfaces with that on roughened solid surfaces. Cohen and Hanratty[C9] were perhaps the first to measure the increased drag due to wavy liquid films in terms of an equivalent sand roughness. Utilizing the "universal velocity profile" for the vapor phase,

$$U = \frac{2.303}{K} u^* \log \frac{Y+}{Z} \qquad (4.1)$$

where u* is "friction velocity", $y+ = y\ u^*/\nu$, K = 0.4 is Von Karman's constant. From Nikuradse's measurements[S8] of the friction factor and their own experiments, they concluded the ratio between equivalent sand roughness and root-mean-square wave amplitude of the liquid film (~2 mm of mean thickness) to be ~4.2. Their velocity profiles were also found to be different from those reported for flows over sand-roughened surfaces.

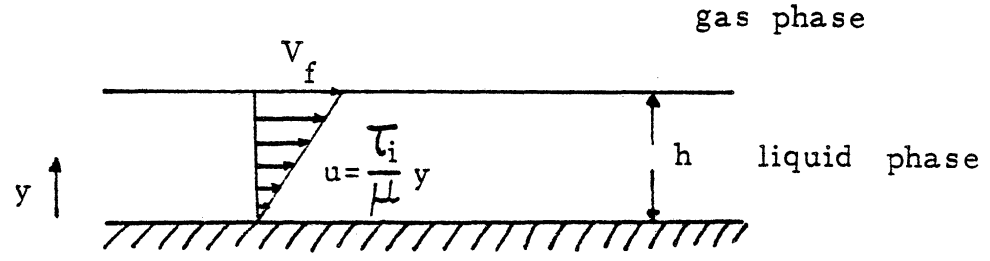
Kordyban[K9] obtained similar results from his experiments for thick liquid films (min. water depth ≅ 30 mm) in an air tunnel (max. air vel. ≅ 6 m/s).

Numerous empirical two-phase pipe flow studies are reported[L5,W7,H13] which generally present the interfacial shear stresses in the form,

$$\tau_i = f_i \frac{\rho_g V_r^2}{2} \tag{4.2}$$

where τ_i is interfacial shear stress, f_i is interfacial friction factor, ρ_g is density of the gas or vapor phase, and V_r is relative velocity between liquid and gas.

For the present study, a simple but physically defensible analysis has been made. The film thickness data from the electrical conductivity gages has been used to compute



the shear, assuming a classical constant shear, Couette flow i.e., a thin laminar film with smooth and flat vapor-liquid interface, and linear velocity profile. A film Reynolds number, Re_f is defined,

$$Re_f = \frac{V_f h}{\nu_f} \tag{4.3}$$

where V_f is the nominal average film surface velocity, h, film thickness, ν_f kinematic liquid viscosity. The velocity profile can then be expressed as

$$u = \frac{\bar{\tau}_i}{\mu_f} Y \tag{4.4}$$

where $\bar{\tau}_i$ is the effective shear stress, μ_f absolute liquid viscosity. The effective shear stress $\bar{\tau}_i$ is discussed later in detail.

Specific flow rate, q, i.e., volume flow rate per unit blade width, is obtained by integrating the velocity profile

$$q = \int_o^h u \, dy = \bar{\tau}_i h^2 / 2\mu_f$$

$$= V_f h/2 \tag{4.5}$$

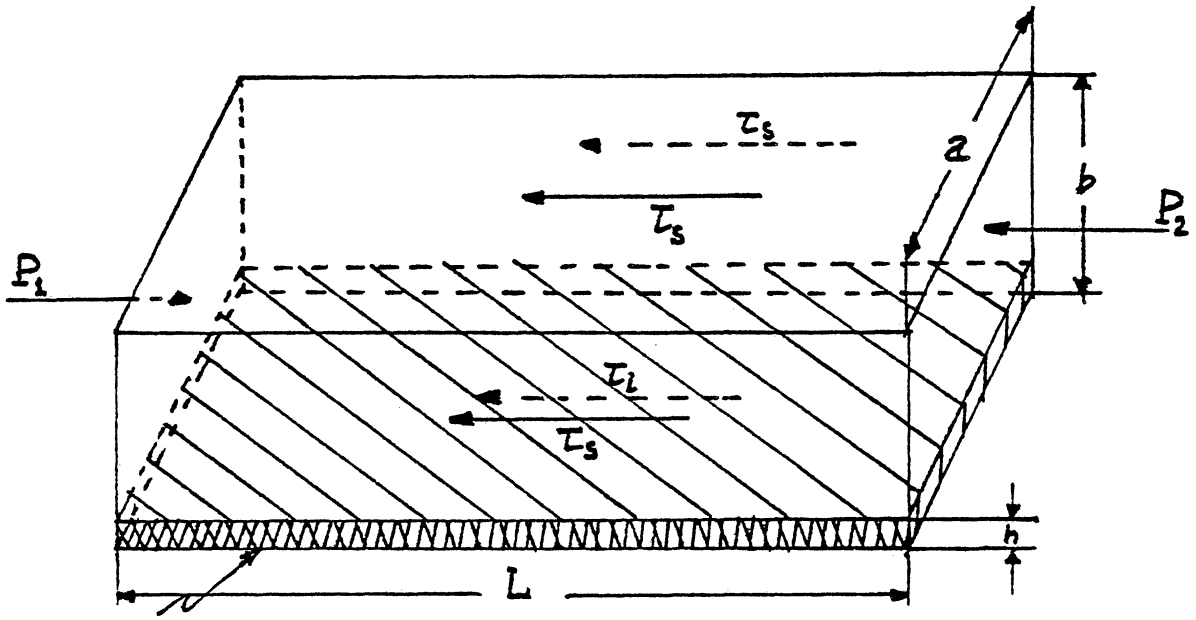
so

$$Re_f = \frac{2q}{\nu_f} \tag{4.6}$$

Then from equations (4.5) and (4.6)

$$\frac{(\bar{\tau}_i/\rho_f)^{1/2} h}{\nu_f} = Re_f^{1/2} \tag{4.7}$$

Figure 4.3 shows schematically the flow regime in the test section. The cross-section of the active portion of the steam flow channel consists of three "Lexan" plates, and the liquid film surface on the blade. Flow is from



τ_s : shear stress from smooth wall

τ_i : shear stress from wavy film

L : axial length of the section

h : average film thickness

P : pressure

Fig. 4.3: Shear stress schematic of test section with liquid film

left to right. Shear stresses exist with the three (hydraullically smooth) Lexan plates and the liquid film, which has an effective roughness due to surface wavelets in most cases. Applying an axial force balance to this geometry, one obtains the following relation:

$$a\ b\ \Delta p = (a+2b)\ L\ \tau_s + a\ L\ \tau_i \tag{4.8}$$

where a and b are the widths of the Lexan walls, L is the test section axial length considered, i.e., blade length, and ΔP is the axial pressure drop for distance L. τ_s is the shear stress due to the smooth plastic wall, and τ_i that due to the roughened liquid film. Also the pressure drop Δp can be expressed as:

$$\Delta p = f \frac{L}{D_H} \frac{\rho_s U_s^2}{2} \tag{4.9}$$

where f is friction factor, D_H is hydraulic diameter, ρ_s the steam density, and U_s is steam velocity.

If it were assumed that approximately the interfacial shear stress τ_i is the same as the smooth wall shear stress, τ_s, then

$$\tau_i = \tau_s = \tau_o \tag{4.10}$$

Combining Eq. (4.8), (4.9), and (4.10) one obtains

$$\tau_o\ 2\ (a+b)\ L = f \frac{L}{D_H} \frac{\rho_s\ U_s^2}{2} \tag{4.11}$$

Substituting the actual dimensions and conversion factors, Eq. (4.11) becomes:

$$\tau_o = 5.4 \times 10^{-3} \left(f \frac{\rho_s U_s^2}{2}\right) \tag{4.12}$$

where dimension of τ_o is lbf/in^2, ρ_s lbm/ft^3, U_s ft/sec.

To improve the precision of Eq. (4.10) separate friction factors can be considered for the walls and the film. Then, weighting f according to wetted perimeters one obtains:

$$\tau_o = 5.4 \times 10^{-3}\left(\frac{a+2b}{2(a+b)} f_s + \frac{a}{2(a+b)} f_i\right)\frac{\rho_s U_s^2}{2} \tag{4.13}$$

where f_s is the friction factor due to solid walls, and f_i to the film. f_s is a function of steam Reynolds number, Re_s, only but f_i is a function of Re_s, and film equivalent sand roughness, $\frac{\epsilon}{D_H}$; i.e., (4.14)

$$f_i = f_i\left(Re_s, \frac{\epsilon}{D_H}\right) \tag{4.15}$$

Using Eqs. (4.5) and (4.15), one obtains the equivalent sand roughness as a function of film thickness, h; i.e. $\epsilon = \epsilon(h)$. An iteration method was used, involving liquid flow rate q, measured film thickness h, steam velocity U_s, and the density and viscosity of each fluid. First results using this method have been already reported.(K7) Figures 4.4a through 4.4g show the measured film thickness as functions of steam velocity and liquid flow rate, and equivalent sand roughness as a function of average measured film thickness. Interfacial shear stress, τ_i, equivalent sand roughness, $\epsilon(h)$, and friction factor, f_i, as functions of steam velocity and liquid flow rate are listed in Table 4.2.

In Fig. 4.5 the variation of friction factor, f_i, is

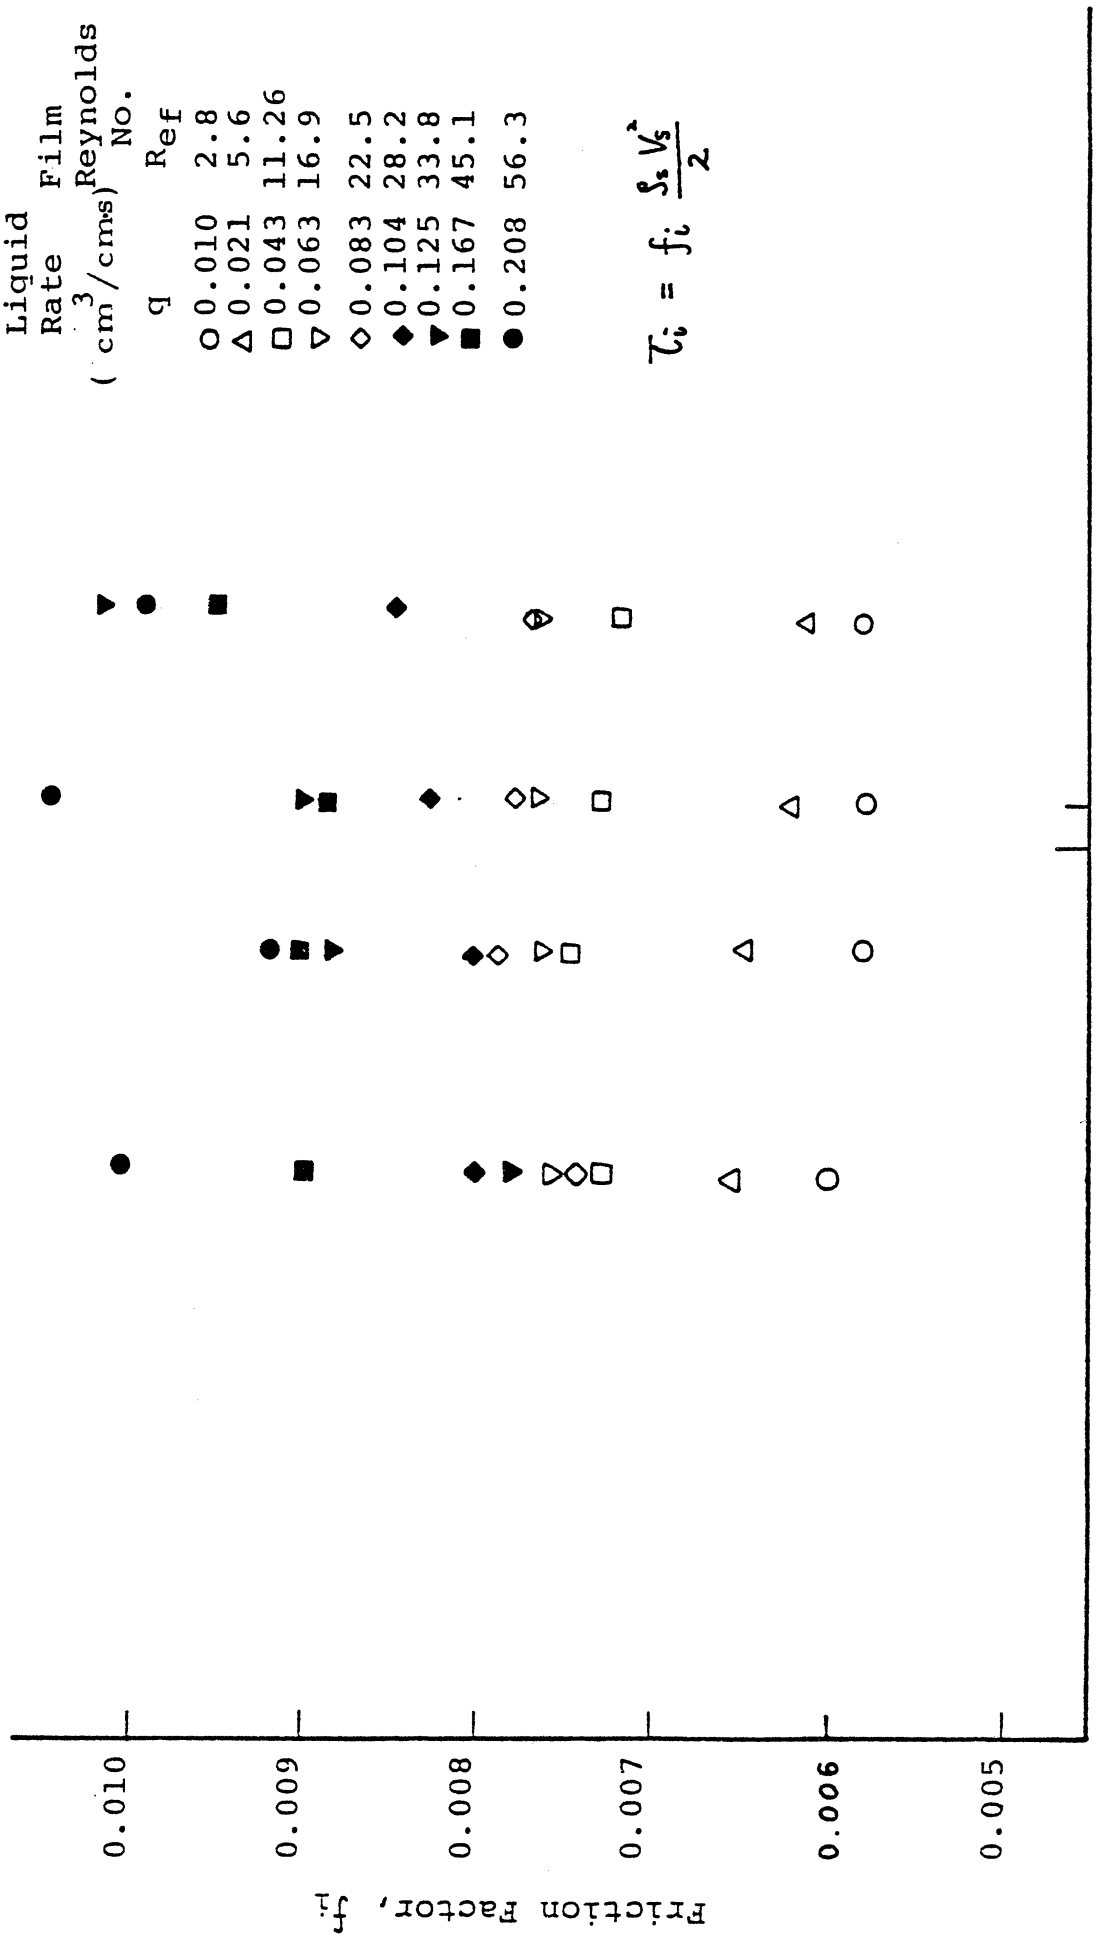

Fig. 4.5 Friction Factor vs. Steam Reynolds Number

shown to be more dependent on the liquid film Reynolds number than on the steam Reynolds number. In general, friction factor increases for an increasing film Reynolds number, Re_f. This is as expected, since film waviness and thus equivalent roughness, increase with Re_f.

For high Re_f, f_i increases for an increase in steam Reynolds number, Re_s, indicating that increased steam turbulence increases waviness, as expected. However, no direct analytical confirmation is available. Author's photographs show large three-dimensional waves and the entrainment of wave crests at these conditions. Both phenomena would likely increase effective friction factor.

In Fig. 4.6 and Table 4.3 ratios of measured to predicted film thickness, based on the smooth wall assumption, are shown. These are always smaller than 1, indicating an effective film roughness for the film, and generally increase with Re_s. The average ratio of the measured film thickness to the predicted film thickness in the author's experimental range is:

$$\frac{h_m}{h_t} \cong 0.55 \qquad (4.16)$$

for $2.8 < Re_f < 56.2$

$4.0 \times 10^4 < Re_s < 1.75 \times 10^5$

There are numerous thickness measurements for high film Reynolds number, ($Re_f > 100$), particularly for pipe flow. These are well summarized in reference (K10). However, for the low film Reynolds number range (author's case), such

thickness measurements hardly exist, even for the pipe flow case. In Fig. 4.7 a non-dimensional film thickness, $h^+ = \frac{h\left(\frac{\tau_i}{\rho_f}\right)^{1/2}}{\nu_f}$ is plotted as a function of Re_f. The form of h^+, generally accepted in most thickness measurement literature, is based on the previously estimated shear stress, τ_i. The only available data, in this low Re_f range, is from the measurements of Charvonia[C12] and Collier-Hewitt.[C13] They both studied air-water flow in a vertical pipe. This data is graphed using solid symbols, while the author's data is plotted with open symbols. The first solid line represents the ideal case, with the shear stress of Eq. (4.7) found assuming a smooth wall.

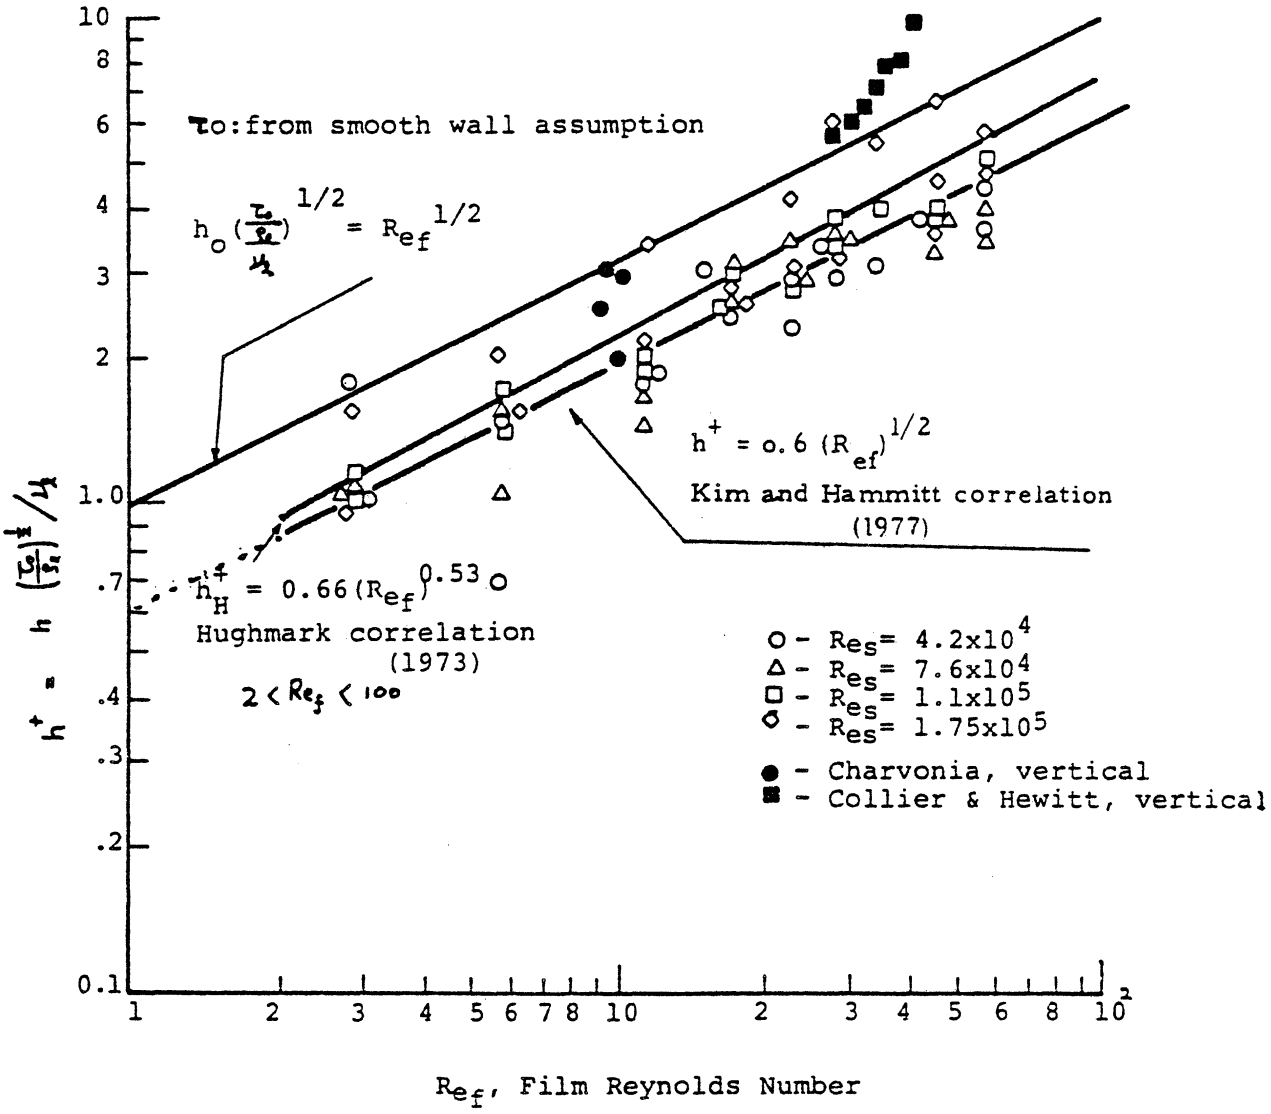
The second solid line is the empirical correlation of Hughmark,[H16] based on data obtained by others for upward flow in vertical pipes. The shear stress used in the friction velocity term for the dimensionless film thickness was not clearly specified. It appears that he used wall (rather than liquid film) shear stress.

The author's data can be correlated by the following expression, using the previously estimated interfacial shear stress,

$$h^+ = 0.6\ Re_f^{1/2} \qquad (4.17)$$

This curve is the best-fitting curve for all the data points in author's entire experimental range. Comparing with the Charvonia and Collier-Hewitt data, one finds that their non-dimensional film thicknesses are always higher than the author's data for the same Re_f.

Fig. 4.7 Film Thickness Factor as a Function of Film Reynolds Number (Comparison with Hughmark Correlation, 1973) (H6)



These deviations can be explained in that their data is for a relatively thicker film and lower gas velocity, while the author's data is for very thin films with very high steam velocity, sometimes accompanying the entrainment of liquid film.

In Fig. 4.8 author's data is plotted in terms of the Henstock-Hanratty[H7] parameter

$$F = \frac{\gamma \, Re_f}{Re_s^{0.9}} \frac{\nu_f}{\nu_s} \left(\frac{\rho_f}{\rho_s}\right)^{1/2} \tag{4.18}$$

which is a Martinelli-type flow parameter.[H7] Here.

$$\gamma = [(0.707 \, Re_f^{0.5})^{2.5} + (0.379 \, Re_s^{0.9})^{2.5}]^{0.4} \tag{4.19}$$

Their correlation

$$\frac{h}{D_H} = \frac{6.95 \, F}{(1+850 \, F)^{1/2}} \tag{4.19}$$

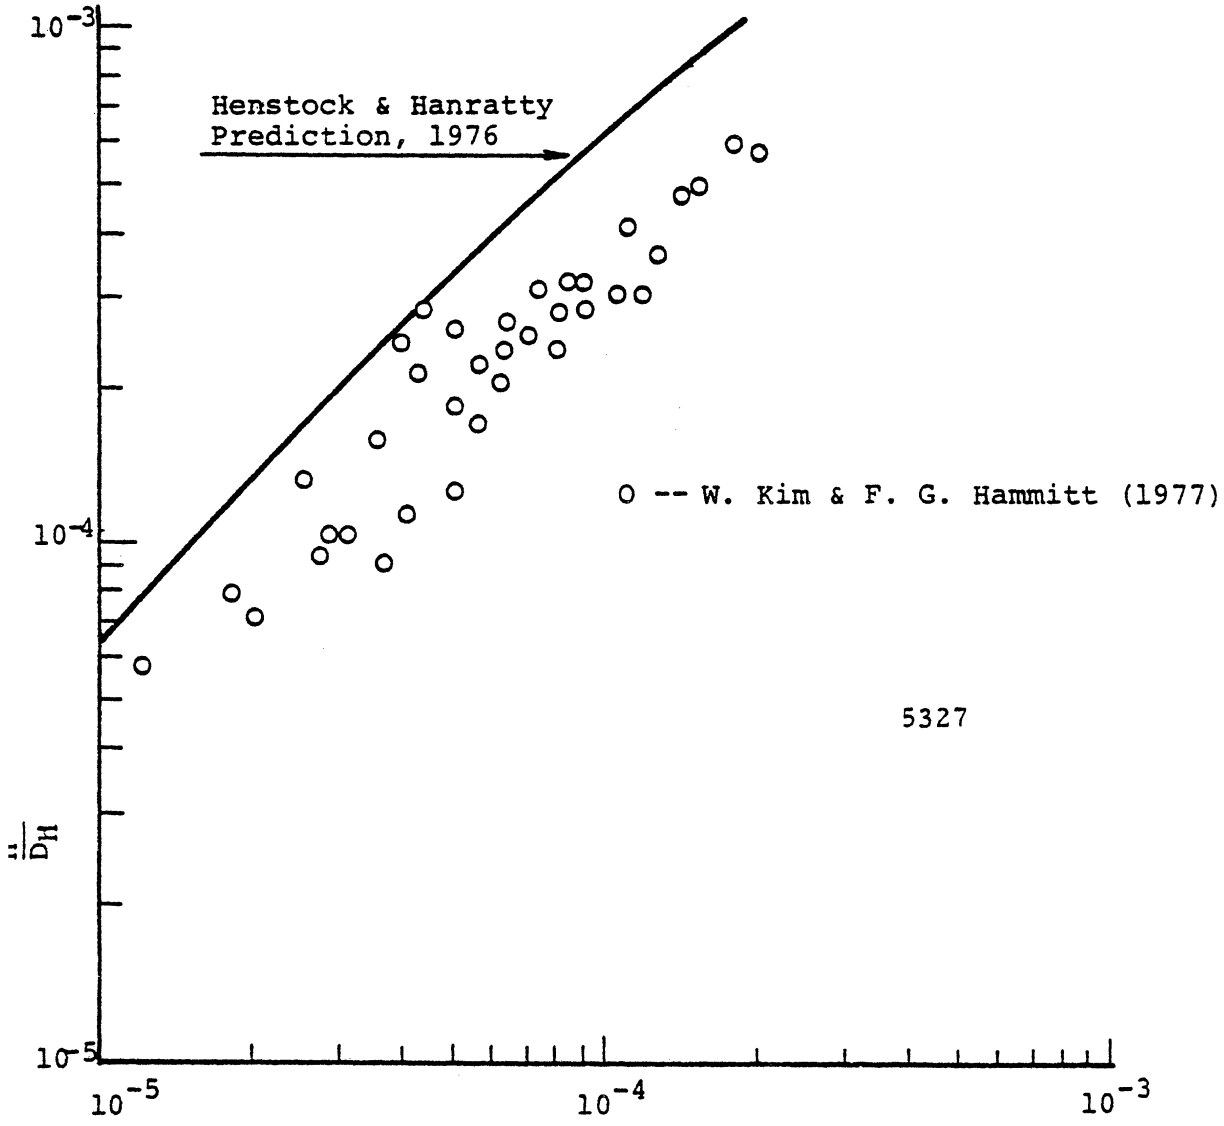
was only tentatively suggested due to the lack of sufficient data. This correlation over-estimates the author's data.

C. RIVULET FLOW REGIME

As already discussed, a thin liquid film flowing over a solid surface under an applied shear stress due to a high speed steam or gas velocity, may separate into a number of filaments (Figs. 4.1 and 4.2). Such rivulets may then occur on turbine stator blade surfaces. In such cases, the spectrum of detached droplets impinging on the next rotating row depends on the rivulet characteristics. This type of film break-up is also related to boiling "dry-spots" in

Fig. 4.8 Nondimensional Film Thickness as a Function of F
(Comparison with Henstock and Hanratty Prediction, 1976)

$$\frac{h}{D_H} = \frac{6.59F}{(1+850F)^{1/2}}$$



$$F = \frac{\gamma(R_{ef})}{R_{es}^{0.9}} \frac{\nu_f}{\nu_s} \sqrt{\frac{\rho_f}{\rho_s}}$$

$$\gamma = [(0.707\ R_{ef}^{0.5})^{2.5} + (0.0379\ R_{ef}^{0.9})^{2.5}]^{0.4}$$

emergency cooling of nuclear powerplants, as well as to various chemical engineering applications. Because of applications to numerous important engineering problems, several models describing such dry-patch or filament stability have been suggested[H2,H3,B2,M3]. These analyses are generally based on force or power balances at the junction between rivulets or dry patches and the continous film. Since the surface tension plays an important role along with the dynamic pressures of liquid and vapor flow at the stagnation junction, the relations for critical (or minimum) flow conditions for rivulet stability should include the contact (or "wetting") angle, θ, between liquid and solid. Unfortunately, θ depends heavily upon other parameters such as surface condition.

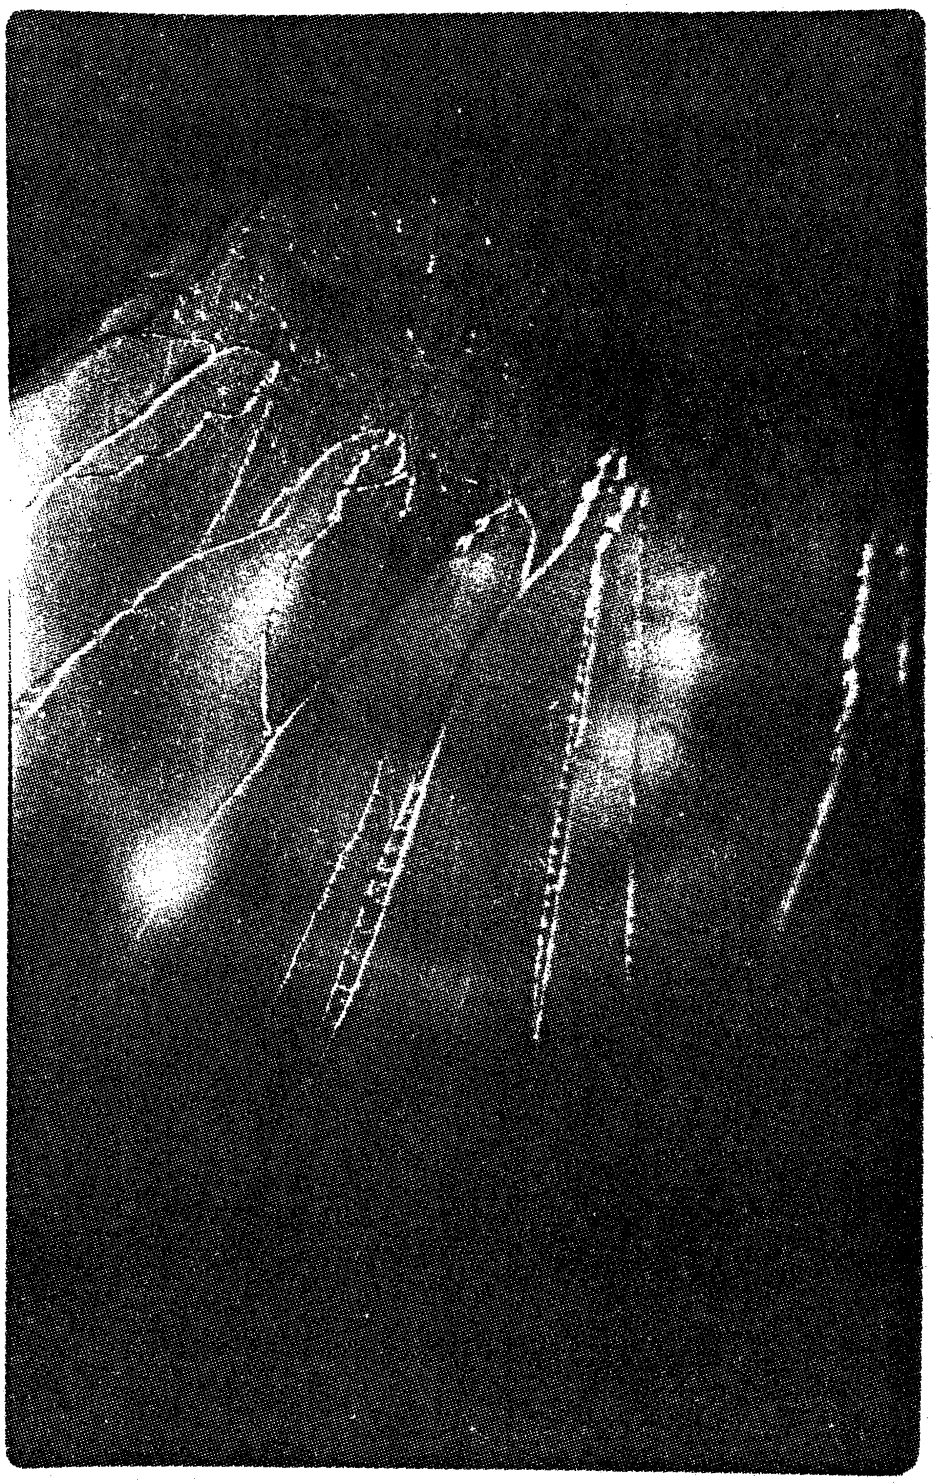
Experimental studies on the formation of rivulet flow were also conducted by Hewitt and Lacey[H4] for air-water flow in a vertical pipe. Even though their experimental geometry and flow conditions are quite different and thus cannot be directly compared with the author's experimental results, some pertinent points should be made. The upward air velocity used in the Hewitt-Lacey work ranged from 18 to 95 m/s, while the downward flow critical liquid film thickness from 30 to 210 μm. This thickness was not directly measured, but estimated using the Hartley-Robert's model[H14]. The film breakdown was studied by artificially producing a dry patch using an air jet directed perpendicularly toward the tube wall. It would no doubt have been more

realistic had they produced the rivulet or dry patches without using such an air jet.

They concluded that for the higher gas flow regime, minimum wetting rate (which Hartley and Murgatroyd[H2] used to express the minimum liquid flow rate required to re-wet the surface after the formation of a dry patch) decreases with an increase in the gas flow rate. At lower gas flow rates, however, the minimum wetting rate passes through a maximum, and then begins to decrease with a decreasing gas flow rate. They ascribed these results to a flow regime change between the climbing film regime and "churn flow", which occurs at higher gas flows in this vertical annular pipe flow. Such a maximum critical wetting rate was not found by present author.

They also observed that at liquid flow rates above the minimum wetting rate, the patch was more or less circular. Rewetting of the surface occurred in a complex manner, usually by splitting of the dry patch by filaments, followed by the disappearance of the ends and sides of the resultant secondary patches. This kind of rewetting process, Fig. 4.9, also was observed on a laboratory turbine blade.[F2]

For cases with strong wall heat flux, additional effects need to be considered. Examples are the thermocapillary effect[Z1] due to the temperature dependent surface tension and vapor-thrust effect[N1,Z1,O1] caused by surface evaporation. These models show that such thermal effects become dominant for the strong wall heat flux cases in determining



5397

Fig. 4.9 Rivulet Formation on Experimental Turbine Blade

Moscow Power Institute)

the stability of dry patches. These thermally dominated situations are most directly applicable to the nuclear power plant "loss of coolant accident" (LOCA), while the isothermal considerations of stability of dry patches are directly pertinent to the steam turbine problem here emphasized.

No new analytical model was developed by author since many models already exist. The need for better experimental data seemed more pressing. However, some modifications of existing models are suggested in the following discussions considering author's experimental results.

Hartley and Murgatroyd (H-M model)[H2] present the first relatively comprehensive theory for the stability of dry patches. Mikielewicz and Moszynski (M-M model)[M3] involves a more complete analysis, which can more usefully be compared to author's experimental criteria.

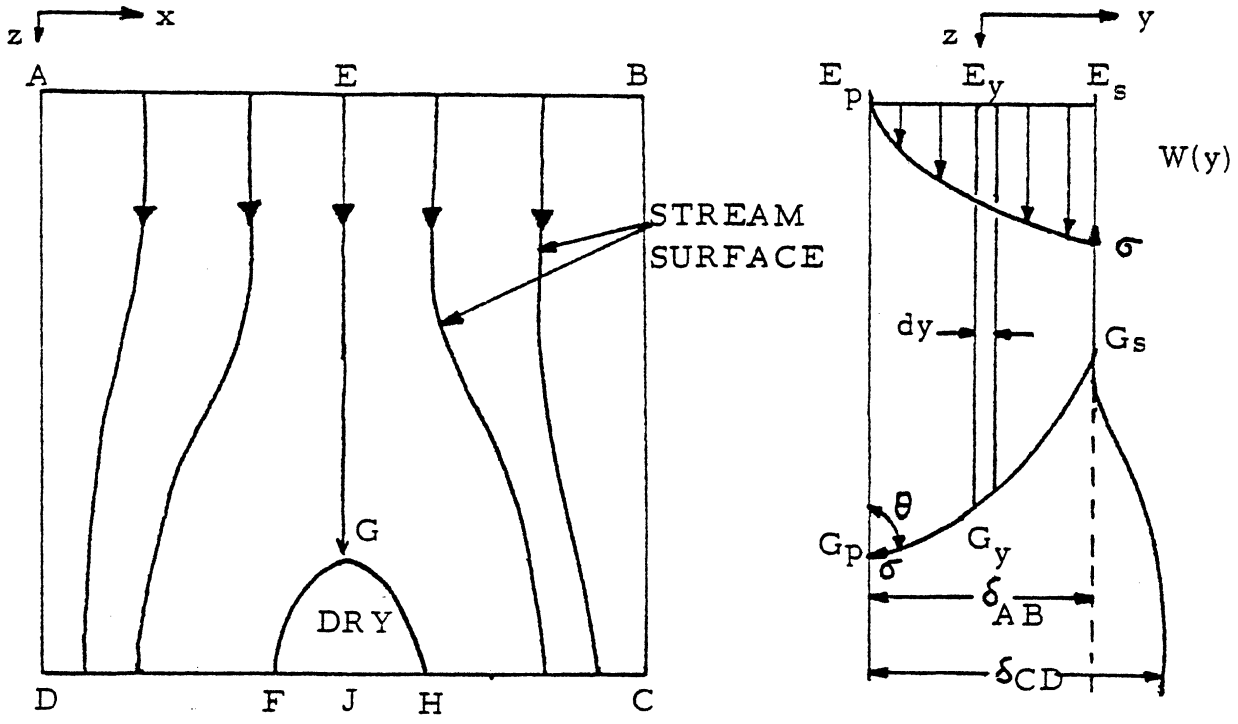
H-M Model[H2]

Hartley and Murgatroyd suggested two models for the stability of dry patches. The first model was based on the balance of forces at the liquid flow stagnation point between dry and wetted regions (points G in Fig. 4.10a).

If the dry patch is stable, the surface tension forces must balance the fluid pressures over the stagnation line $G_s G_p$ in Fig. 4.10a . Surface tension and pressure terms can be expressed respectively as,

$$F_\sigma = dX \cdot \sigma \cdot (1-\cos\theta)$$

$$F_p = dX \int_0^{\delta_{AB}} \rho_f [W(y)]^2/2 \, dy$$



$$F_p = dx \int_0^{\delta_{AB}} \rho_f \left[W(y)\right]^2/2 \, dy$$

$$F_\sigma = dx \cdot \sigma \cdot (1 - \cos\theta)$$

By $F_p = F_\sigma$

$$h_c = 1.82 \left[\sigma(1 - \cos\theta)/\rho_f\right]^{1/3} (\mu_f/\tau_i)^{2/3}$$

$$q_c = 3.3 (\rho_f \mu_f/\tau_i)^{1/3} \left[\sigma (1 - \cos\theta)\right]^{2/3}$$

θ should be $4 \sim 8^\circ$ in comparison with our data

Fig 4.10.a : RIVULET FLOW MODEL
HARTLEY and MURGATROYD (1964)

1. FORCE BALANCE MODEL

where θ is the contact angle between the liquid and solid

σ liquid surface tension, dX the unit length in X direction, W(y) the velocity profile, δ_{AB} the fluid thickness before the stagnation point.

Assuming a linear velocity profile and $F_\sigma = F_p$ for neutral equilibrium, the minimum (or critical) film thickness and flow rate become,

$$h_c = 1.82\ [\sigma (1-\cos\theta)/\rho_f]^{1/3}\ (\mu_f/\tau_i)^{2/3} \qquad (4.20)$$

$$q_c = 3.3\ [\sigma (1-\cos\theta)]^{2/3}\ (\rho_f\ \mu_f/\tau_i)^{1/3} \qquad (4.21)$$

where h_c is the critical film thickness and q_c the critical flow rate, μ_f the liquid viscosity, τ_i the interfacial shear, and ρ_f the liquid density.

A comparison between author's experimental criterion observed from the "map", Fig. 4.2 , and Eq. (4.21) discloses that the contact angle, θ, would need to be between $4 \sim 8°$ (see Table 4.4). However, the static contact angle of a water drop on stainless steel is known to be about 50° (see Fig. 4.11 and Ref. H4) at room temperature and atmospheric pressure. Thus the values required by the H-M model are not realistic. Of course, the contact angle is dependent on many parameters such as temperature and surface conditions (wet or dry, cleanliness, roughness, time of exposure*, etc). A possible source of this apparent discrepancy is the geometric consideration of the stagnation point in their model. (See point G of Fig. 4.10a).

*Shown by author's work measuring changes in θ as droplet size decreased due to evaporation (Fig. 4.11).

Fig. 4.11 Photograph of Contact Angle Between Water Droplets and Stainless Steel Plate at Room Temperature.

(taken by H. Hamed and W. Kim, 1977)

In the H-M model (Fig. 4.10a), the stagnation line $G_s G_p$ is assumed to decrease smoothly from the upstream thickness δ_{AB}. However, author's rivulet pictures (plates #2.1,2.2 and 3.2 of Fig. 4.1) show an abrupt bulge in the liquid at the stagnation point ahead of a dry patch. There is no doubt that the bulge geometry may change the force balance considerably.

Another factor, which complicates an adequate modeling, is the existence of waves in the upstream liquid film. Such waves always exist in the author's rivulet pictures. They suggest that a modification of the H-M force balance model to include their effect is necessary.

The other H-M model, called "minimum power model", is based on the assumption that the film will attain a condition such that the sum of surface and kinetic energy across a rivulet cross-section will be a minimum.

For such a stable rivulet (Fig. 4.10b), the kinetic energy flux E_k is

$$E_k = X \int_0^{\delta_{PQ}} \frac{\rho_f [W(y)]^3}{2} \, dy$$

where $W(y)$ is the velocity at element $P_y Q_y$. Also surface energy flux E_σ is

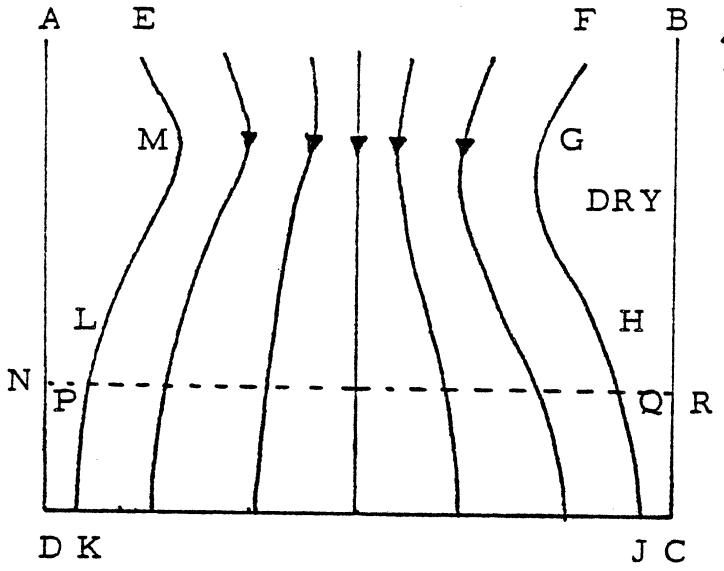
$$E_\sigma \cong X \cdot \sigma \cdot W(\delta_{PQ}).$$

Then the total energy flux, E_T is

$$E_T = E_k + E_\sigma$$

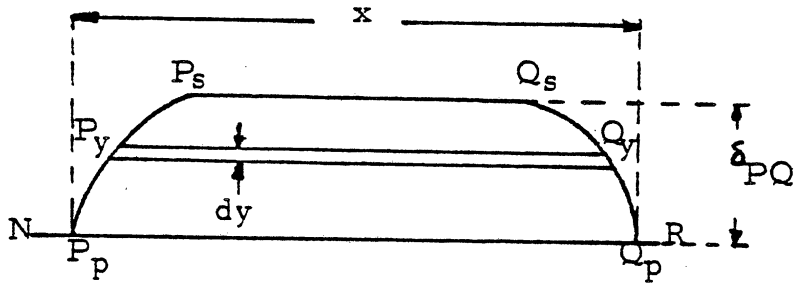
The minimum for E_T is obtained by setting

$$\partial E_T / \partial \delta = 0$$



$$E_K = x \int_0^{\delta_{PQ}} \frac{\rho}{2} \left[W(y) \right]^3 dy$$

$$E_\sigma = x \cdot \sigma \cdot W(\delta_{PQ})$$



$$E_T = E_p + E_\sigma$$

By $\partial E_T / \partial \delta = 0$

$$h_c = 1.59 \, (\sigma / \rho_f)^{1/3} \, (\mu_f / \tau_i)^{2/3}$$

$$q_c = 2.52 \, (\rho_f \mu_f / \tau_i)^{1/3} \, \sigma^{2/3}$$

Fig 4.10.b : RIVULET FLOW MODEL
HARTLEY and MURGATROUD (1964)

2. MINIMUM ENERGY MODEL

Assuming a linear velocity profile in the liquid as in the first H-M model and author's analyses, one obtains the critical flow rate as

$$h_c = 1.59 \left(\sigma/\rho_f\right)^{1/3} \left(\mu_f/\tau_i\right)^{2/3} \tag{4.22}$$

$$q_c = 2.52 \left(\rho_f \mu_f/\tau_i\right)^{1/3} \sigma^{2/3} \tag{4.23}$$

Equations (4.22) and (4.23) do not include the contact angle, rather assuming the rivulet cross section to be rectilinear, i.e. $\theta = 90°$. Thus a portion of the surface energy of the rivulet was neglected.

Comparison between author's direct measurement of the critical film thickness and the H-M power model (Eq. 4.22) shows that the predicted critical film thickness is $\sim 4x$ that measured by present author (Table 4.5). A partial explanation of the difference may be their assumption of a rectilinear rivulet cross-section. In light of the minimum surface energy, the cross-section should not be flat but rather it approaches a circular segment. This shape requires less energy than a flat form. Present author observed from his rivulet photographs (plates #1.1 and 3.1 of Fig. 4.1) that a stable approximately flat cross sectional rivulet continued to be stable. Of course, the exact rivulet shape is not known at this time.

Another possible reason for the difference in measured and predicted critical stability parameters is the negligence of wave effects in the rivulets for the H-M minimum power model. Two-dimensional waves moving in the rivulet flow

V_s (m/s) / h_c x10^3(cm)	73.2	133	191	305
Measured (W. Kim)	8.13	4.57	2.7	1.78
Predicted (H&M)	32	16	11	6

Predicted Critical Film Thickness is $\sim$ 4 times larger than Measured Film Thickness.

Table 4.5: COMPARISON OF THE MEASURED AND PREDICTED MINIMUM POWER CRITERION OF H-M MODEL

direction were observed (see plates in Fig. 4.1) and should be considered in any rivulet film flow stability model.

M-M Model

More recently Mikielewicz and Moszynski[M3] proposed a modified H-M minimum power model based on Hobler's[H3] basic approach. As an improvement over the H-M model, they assumed the rivulet cross-section to be a circular segment.

Assuming that the rivulet is stable when the total energy flux (kinetic plus surface) is minimum, they obtained the following equation for the critical film thickness for critically stable rivulet flow,

$$h^+ = 3.2^{-2/3}\left(\frac{\theta}{\sin\theta} - \cos\theta\right)^{1/3} h^{+2/3}\, g(\theta)^{2/3}\, \frac{\sin\theta}{\phi(\theta)}\,(1-\cos\theta) \qquad (4.24)$$

where

$$h^+ = \frac{\rho_f\, \tau_i^2\, h^3}{\mu_f^2\, \sigma}$$

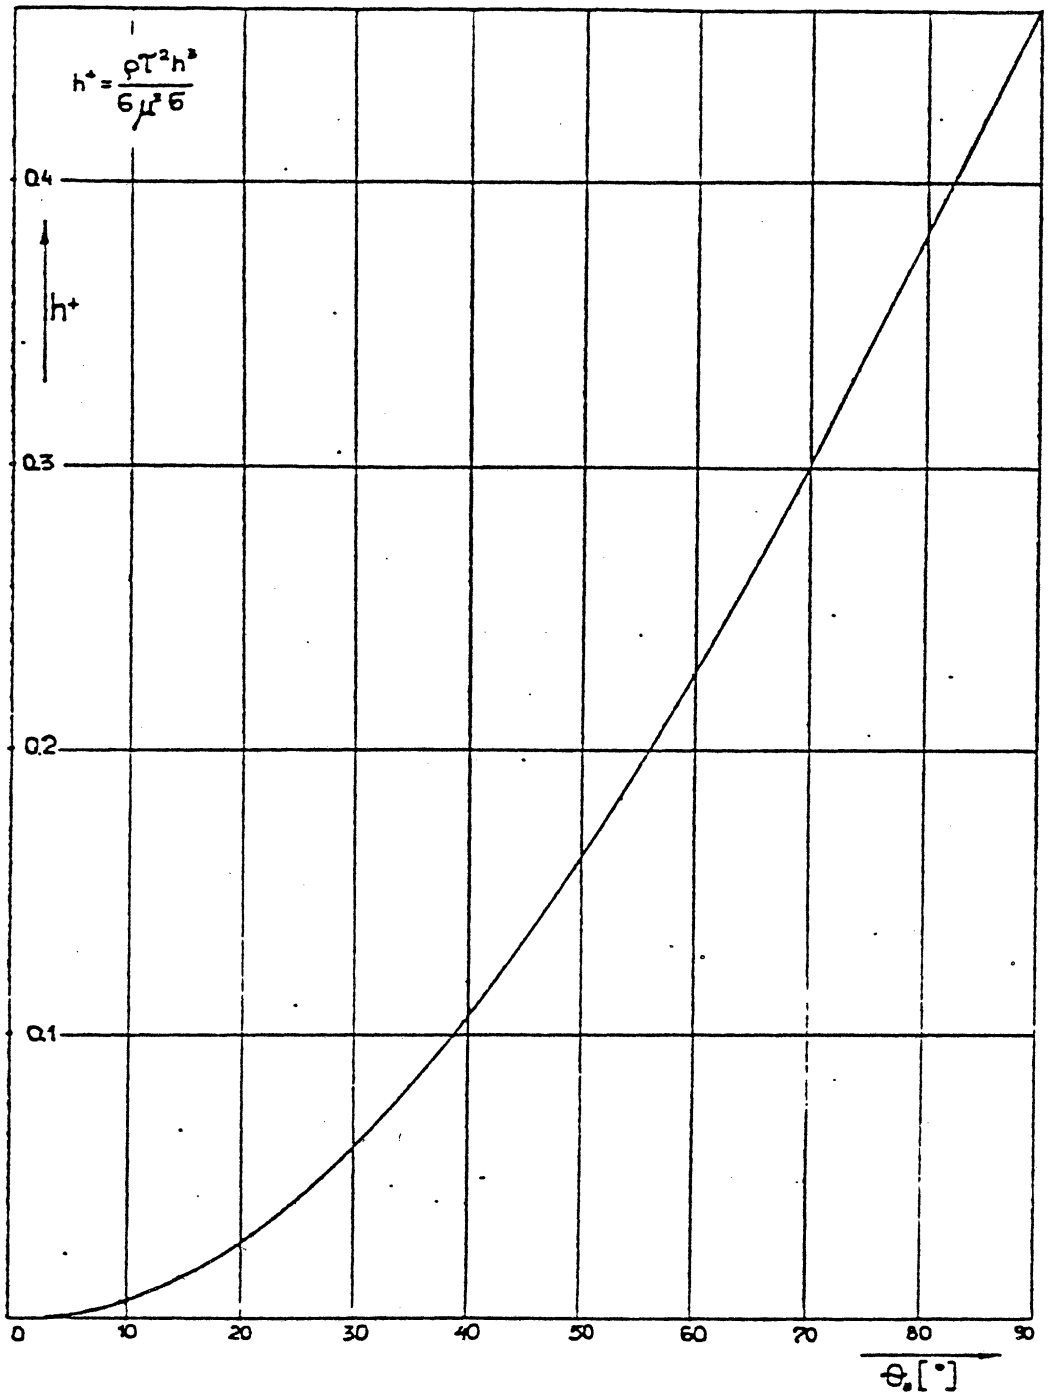
is the non-dimensional thickness,

$g(\theta) = -1/4\cos^3\theta - \frac{13}{8}\cos\theta + \frac{15\,\theta}{8\sin\theta} - \frac{3}{2}\theta\sin\theta,$

$\phi(\theta) = \sin\theta - \frac{1}{3}\sin^3\theta - \theta\cos\theta.$

In this analysis, the velocity profile of the liquid film was assumed linear. They presented a graphical solution for the above expressions (Fig. 4.12).

Comparing the author's critical film thickness measurement with the predicted M-M model, the contact angle θ should be about 10° for the model to be compatible with the experiments. (see Table 4.4). This presents substantial improvement



$$h^+ = 3 \cdot 2^{-\frac{1}{2}} \left(\frac{\theta_0}{\sin\theta_0} - \cos\theta_0 \right)^{\frac{1}{2}} h^{+\frac{3}{2}} g(\theta_0)^{\frac{1}{2}} \frac{\sin\theta_0}{\phi} - (1 - \cos\theta_0),$$

where

$$h^+ = \frac{\rho\tau^2 h_0^3}{6\mu^2 \sigma_{2-3}}.$$

Fig. 4.12 Dimensionless Minimum Film Thickness as a function of the Contact Angle (Mikielewicz-Moszynski, 1975)

over the H-M minimum power model, but still the required contact angle, θ, is less than half that of measured contact angle ($\sim 25°$) [M15] in such a single curvature flow as rivulet. An important reason for the discrepancy with author's experiment may well be the neglect of rivulet film waviness.

D. WAVY FILM REGIME

When the liquid flow rate is increased at fixed steam velocity, the liquid film covering the blade surface becomes continuous, and rivulets and dry patches disappear.

For the range of steam velocities here used, the surface of the liquid film is only rarely entirely smooth. Rather it is nearly always somewhat wavy (see plates in Fig. 4.1). The shape of these wavelets for low steam velocities and liquid flow rates is two-dimensional with relatively small wave lengths ($\sim$0.5 cm) in direction of flow. With further increase of liquid flow rate or steam velocity, the wavelet shape becomes more complicated with much larger wave lengths ($\sim$2 cm). The author has defined this wave form as "three-dimensional." These larger waves are usually preceded by a parasitic group of much smaller wavelets. In the "film map" Fig. 4.2, the division between two dimensional and three-dimensional wave regimes is indicated by the broken line. This division is not "sharp", so that in the three dimensional wave region (Fig. 4.2), two dimensional waves sometimes exist, appearing and disappearing.

Extensive measurements of film thickness, wave length, and wave propagation speed have been performed for the

different steam and liquid flow conditions attainable. Test points (Tables 4.6, 4.7) were selected to cover with adequate detail the full range of steam velocity (steam Mach number) and film flow (film Reynolds number). Calculated results include interfacial shear stress (section B of Chapter IV) wave number, capillary wave celerities and other important parameters.

The measured wave length data for the two-dimensional and three-dimensional waves are shown in Figs. 4.13 and 4.14. Figure 4.13 shows that the wave length, λ, of two-dimensional waves decreases as the liquid film Reynolds number, Re_f increases, for lower steam velocities, while it slowly decreases with increasing Re_f for very high steam velocity. The Mach number is then high subsonic (M=0.61 and 0.72), so that compressibility may importantly influence the flow. In general, the wave length, λ, decreases with increasing steam velocity or Mach number for a given Re_f. Also the data scatter decreases with increasing steam velocity, perhaps because the relative precision of the measurement of these larger parameters improves.

For three-dimensional large waves, λ, deceases with increasing Re_f at lower steam velocities, but increases with Re_f for higher velocities. This trend is not found for the two-dimensional waves.

Figures 4.15a and 4.16 show measured data on propaga_ tion speed of two and three dimensional waves for various Re_f and steam Mach numbers, M. These were directly measured

from the high-speed motion picture frames.

The wave propagation speed, C, increases with both M and Re_f for two-dimensional waves (Fig. 4.15.a). Solid symbols represent average values, while open symbols are individual points. To help clarify the operative wave-propagation mechanisms, the celerity of capillary-gravity wave Vc has been computed (Table 4.6).

The classical solution for combined capillary and gravity waves (long waves), Vc, is expressed as[C17,L6]

$$V_c = [\frac{g}{k} + \sigma \frac{k}{\rho_f}]^{1/2} \qquad (4.25)$$

where g is gravitational acceleration and $k = 2\pi/\lambda$ is wave number.

Comparing measured wave speed, C, with capillary wave speed, V_c, it is found that the measured speed is 1.86 ± 0.36 x that calculated from the conventional capillary-gravity model for author's two-dimensional waves. Thus the celerity of the two-dimensional waves is in reasonably good agreement with the classical capillary gravity model.

Recently Wurz[W14] proposed a two-dimensional film wave propagation speed model, compared with his own experimental data. Using "universal" velocity profiles (laminar and laminar-turbulent) for the film, two limiting correlations are suggested; $C^* = 2^{3/2} Re_f^{1/2}$

and

$$C^* = 2^{9/4} 9^{-1/3} Re_f^{1/3}$$

where

$$C^* = C/U_\tau = C/\sqrt{\tau_i/\rho_f}$$

Most of author's high subsonic data (M = 0.61) falls into his limiting "envelope" (Fig. 4.15.b). However Wurz's model does not adequately explain the lower subsonic portion of author's data. For this range of data, a more accurate estimate or measurement of the interfacial shear stress appears necessary. Alternatively a more sophisticated model may be required.

However, the propagation speed of three-dimensional waves (Fig. 4.16 and Table 4.7) is much greater (C/Vc = 32.2 ± 20.7) and the data more scattered, especially for high Mach numbers. Their speed is the order of ~10 m/s, while that of two dimensional waves is ~ 1 m/s.

The basic wave initiation and growth mechanisms are yet in question. No adequate calculating model for the three dimensional wave celerity is yet available. As shown in Fig. 4.17 and 4.18, dimensionless wave speeds $C'=C/V_f \geq 1$, i.e., the wave velocity is always greater than the liquid surface velocity, so that as expected, the waves are always progressing downstream.

Since wave propagation speed is always much smaller than the average steam velocity, a resonance mechanism of the type suggested by Phillips[P5] is not applicable to the present case. Turbulent steam pressure fluctuations with wave lengths comparable to those here observed would have velocities much larger than the wave velocities observed.

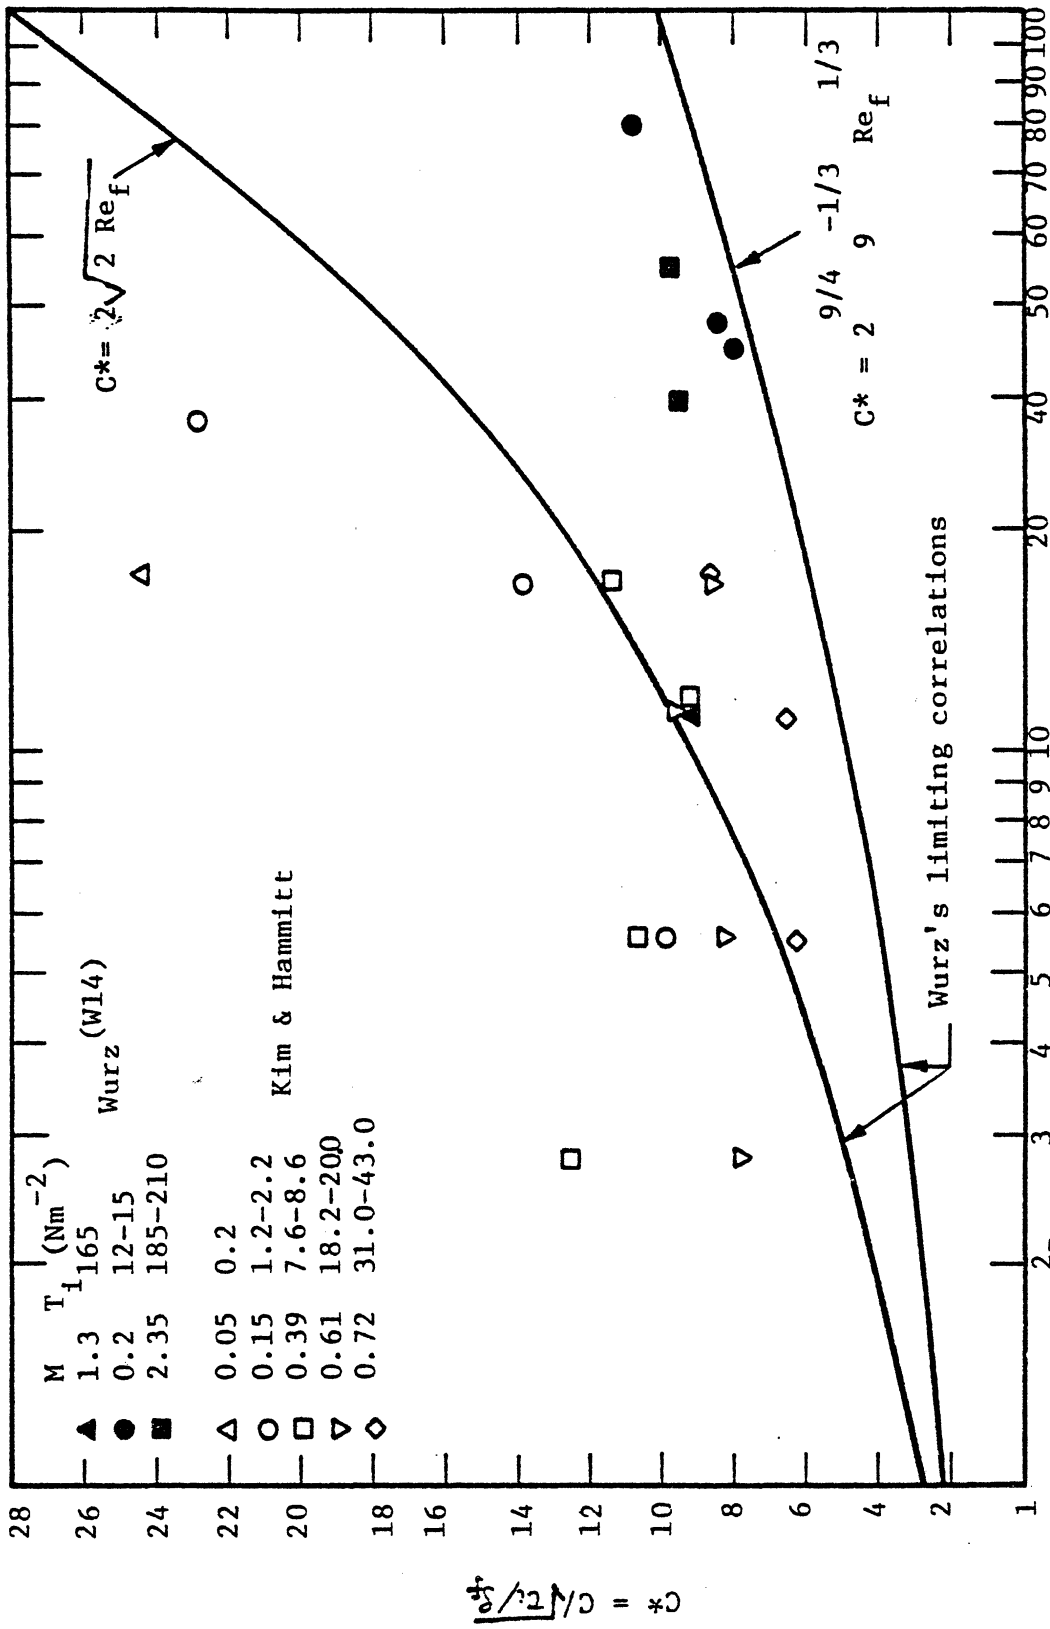

Fig. 4.15.b Non-Dimensional Wave Propogation Velocity, C*, vs. Film Reynolds Number, Re_f.

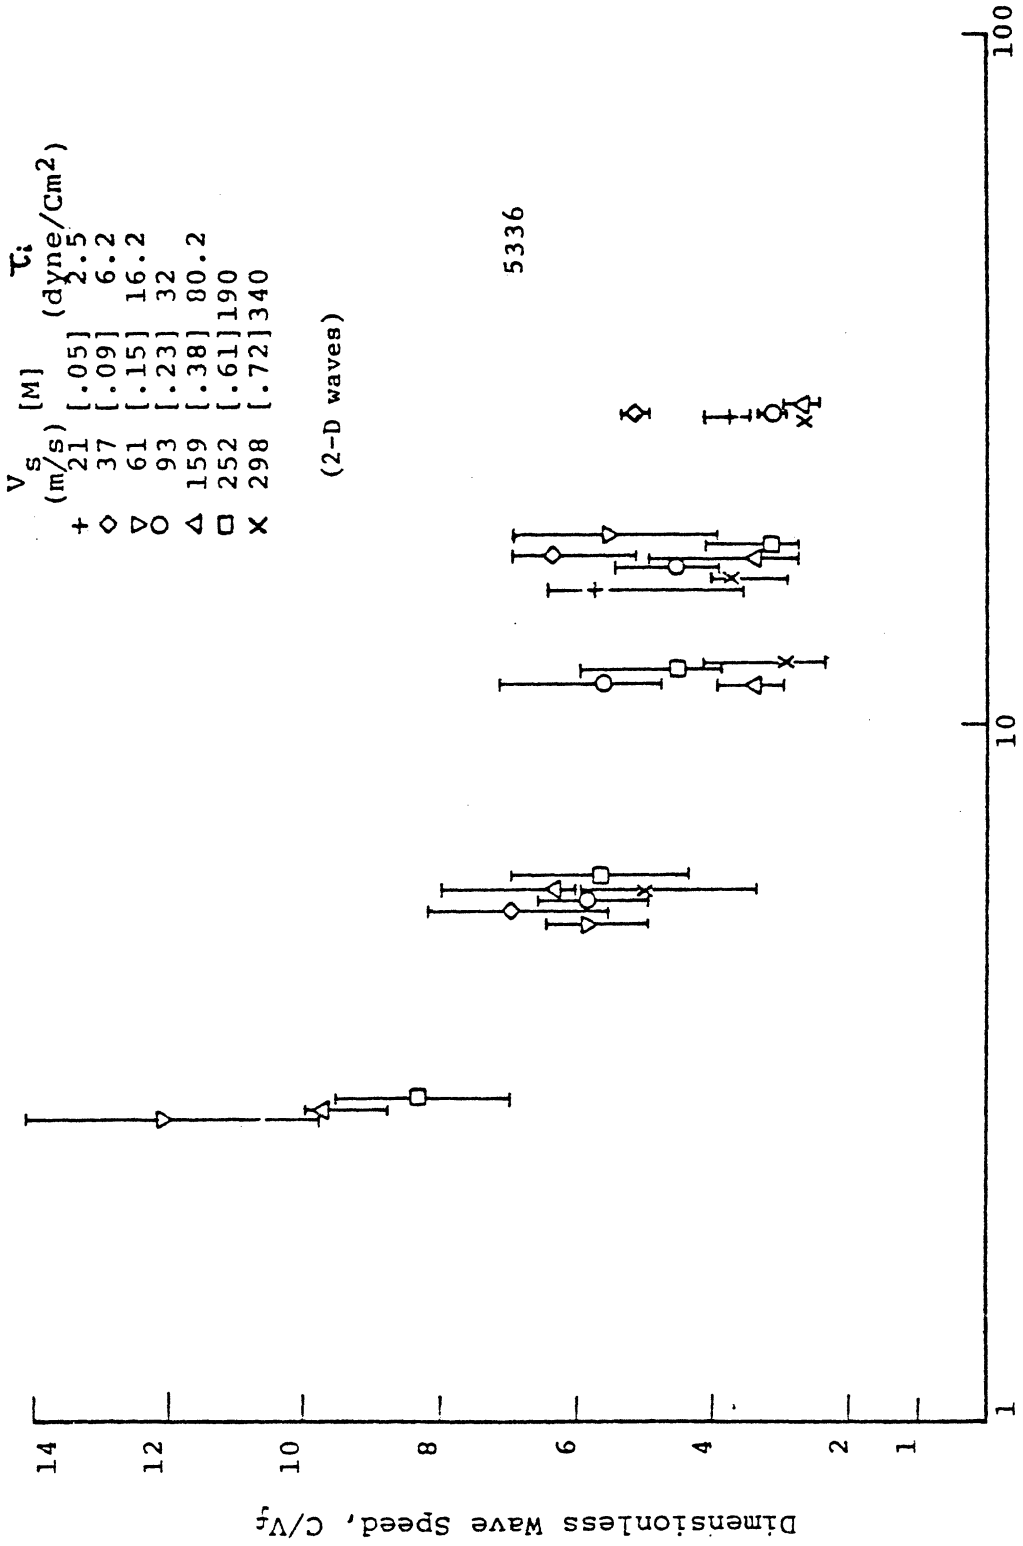

Fig. 4.17 Dimensionless Wave Speed vs Film Reynolds No. (2_{-D} waves)

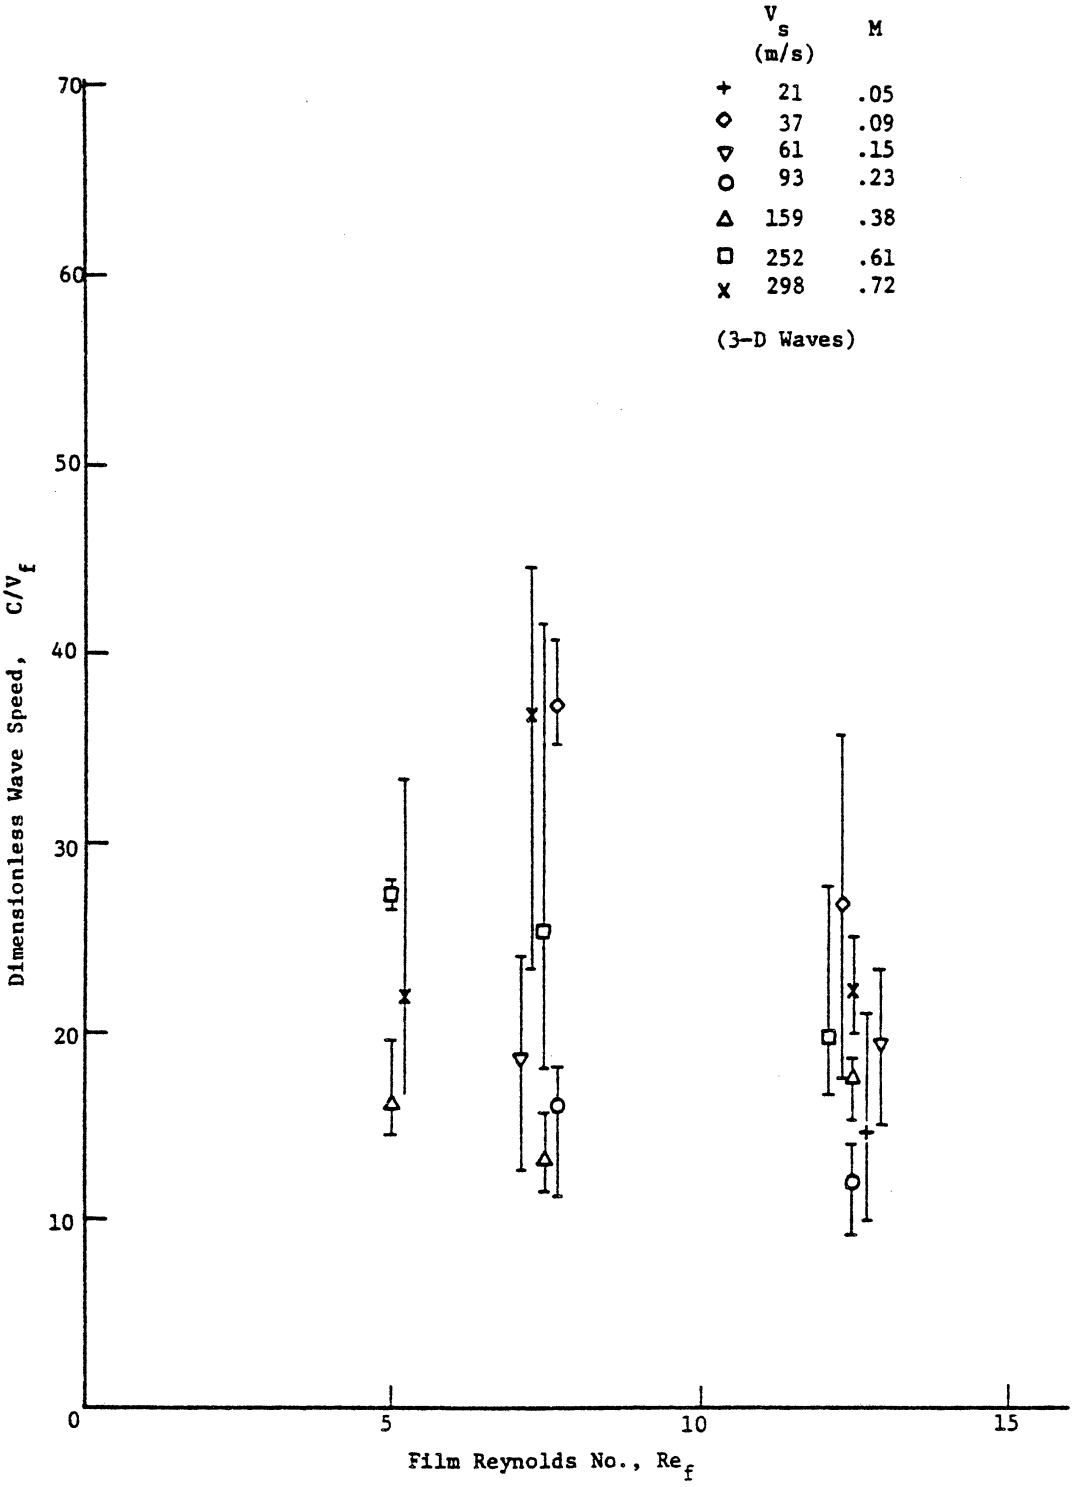

Fig. 4.18 Dimensionless Wave Speed vs Film Reynolds No. (3-D waves)

Thus only a very weak coupling to this type is possible.

The mechanism responsible for wave generation in thick film liquid flows (author's case is thin film) is understood as follows. Disturbance in the steam velocity field caused by the waves creates pressure and shear variations over the wavy surface. These transfer energy from the steam to the liquid film. If the rate at which energy is transmitted to the waves by these mechanisms is not larger than the rate of viscous dissipation in the liquid, the waves will decay.

In thick film cases, shear perturbations are very small compared to pressure perturbations.[C7,C10] Therefore, the contribution of the shear perturbation as an instability factor can be neglected. Based upon the pressure perturbation mechanism alone, Cohen-Hanratty,[C7] Nachtsheim,[N6] and Nayfeh-Saric[N3] formulated stability analyses for thick liquid films below a horizontal cocurrent gas flow.

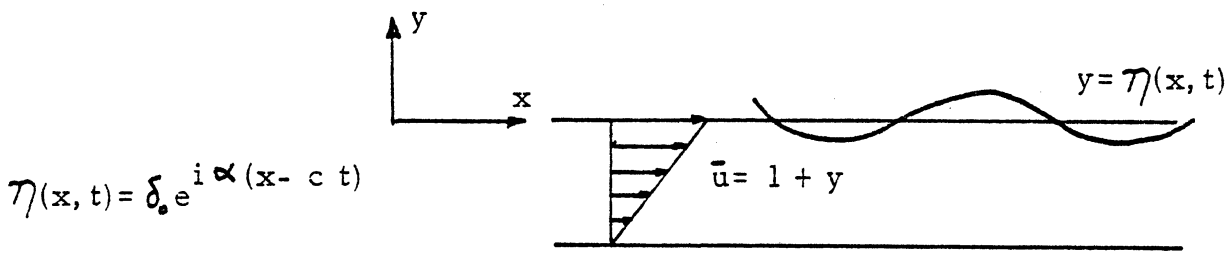
To evaluate the pressure perturbation magnitudes, Cohen-Hanratty used the Jeffreys[J2] and Miles[M6] models. One of the important findings of the Cohen-Hanratty analysis is that viscous dissipation at the interface is predominant for short wavelengths (compared to their height), while viscous dissipation at the solid wall is important for long waves.

Because of their interest in a transpiration cooling system for missile nose-cones, the Nachtsheim and Nayfeh-Saric analyses were focused on highly supersonic gas flows over relatively thick liquid films. Their linear analyses neglected shear perturbations, and derived the rate of wave

growth and wave propagation velocity in terms of body force, surface tension and pressure perturbations. As normally expected they conclude that while surface tension is stabilizing, pressure perturbations are destabilizing, and body force can be either, depending on its direction (downward is stabilizing). They also found that films adjacent to supersonic streams are more unstable than those adjacent to subsonic streams.

In later non-linear analyses, Nayfeh-Saric[N4,N5] and Saric-Nayfeh-LeKoudis[S3] modified these conclusions. According to their non-linear theory,[N4,N5] linear unstable disturbancies do not grow indefinitely, but achieve steady-state amplitudes in the supersonic case, provided disturbance layer is larger than the subsonic layer.

For very thin films, a quite different stability mechanism was suggested by Craik[C10]. According to his analysis, small wave-like disturbances become unstable when the normal stress component in phase with the wave slope is sufficient to overcome the resistance to motion of the liquid surface due to gravity and surface tension. He also held that the destabilizing role of the tangential stress component became important for very thin films, and that instability may occur whatever the velocity of the gas stream is, provided the film is sufficiently thin. It is appropriate to examine the wave behavior in author's experiment using the Craik model.[C10] He assumed a two dimensional wave of the sinusoidal form, where $\alpha = k\,h =$



$\frac{2\pi}{\lambda}$ h is the (real) non-dimensional wave number and C is the non-dimensional wave velocity, which may be complex. The non dimensional wave amplitude δ_o was assumed to be sufficiently small for the problem to be linearized.

Using a perturbation stream function with the linearized Navier-Stokes equations, the Orr-Sommerfeld equation is obtained. This is a fourth-order differential equation for the perturbation stream function. To solve it Craik assumed a perturbation solution in powers of dimensionless wave number α. To specify the required 4 boundary conditions he used the Benjamin[B4] expressions for shear and pressure perturbation stresses at the wavy interface, together with no-slip, no-penetration conditions at the solid wall. In Benjamin's derivation for perturbation stresses over a wavy wall, it was assumed that the disturbances introduced into the gas flow by the waves do not interact with the turbulence in the gas.

Substituting a power solution for the perturbation stream function into the four boundary conditions, he obtained four homogeneous equations, whose determinant should vanish in order for the equations to be consistent.

Neglecting the higher order terms, he obtained,

$$T\alpha^2 + G - \Pi + \frac{3i\Sigma}{2\alpha} = (1-c)\left(\frac{3}{i\alpha Re_f} + \frac{6}{5}(1-c) - \frac{7}{8} + \frac{27}{5}\frac{2}{i Re_f} \right) \tag{4.26}$$

where

$T = \frac{\sigma}{\rho_f V_f^2 h}$ reciprocal Weber number

$G = \frac{g h}{V_f^2}$ reciprocal Froude number

$\alpha = k h = \frac{2\pi}{\lambda} h$ dimensionless wave number

$\Pi = \Pi_r + i\Pi_i$ pressure perturbation (Benjamin, 1959 (B4))

$\Sigma = \Sigma_r + i\Sigma_i$ shear perturbation (Benjamin, 1959 (B4))

$C = C_r + iC_i$ dimensionless wave speed normalized by film velocity, V

$Re_f = \frac{V_f h}{\nu_f}$ film Reynolds number

On separating the real and imaginary parts,

$$\frac{6}{5}(C_r-1)^2 + \frac{7}{8}(C_r-1) - (Ci/\alpha Re_f)(3+\frac{27}{5}\alpha^2+\frac{6}{5}\alpha Re_f C_i) = T\alpha^2 + G - \Pi_r - (3\Sigma_i/2\alpha) \quad (4.27)$$

$$C_i\left[\frac{12}{5}(C_r-1)+\frac{7}{8}\right] + \left[(C_r-1)/\alpha Re_f\right](3+\frac{27}{5}\alpha^2) = -\Pi_i(3\Sigma_r/2\alpha) \quad (4.28)$$

From Eqs. (4.27) and (4.28), the rate of wave amplification $\alpha C_i Re_f$ and wave velocity, C_r, can be found.

$$\alpha C_i Re_f = \frac{(\alpha Re_f)^2}{3}(\Pi_r + \frac{3}{2}\frac{\Sigma_i}{\alpha} - T\alpha^2 - G) \quad (4.29)$$

$$C_r - 1 = \frac{-\frac{7}{8}(\alpha C_i Re_f) - \alpha Re_f \Pi_i + \frac{3}{2} Re_f \Sigma_r}{3 + \frac{27}{5}\alpha^2 + \frac{12}{5}\alpha C_i Re_f} \quad (4.30)$$

It is seen from Eq. (4.29) that instability occurs when

$$\Pi_r + \frac{3}{2}\frac{\Sigma_i}{\alpha} > T\alpha^2 + G$$

i.e. when the effect of the surface stresses is sufficient to overcome the restoring forces of surface tension and

gravity. Although the pressure perturbation component Π_r is generally much greater than the shear perturbation component Σ_i, the effect of the variable shear stress cannot be neglected when α is small. The term in Σ_i becomes dominant for sufficiently thin films. Because of this, instability is more likely to occur for sufficiently thin films. The present author defines this as the "shear perturbation mechanism". These results are in good qualitative agreement with the author's experimental observations reported in section 4 of Chapter IV, that waves always exist over the entire range of the experiment including even the rivulet film flow regime.

One can explain this wave formation mechanism in the following way:

The component of normal stress, Π_r, is in phase with the wave displacement, and it attempts to deform the liquid surface by exerting an upward force upon the crests and a downward force upon the troughs of small periodic disturbances. Also, the tangential stress component, Σ_i, is in phase with the wave slope, and it has the effect of accelerating the liquid on the windward slopes while retarding that on the leeward slopes. This mechanism tends to displace liquid toward the crests and away from the troughs of existing wavelets, thereby increasing their amplitude. The thinner the mean film compared to the wave amplitudes, the more effective is this mechanism . Thus it should be highly effective in author's case.

Compared with the pressure perturbation instability mechanism for thicker films, the shear perturbation mechanism is a entirely different one from the pressure perturbation mechanism.

In the pressure perturbation mechanism instability is caused by an irreversible energy transfer from the vapor flow to the disturbance through the stress components represented by Π_i and Σ_r. The flow becomes unstable when film viscous dissipation is less than energy input. This energy transfer takes place through non-conservative forces, provided by the normal stress component in phase with the wave slope, and the tangential stress component in phase with the wave displacement (articles 348-350 in Lamb's "Hydrodynamics" [L6]). However, the stress components causing the instability in the shear perturbation mechanism are Π_r and Σ_i (Appendix B) both of which act conservatively on the wave.

The disturbance growth rate $\propto C_i R$, calculated from Eq. (4.29), is shown in Fig. 4.19 . It is essentially a frequency-response curve for infinitesimal initial conditions. Very large wave number disturbances (greater than the critical wave number, α_c) remain stable because of the dominant effect of surface tension. The smaller wave number disturbances are unstable because of the controlling effect of the tangential and normal perturbation stresses.

A precise estimate of perturbation stresses is essential. Author's calculations of the normal (Π), and tangential (Σ)

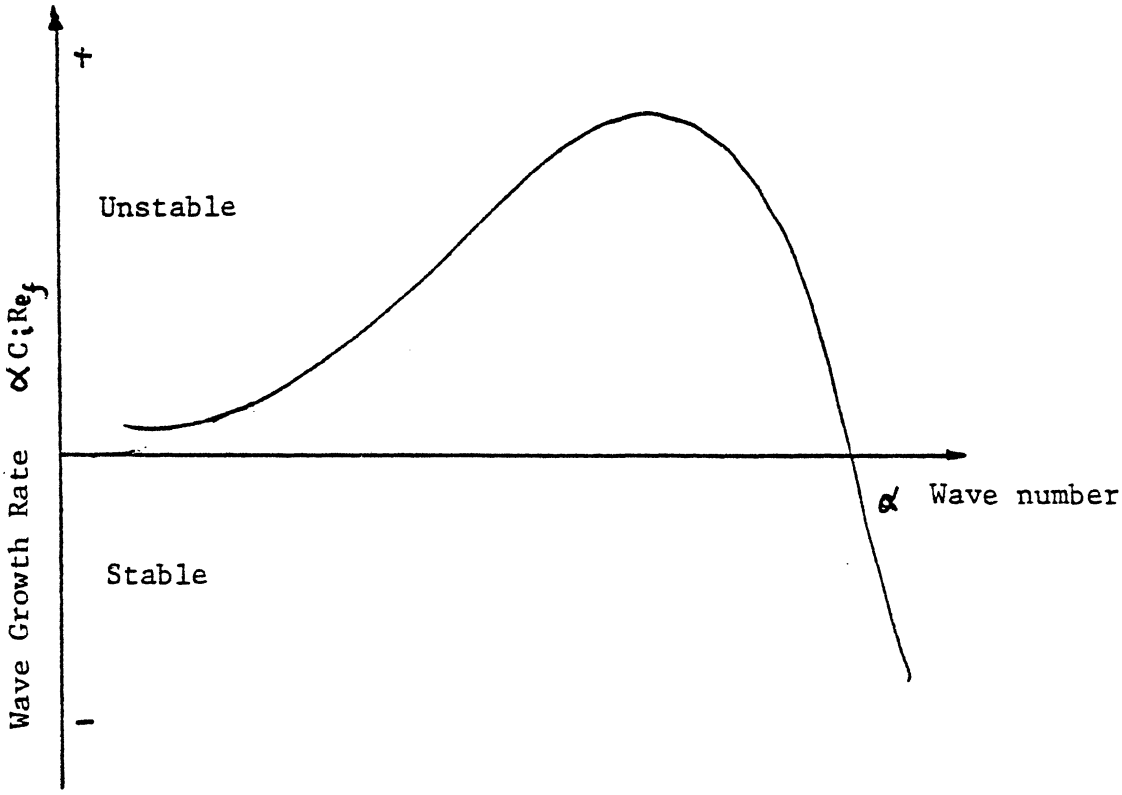


Fig. 4.19 Disturbance Wave Growth Rate as a Function of Wave Number

perturbation stresses based on Benjamin's [B4] analysis, with listing of related computer programs, are given in Appendix B.

Figure 4.20 compares author's observed wave numbers with the critical wave numbers calcualted from Eq . (4.29). Since the analysis is based on a linear small perturbation theory, it is applicable only to the small two-dimensional wave regime.

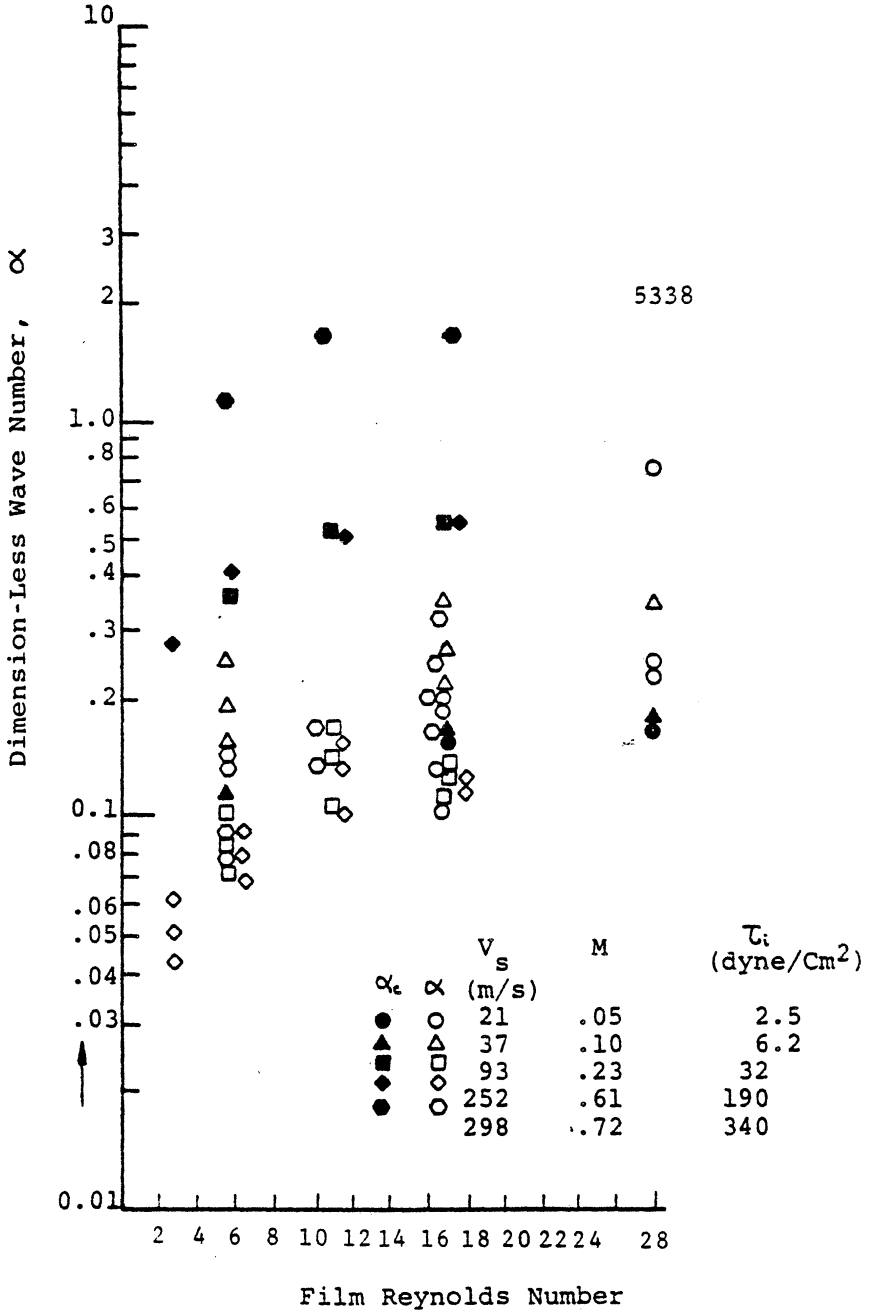
Most of the observed wave numbers for high steam velocity are smaller than the calculated critical wave numbers, and hence are in the unstable region, (Fig. 4.20).

However, the observed wave numbers for low steam velocities (21 and 37 m/s) are either larger than, or in the range of, the calculated critical values. These are in the relatively stable region indicated in Fig. 4.19. Comparing with the flow regimes in author's "map" (Fig. 4.2), most of the measured wave numbers are in the unstable region. Obviously there are inherent uncertainties in calculating the critical wave numbers. First the analysis is based on a small perturbation linear analysis and a "universal" turbulent steam velocity profile. Second the estimate of interfacial shear (see Section B, Chapter IV)may involve errors. Nevertheless, the results of Fig. 4.20 seem reasonably acceptable for such a highly complex problem.

E. FILM ENTRAINMENT

For very large waves, as already mentioned, entrainment from the wave crests occurs. Good understanding of all

Fig. 4.20 Comparison of Measured Wave Number, α with Analytic Critical Wave Number (C10), α_c (2-D wave)



pertinent liquid entrainment mechanisms is important for both steam turbine blade erosion and moisture performance effects, as well as numerous other applications. These include annular duct flows important in many chemical process applications. Thus the critical condition for the onset of such entrainment has been studied by many researchers in both vertical[S4,G7,G8] and horizontal ducts.[V2,W1]

VISUAL OBSERVATION

Plates #5.4 to 5.7 and 6.4 to 6.7 of Fig. 4.1 reveal such liquid film entrainment. The interfacial structure is characterized by a series of liquid flow surges, i.e. large waves. The surface becomes then highly agitated, with sudden increases in liquid film thickness. Imposed on this main wave structure are complex smaller wavelets resulting from a chaotic tumbling at the wave front, like an ocean breaker. The entrained liquid droplets usually appear frothy (i.e., not well-defined). Sometimes several clear large droplets are seen together.

Author's high speed motion pictures show some features of the surface entrainment mechanisms. They include "splashing" of the liquid interface, after the impingement of a large liquid droplet. Most of the surface droplet entrainment, however, was observed to occur following rapid acceleration, lifting, and then shattering of small complex ripples present at the top of large waves. The bursting of air bubbles trapped in the liquid, as suggested by other researchers,[B7,N7,W14] was not observed here.

In author's "map" (Fig. 4.2), the transition between wavy-film and entrainment regimes is shown. As liquid flow rate decreases, the steam velocity for surface entrainment increases. For high steam velocities, or for thin films, a limiting behavior was observed for which the critical conditions are insensitive to changes in steam velocity, i.e., there is a limiting liquid flow rate below which no surface entrainment occurs ($\sim$0.07 cm^3/sec cm).

Similarly, a minimum steam velocity for entrainment even for large liquid flow rates is expected. However, it was not possible to test this possibility due to facility limitations on minimum steam velocity.

COMPARISON WITH OTHER RESULTS

Author's critical steam velocity criterion for surface entrainment is compared to other results in Fig. 4.21. There are numerous studies concerning such entrainment inception for two-phase annular flow in vertical pipes (Z2,S4,C18,U1). Much less experimental data is available for horizontal channels. It is of course necessary that experiments be reasonably similar for meaningful comparison. The channel heights of Van Rossum (V2) and Woodmansee-Hanratty (W2) were 10 cm and 2.5 cm respectively, while author's is 4 cm. Thus they are of the same general magnitude. The ratio of liquid film thickness to channel height has an important effect on critical gas phase velocity for entrainment. However, for relatively very thin films, as in author's case, precise value of this ratio becomes less important. The

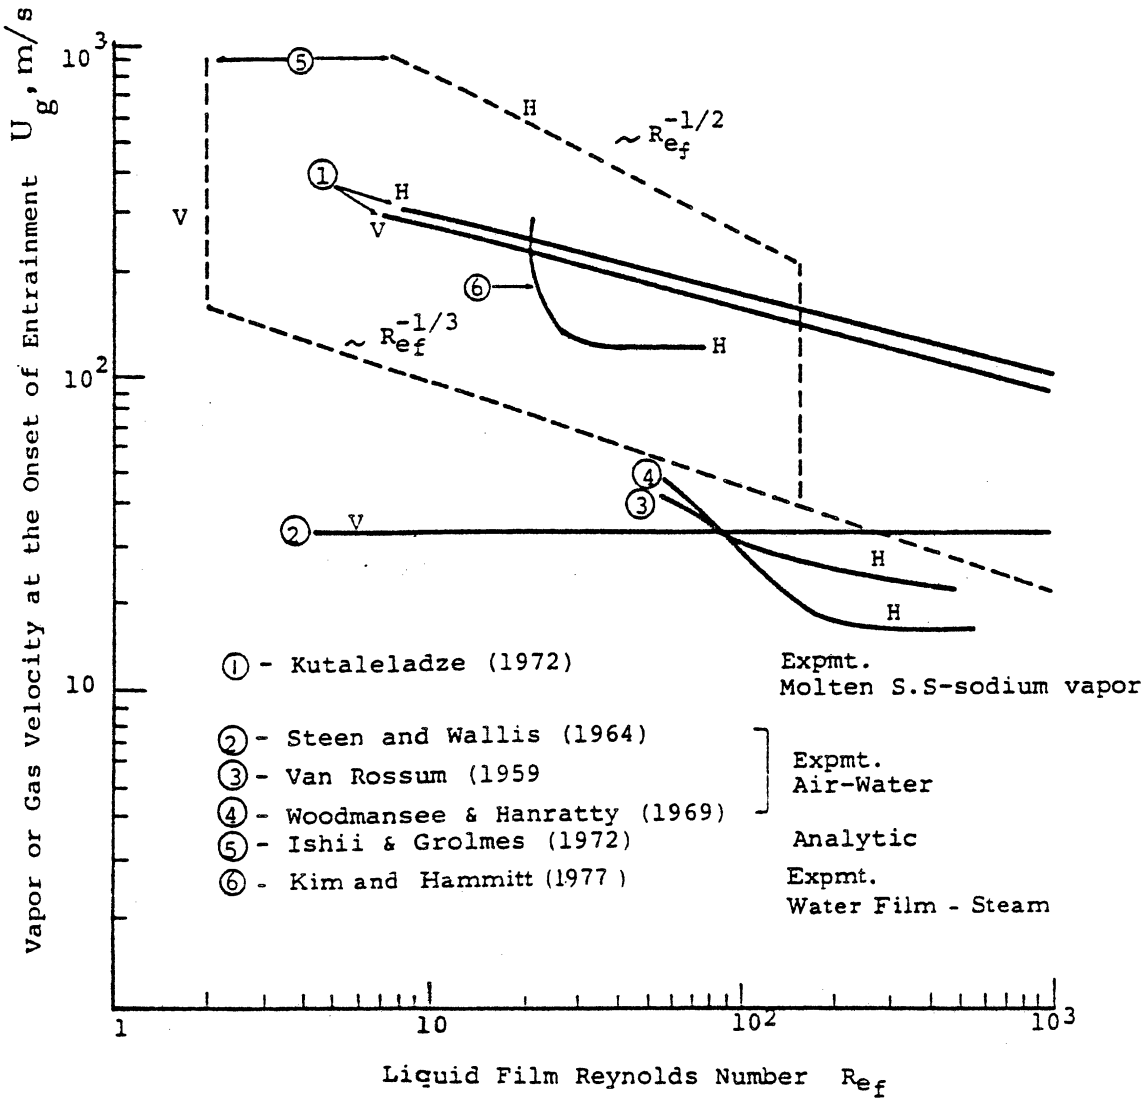


Fig. 4.21 Comparison of Various Entrainment Inception Criteria

U_g vs Re_f

experimental data ③ (V2) and ④ (W2) in Fig. 4.21 can thus be properly compared with author's results 6 for which the critical steam velocity is much higher.

Except for Zhivaikin (Z2) ①, (using sodium vapor and molten stainless-steel) and the author ⑥, fluids were air and water. The analytical correlation ⑤ (I2) is discussed in the next section. The air-water experiments ② (S4) for annular upward pipe flow indicate that the entrainment air velocity is constant with liquid flow rate. The cause for this discrepancy with horizontal geometry results is unknown.

ENTRAINMENT MECHANISMS

Wicks and Duckler (W5) proposed an empirical entrainment correlation for upward vertical annular flow as observed by Collier and Hewitt. (C15) Hughmark (H6) proposed a completely empirical correlation based on the experiments of various other researchers. (C15,A3,C18)

More recently, a theoretical correlation was proposed by Ishii and Grolmes. (I2) Based on Zuber's analysis, (Z3) they analyzed a smooth roll-wave geometry with an internal flow in the roll-wave crest. They then assumed that interfacial shear stresses at the wave crests induce a velocity within the wave of the same general magnitude as the film velocity, with a linear velocity profile within the wave-crest. To express the roll wave amplitude, they used a modified Hughmark (H6) correlation for the friction coefficient, and concluded that the critical non-dimensional gas velocity for entrainment was proportional to $Re_f^{-1/3}$ for a relatively

thick film ($Re_f > 160$).

For low film Reynolds number, based on assumed similarity between droplet disintegration (critical droplet Weber number[H15] concept) and liquid film entrainment, they derived an expression showing that critical non-dimensional gas velocity is proportional to $Re_f^{-1/2}$.

As discussed in Section IV-D, the shear perturbation instability predominates for very thin films. However, the analysis applies for wave generation inception rather than film entrainment. Author observed entrainment to occur from the wave crests, i.e., from the thickest part of the liquid film. Therefore, the pressure-perturbation mechanism, important for thick films, is here the most probable entrainment mechanism.

From author's photographic studies, the crests of the large waves, when entrainment is observed, are usually not smooth, but composed of many small wavelets. Thus Ishii and Grolmes'[I2] assumption of smooth wave crests and linear velocity profiles within the waves is questionable.

In any studies of critical conditions, it can be concluded that film entrainment will occur whenever the destabilizing components of hydrodynamic forces applied to the surface (pressure and shear) are not balanced by the stabilizing components, such as primarily surface tension and gravity. A completely comprehensive analysis is unfortunately not yet available, and probably impossible in the present state of the art.

Figure 4.22 is a schematic of wave profiles before entrainment commences. For large wave amplitudes, the steam streamline network around the waves is contracted, so that a pressure reduction at the wave crests will occur. This negative pressure differential, P_k, at the crest is proportional to $\rho_s(U_s-C)^2$. P_k should also increase, in general, with increasing wave amplitude, A, (due to increased streamline curvature), and decrease with increasing wave length, λ. Then for correlation purposes, it might be assumed that A and λ effects are linear. Then:

$$P_k \propto \rho_s (U_s-C)^2 \left(\frac{A}{\lambda}\right) \tag{4.31}$$

where U_s is the average vapor velocity, C wave propagation velocity, A amplitude and λ wave-length. The surface tension stress, P_s can be expressed as

$$P_s \propto \frac{\sigma}{\lambda} \left(\frac{A}{\lambda}\right) \tag{4.32}$$

where σ is surface tension. In cases with high velocities and thin films (such as authors), the gravity term is negligible compared to P_s, if λ is small.

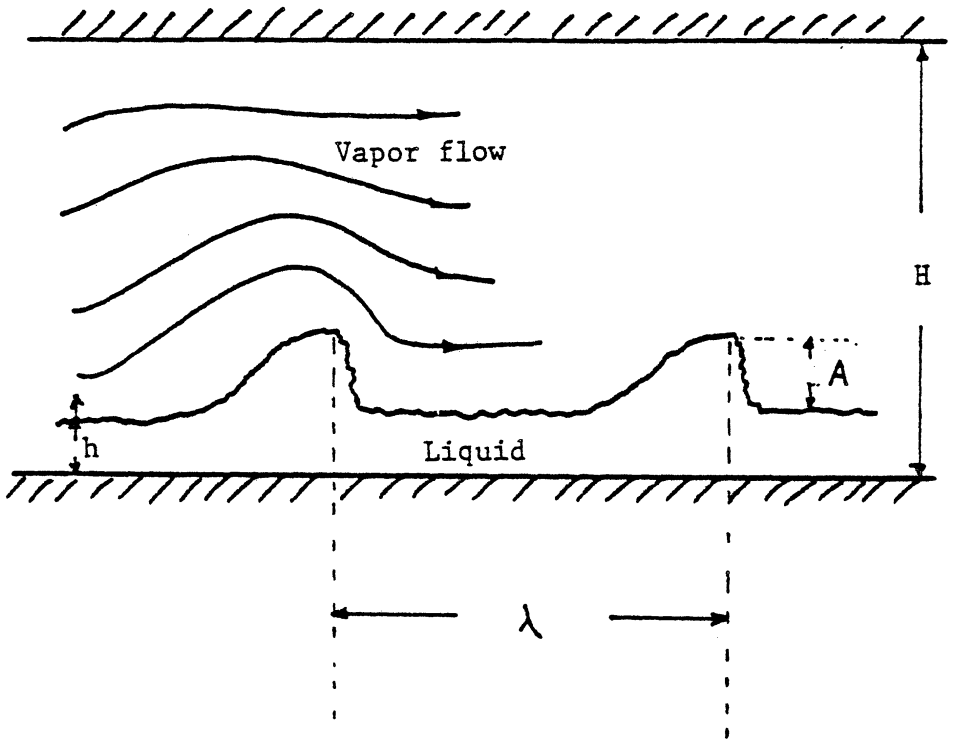
Following these arguments, entrainment should occur whenever,

$$P_k \gtrsim P_s$$

or

$$\frac{\rho_s (U_s - c)^2}{\sigma} \gtrsim \text{const} \tag{4.33}$$

According to this model the critical condition is affected by steam or liquid viscosity only, as they affect wavelength, λ. Author's observations and others[Z4,M11]



h : mean film thickness

λ : wave length

a : wave amplitude

H : channel height

Fig. 4.22 Schematic of 3-D Wave Formation in Entrainment Regime

show that λ is a strong function of film thickness, h. Due to viscous damping at the solid plate, the wavelength λ, cannot be sustained, if it is too long compared to the film thickness, h. Assuming that approximately, $\lambda \propto h$, Eq. (4.33) becomes

$$\frac{\rho_s (U_s-C)^2 h}{\sigma} \gtrsim K \qquad (4.34)$$

Combining Eq. (4.17) for h with Eq. (4.34), a critical non-dimensional relationship is obtained:

$$(U_s-C) \frac{\mu_f}{\sigma} \sqrt{\frac{\rho_s}{\rho_f}} \gtrsim \frac{K}{0.6} \sqrt{\frac{f_i}{2}} \, Re_f^{-1/2} \qquad (4.35)$$

where f_i is friction factor.

The constant in Eq. (4.34) is similar to a critical Weber number for film entrainment.[V2,W2] Two different critical Weber numbers were defined, i.e., We_h based on average film thickness h, and We_p based on the maximum wave height h_p. Data from Van Rossum[V2] and Woodmansee-Hanratty[W2] together with author's results are listed in Table 4.8. Their critical Weber number, We_h, are of the same order as author's. The critical air velocities found by Van Rossum and Woodmansee-Hanratty , however, are much less than the critical steam velocities of present author, while their Re_f values are much higher. From Van Rossum,[V2] the maximum limiting critical Weber number was found to be 17. This is not comparable, for causes unknown, to either W-H[W2] data or author's.

The critical Weber numbers, We_h, for entrainment agree

reasonably well in all cases, in spite of the use of different gases and geometries.

Using an average K = 2.5 (Table 4.8) friction coefficient f_i = 0.005 (Table 4.2 and Ref. W8), the critical condition of Eq. (4.35) becomes

$$(U_s - C)\frac{\mu_f}{\sigma}\sqrt{\frac{\rho_s}{\rho_f}} \gtrsim 0.21\ Re_f^{-1/2} \qquad (4.36)$$

Although the wave propagation velocity C is relatively variable, it is always much smaller than steam velocity, U_s (Table 4.7). Therefore, the steam velocity U_s itself is used rather than the relative steam velocity, U_s-C, in calculating the critical non-dimensional gas phase velocities. Eq. (4.36) then becomes

$$U_s \frac{\mu_f}{\sigma}\sqrt{\frac{\rho_s}{\rho_f}} \gtrsim 0.21\ Re_f^{-1/2} \qquad (4.37)$$

This relation is plotted in Fig. 4.23 . For given Re_f, author's critical non-dimensional steam velocity is much smaller than that predicted from Ishii-Grolmes[I2] shown as ⑤ in Fig. 4.23 . Their results are primarily for data from vertical pipe flows, with little data for horizontal flows. They based their analysis on the similarity between droplet disintegration (i.e., critical Weber number We_h = 22 from Hinze's[H15]) and film entrainment in this Re_f range.

Therefore, the critical gas velocity for entrainment in Eq. 4.37) is appropriate for the horizontal duct data (curve ③, ④, ⑥ in Fig. 4.23). However, a comparison of the measured critical data and predictions based on the proposed

mechanism is limited not only by the lack of detailed information on the large wave shape, but also by an inability to adequately calculate the pressure variations over waves of arbitrary shape and size.

CHAPTER V

FORMATION OF LIQUID FINGERS AND SECONDARY DROPLETS

The characteristics of the liquid phase motion in the wake behind the trailing edge are very important from the erosion viewpoint, since the upper size limits and velocities of droplets reaching downstream rotor blades are directly influenced. Such information is crucial for the prediction of droplet impact blading erosion rates.

Liquid shed from the stator blades enters a highly complex flow region. Author's high-speed motion pictures of the blade wake region show a region of liquid "fingers." These grow relatively slowly, but extend deep into the wake before disintegrating into droplets, which then are rapidly accelerated by the high-velocity steam. Larger droplets then rapidly become unstable, disintegrating into a spray of much finer droplets. These processes are obviously closely involved with the blade erosion problem.

A. CHARACTERISTICS OF FINGER FORMATION

1. Visual Observations

Still photographs (Fig. 5.1) show typical finger shapes, as well as droplet distributions down stream of the finger region. Stream conditions and liquid flow rates, as well as location of each photograph, are listed in Table 5.1. The two concentric circles in some of the photos indicate a pressure tap in the far wall of the test section. The diameter of the inner circle(0.95 cm) provides a useful scale, since the lens focal length is long compared to the test section

width, so that little optical distortion is involved. Flow is from left to right.

Finger shape varies with steam velocities at fixed liquid flow rate. One finger in plate #1.1 of Fig. 5.1 appears, e.g., as an approximate conical tube, with wide base commencing at the trailing edge. Other fingers appear more as cylindrical spikes of smaller diameters aligned with the flow axis. Plate #1.2 (Fig. 5.1), with the same flow conditions as Plate #1.1, shows one long spike-like finger and others of irregular shape (upper part of photo). The liquid sheet from which the fingers are formed, is wavy in the transverse direction, no doubt affecting the location, formation frequency, and size of these fingers. As steam velocity is increased, more and smaller fingers are observed. (Plates #2.1, 2.2, 3.1, and 3.2 of Fig. 5.1).

Detailed study of the fingers is necessary to understand resultant droplet formation. Finger lengths, L, and the distances between them, λ_f, vary with steam velocity and film flow rate. (Plates #2.2 and 3.2 of Fig. 5.1).

As shown by the photos, fingers of differing lengths exist at any given time. The maximum observed finger length, L, is here called the "characteristic" finger length.

One finds that maximum finger length, L, and finger wave length, λ_f, (average distance between fingers) decreases as steam velocity increases (see plates #1.2, 2.2, and 3.2) at fixed liquid flow rate.

With higher liquid flow rates, more complex finger

patterns appear along with more complicated liquid film patterns (i.e. waves, etc). As steam velocity is increased at fixed liquid flow rate, more fingers appear. Larger fingers are very unstable, and do not extend so far axially as do the smaller fingers, appearing at lower liquid flow rates. Sometimes several holes appear in such fingers. At inception, they may be of triangular shape with thick cylindrical boundaries (plate #6.1). These grow to more nearly circular shapes probably because of surface tension, before the finger disintegrates. Plates #5.2 and 6.1 show this intermediate process and the final shattering.

Author defines maximum finger length, L, as axial distance from blade trailing edge to downstream end of the finger. For the highest liquid flow rate (plates #7, 8 and 9), the blade trailing-edge flow appears in total chaos, and of extreme complexity, so that L and λ_f cannot be measured. However, they are still well discernable for lower steam velocities, even at higher steam velocities, except for the exact instant of finger disruption.

2. Reduction of Experimental Photographic Results

Finger formation at the blade trailing edge has been recorded (as already discussed) using both a still polaroid camera, and Fastax high-speed movie camera. The better optics of the still camera enables better observation of the forms occurring at the trailing edge, but cannot provide any information on the flow kinetics. However, the time-dependent processes at the trailing edge were measured

by the high-speed motion picture camera at 5000 Hz.

In most cases, every 80th frame (every 16 ms of real time) was examined with a calibrated viewer-screen. Observer error was estimated to be $\pm$ 15%, for the same film comparing 5 different observers.

Finger formation dependent parameters are maximum finger length, L(t), and finger wave length, $\lambda_f(t)$. The number of fingers, N, was counted for a given transversal length, X. Then $\lambda_f = X/N$.

Typical measurements of maximum finger length, L(t), as a function of time, are shown in Figs. 5.2 to 5.4. For all liquid flow rates, upper limit of maximum finger length, L_u, decreases as U_s is increased. For all U_s average of L increases as liquid flow rate is increased. Also there exist somes "dead" periods before a new finger is formed after one is shed.

The number distribution of maximum finger length, L, was investigated for all flow conditions. Finger length was measured in 2100 frames (70 frames on each of 30 rolls of 100 ft. length). Thus samples used are statistically meaningful and reproducible. The number of maximum fingers in each length increment was normalized by the total number of observations for a given flow condition. Typical maximum finger size distributions are shown in Figs. 5.5 to 5.9.

The largest number of finger lengths (number peak) occurs between 2.5 and 4 mm for all steam velocities for

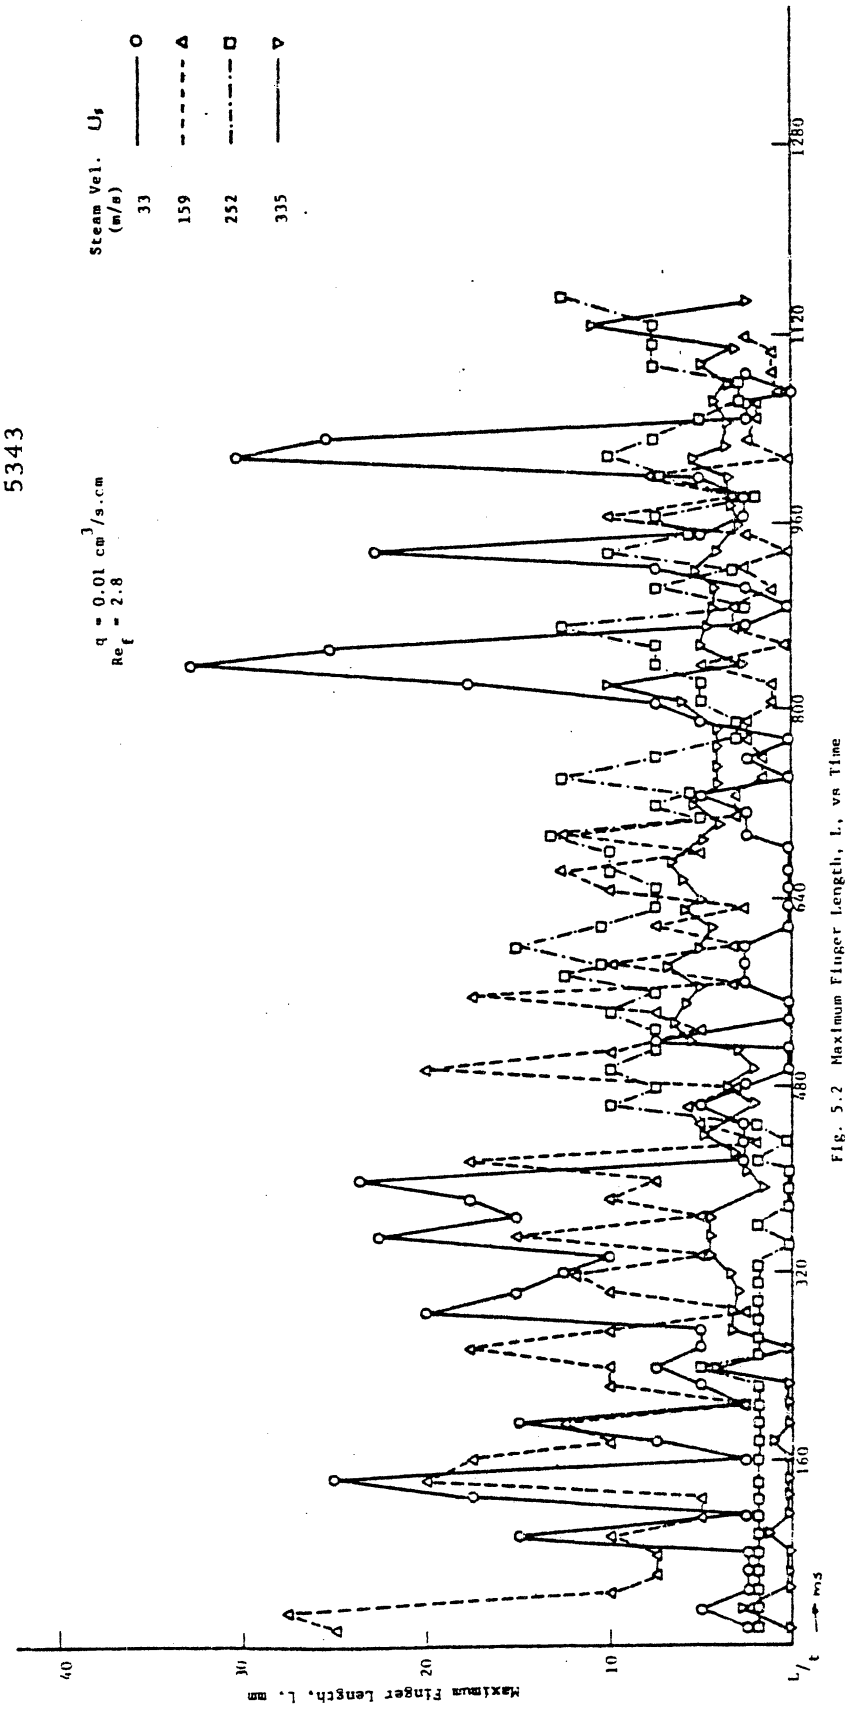

Fig. 5.2 Maximum Finger Length, L_f vs Time

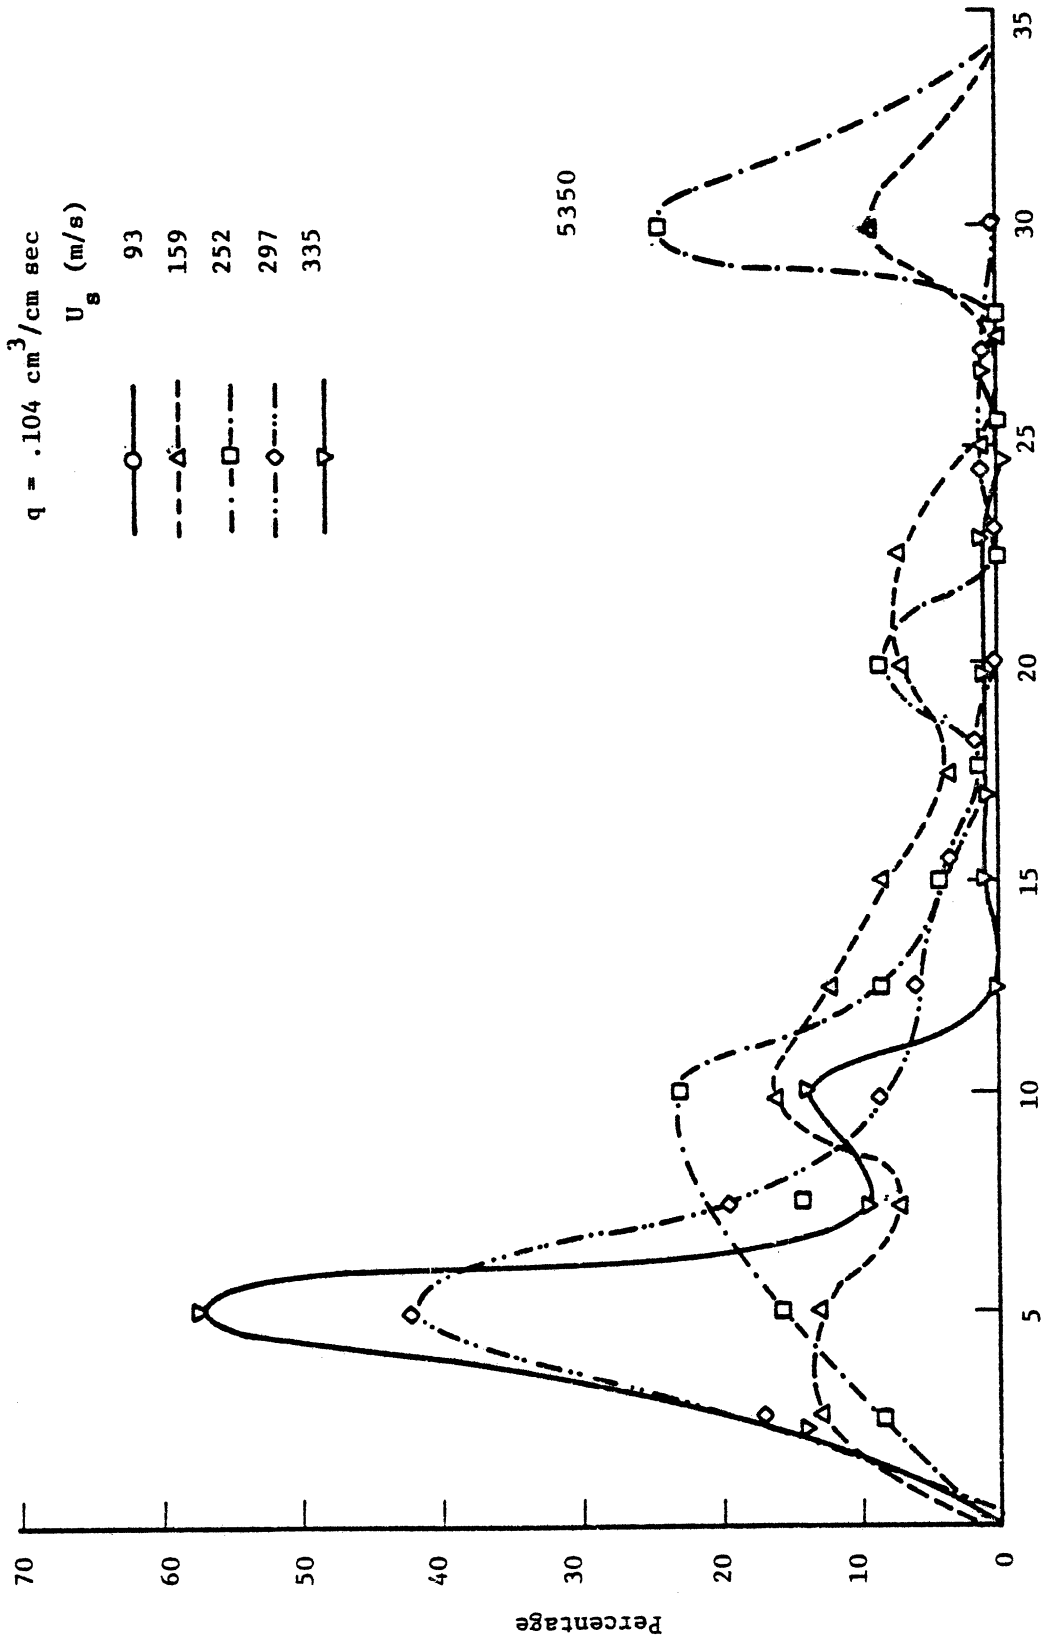

Fig. 5.9 Finger Length Distribution

liquid flow rate, q = 0.010 $cm^3/cm.sec$ (Fig. 5.5). The number peak density increases with increase of steam velocity. This is presumably due to increased finger instability as steam velocity is increased.

An increase in number peak length was also observed at higher liquid flow rate and lower steam velocity (Fig. 5.7 for q = 0.043 $cm^3/cm.sec$). For higher liquid flow rate (Fig. 5.9, q = 0.104 $cm^3/cm.sec$), an increase of number peak L at higher steam velocity was found. For two higher steam velocities (297 and 335 m/s), no peak shift was noted. Time-average maximum finger length, $\bar{L}$ was calculated from the distribution curves in Figs. 5.5-5.9.

Figure 5.10 shows the dependence of $\bar{L}$ on the various flow parameters. At a given steam velocity, $\bar{L}$ always increases with increase of liquid flow rate, q. An increase of U_s at fixed q gives a decrease in $\bar{L}$ in the low U_s region. However, all L's are strongly increased by increasing steam velocity from 297 to 335 m/s. Minima of $\bar{L}$ for all liquid flow rates are observed (Fig. 5.10) at U_s = 297 m/s. The reason for the occurence of these minima is unknown at this time. It cannot involve shock-wave phenomena since the steam velocity is well subsonic (M = 0.72). The data scatter (Fig. 5.10) is reduced for increasing U_s and decreasing q. The bar indicates the full observed range of data.

The frequency of appearance of fingers longer than $\bar{L}$ has been computed from the L vs. t curves (Figs. 5.2-5.4), dividing the time increment for a particular data

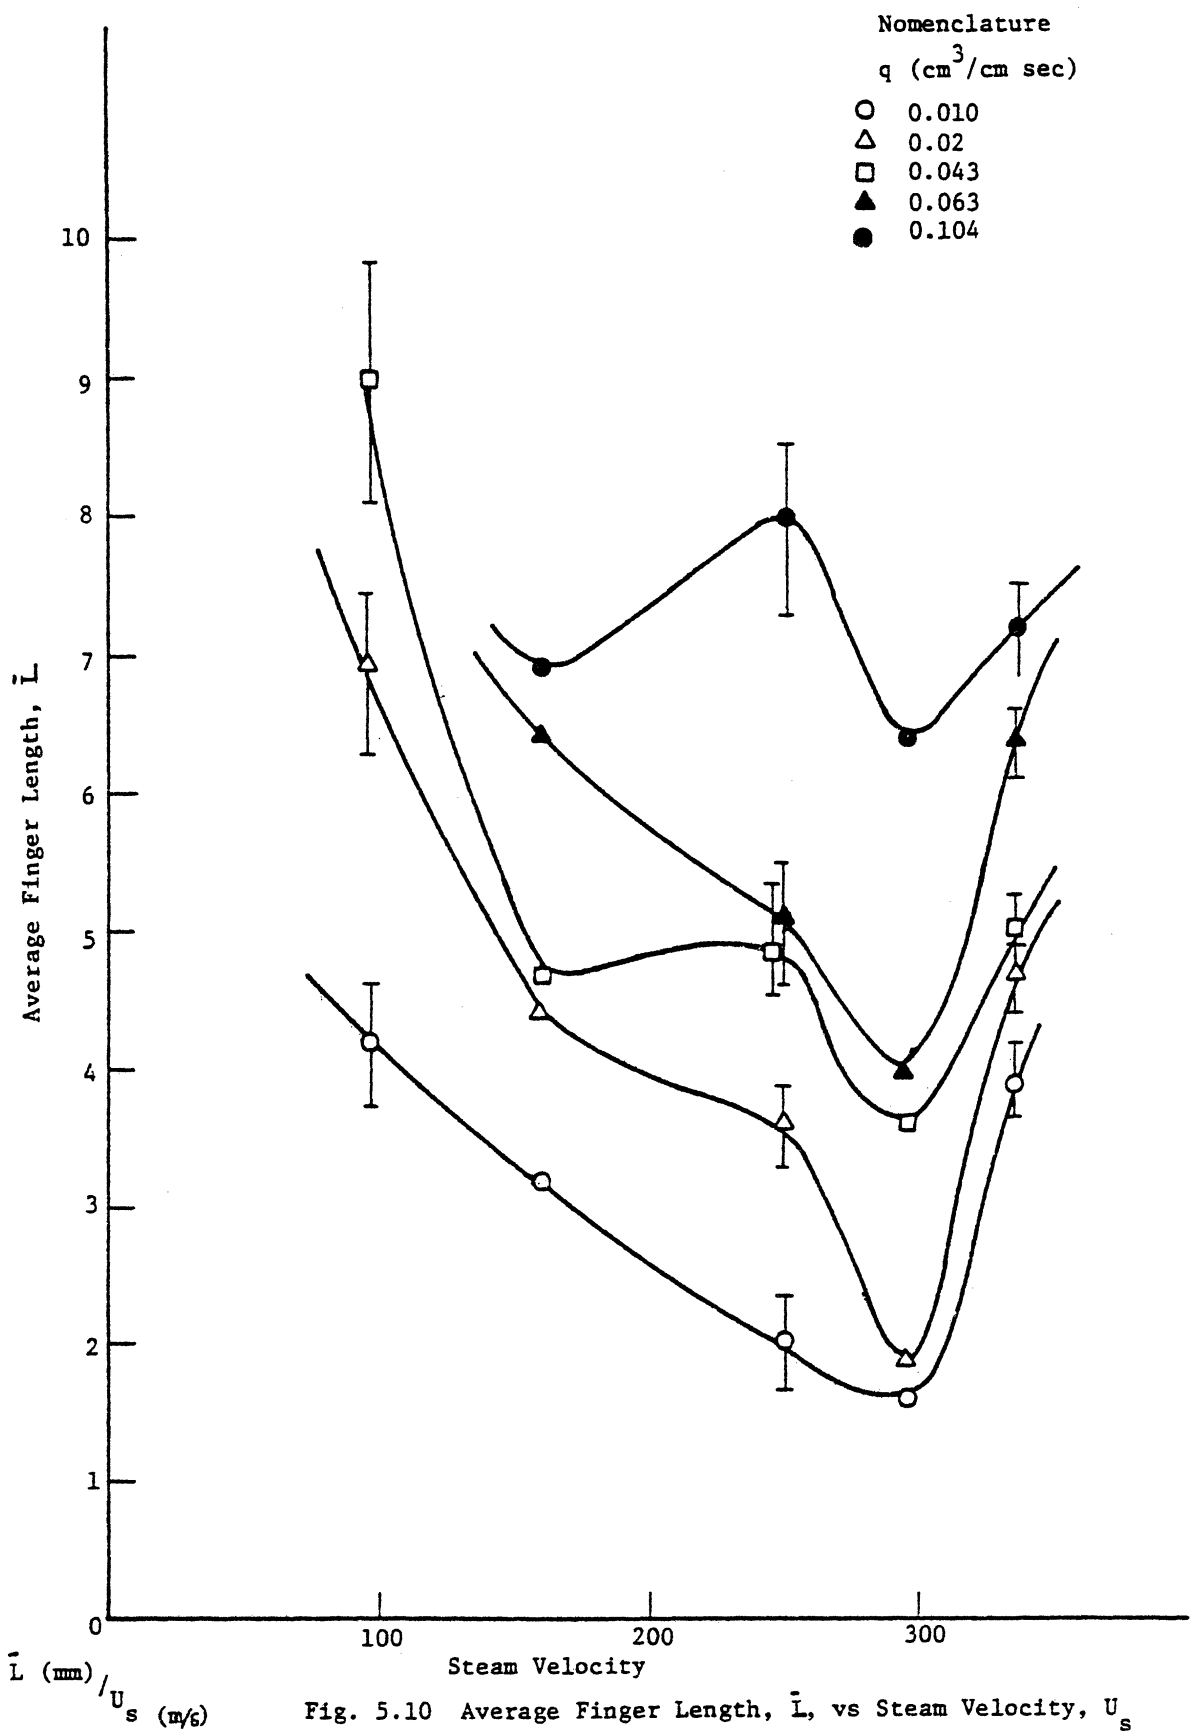

Fig. 5.10 Average Finger Length, $\bar{L}$, vs Steam Velocity, U_s

set by the total number of peaks found therein. This gives the average interval, ΔT, between the appearance of fingers larger than the time averaged finger length, $\bar{L}$.

Figure 5.11 shows ΔT vs. U_s. In general, ΔT increases with increasing U_s, and decreases with an increase of q. The general dependency of ΔT on U_s for fixed q can be explained as follows. An increase of U_s causes a thinning of the vapor boundary layer along the blade, and at the trailing edge. It also leads to an increase of interfacial shear (Table 4.2). Both vapor boundary layer thinning and increased shear stress enhances liquid removal at the trailing edge, due to increased entrainment, because of the closer approach of high velocity steam with consequent greater shear stress. It thus requires a longer time for sufficient liquid to be accumulated for the next such removal. For given U_s, a given quantity of liquid of course accumulates more quickly for increased q, as shown by data (Fig. 5.11). An unexplained deviation from the general trends occurs for q = 0.021 $cm^3/cm \cdot sec$ (Fig. 5.11). ΔT increases with increasing U_s up to U_s = 250 m/s and decreases thereafter, while for all other q, ΔT always increases with increasing U_s.

Two finger Strouhal numbers have been here defined, based on film and steam velocities respectively,

$$S_{f_1} = \frac{\bar{L}}{\Delta T \, V_f} \qquad (5.1)$$

and

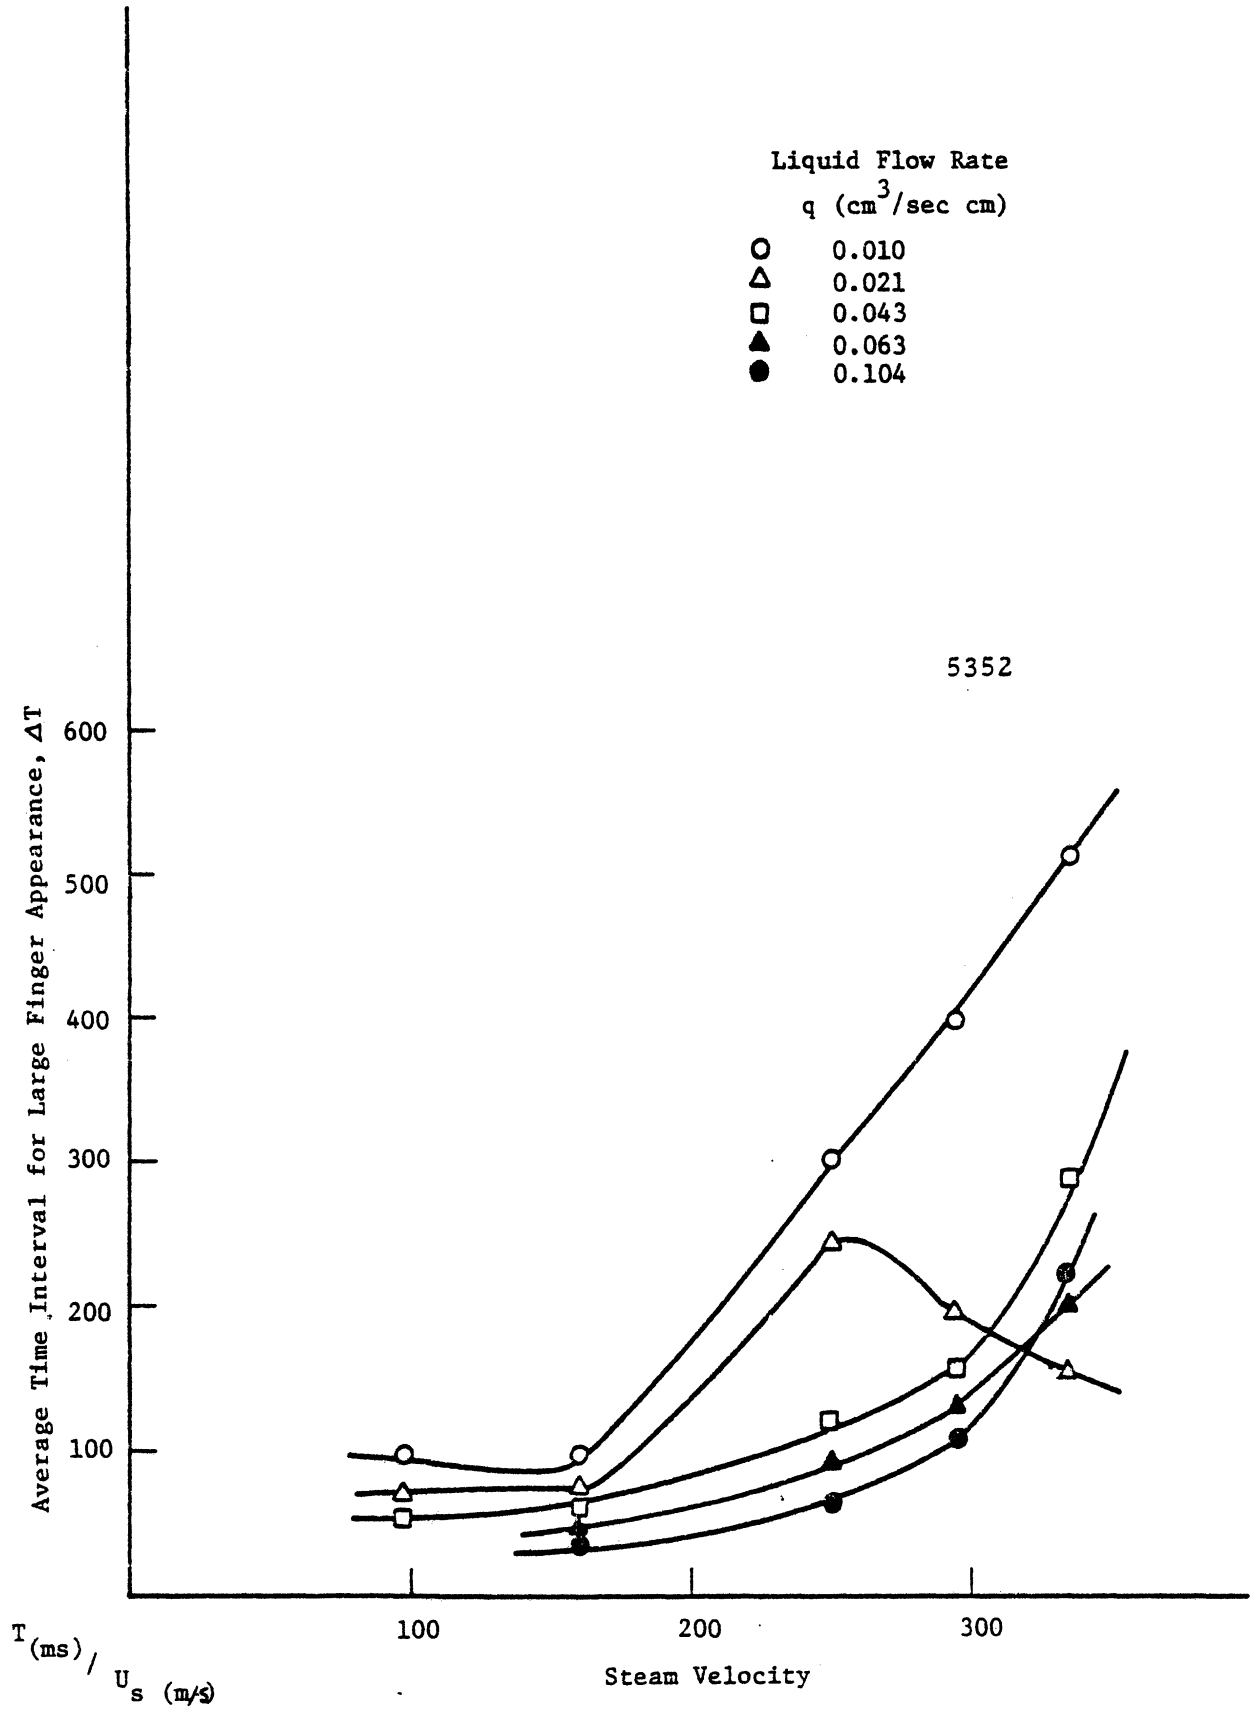

Fig. 5.11 Average Time Interval for Large Finger Appearance, ΔT, vs Steam Velocity, U_s

$$S_{f_2} = \frac{\bar{L}}{\Delta T\, U_s} \qquad (5.2)$$

to correlate finger formation frequencies. Figures 5.12 and 5.13 show the relation between S_{f_1}, S_{f_2} and steam Reynolds Number, Re_s. In general, S_{f_1} and S_{f_2} decrease as Re_s increases. Also for fixed Re_s, both S_{f_1} and S_{f_2} increase with film Reynolds number, Re_f. S_{f_1} and S_{f_2} differ by the ratio of film to steam velocity. S_{f_1}, then, varies from 0.04 to 0.93, thus being in the same range as Strouhal numbers measured in other experiments. On the other hand, S_{f_2} is $\sim 10^{-4}$, and thus not consistent with usual S data.

The finger shedding phenomenon seems obviously closely related to vortex-shedding from a circular cylinder. Such results by Roshko[(R3)] show a Strouhal number increase with Re up to S = 0.21 at Re = 10^3. No futher increase of S occurs for a further Re increase. Here,

$$S = \frac{nD}{V} \quad \text{and} \quad Re = \frac{VD}{\nu}$$

where n = vortex shedding frequency

D = cylinder diameter.

Author's Strouhal number trends with Re_s (Figs. 5.12 and 5.13) differ considerably from those for cylinders. Both S_{f_1} and S_{f_2} decrease with increasing Re_s. Thus the similarity between these processes is limited.

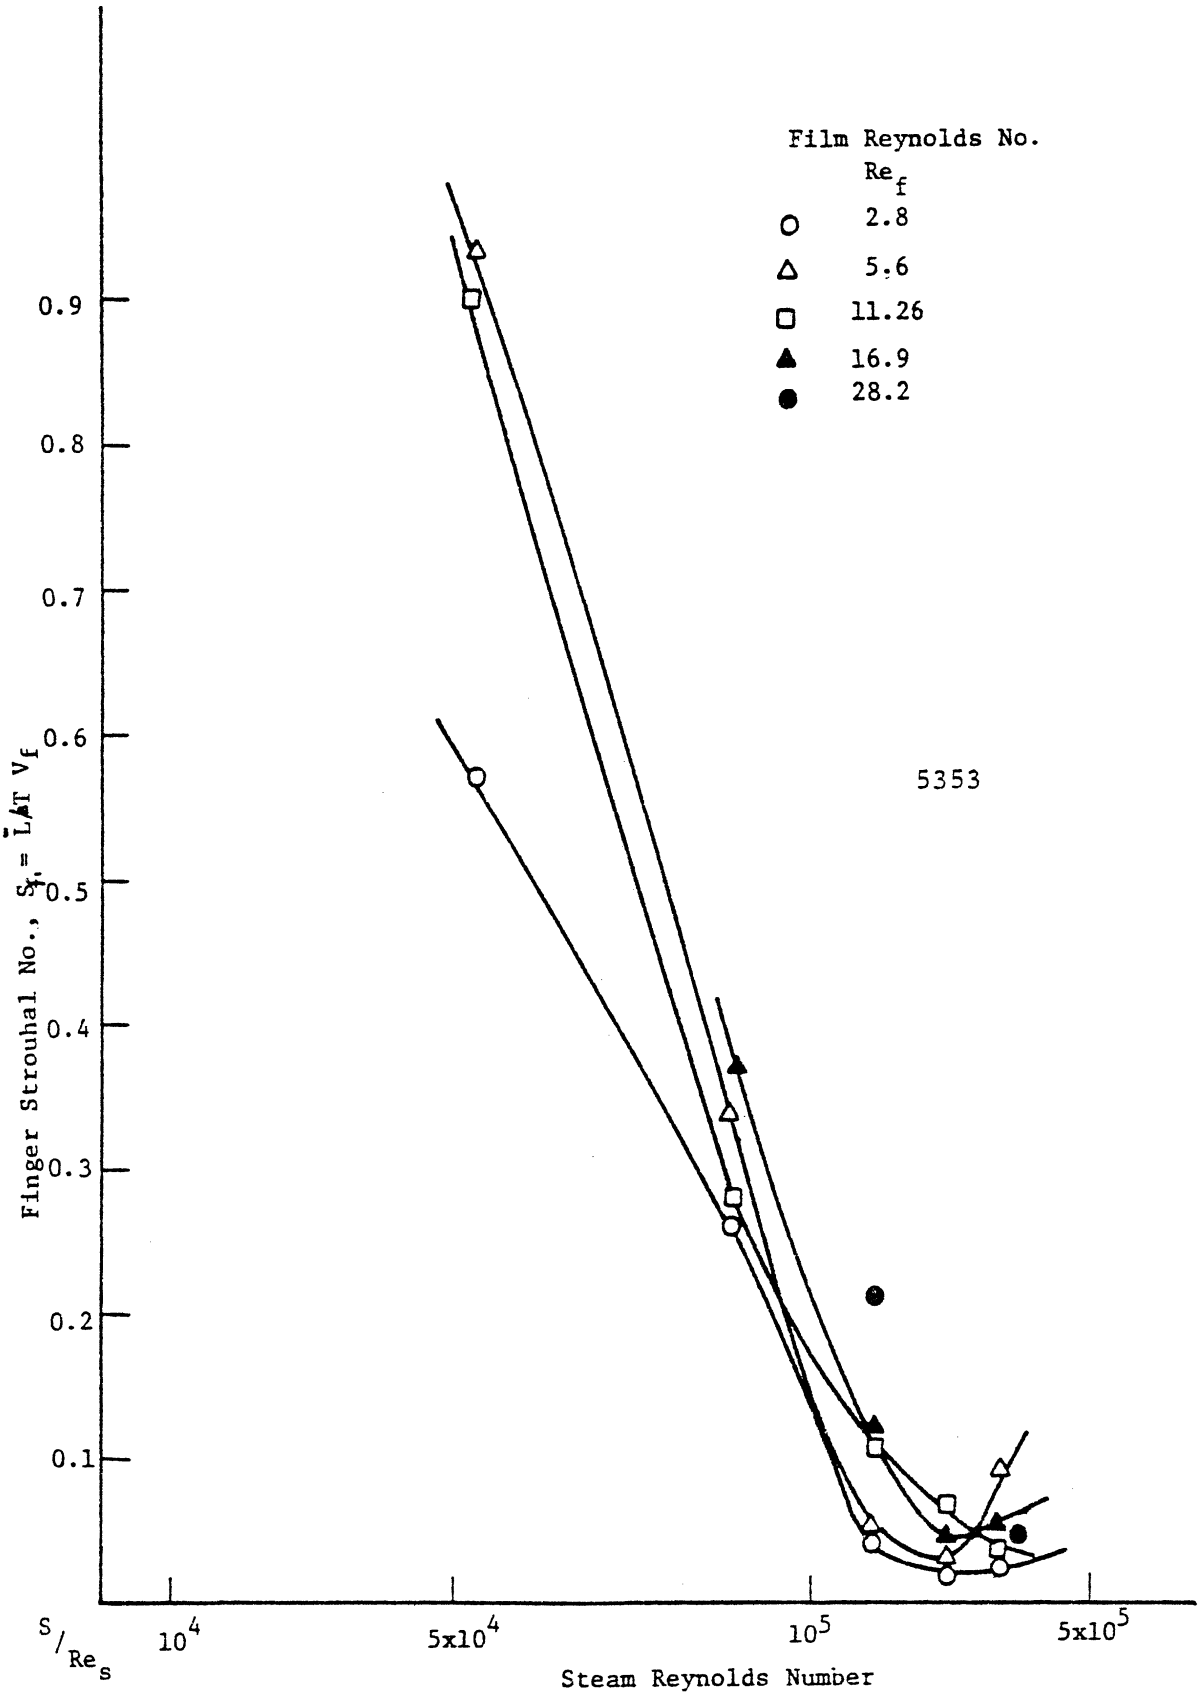

Fig. 5.12 Finger Strouhal No. $S_{f'}$ vs Steam Reynolds No. Re_s

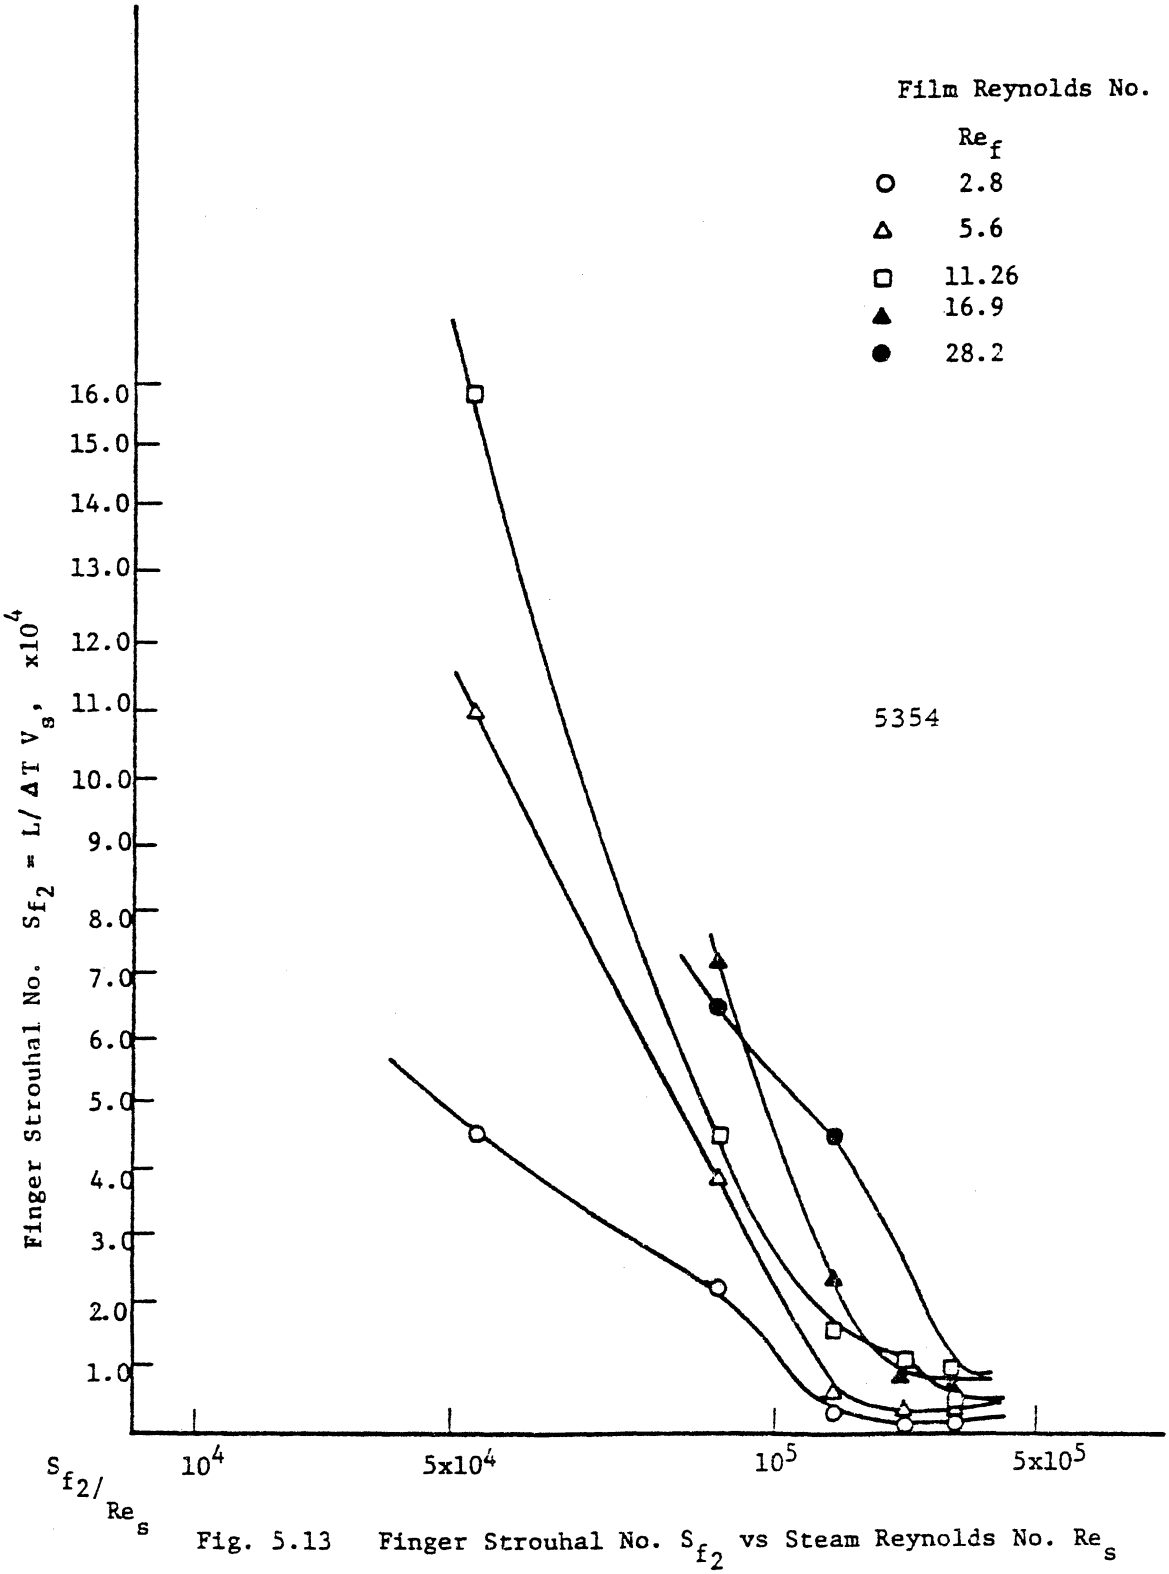

Fig. 5.13 Finger Strouhal No. S_{f_2} vs Steam Reynolds No. Re_s

Reference (B.9) provides a good summary of Strouhal number and Reynolds number correlations for various geometries. There, Strouhal number for flow past a thin flat plate (as author's case) is given as 0.156, which falls within author's range for S_{f_1} (Fig. 5.12). Since S_{f_1} is based on liquid rather than steam velocity, it appears that the vortex shedding in the steam in not a major factor for finger formation frequency.

Presumably liquid finger shedding is related to a balance between the driving forces and the stabilizing effect of surface tension. To study these effects, two new dimensionless parameters have been selected, the first being a non-dimensional time, τ:

$$\tau = \frac{U_s \Delta T}{\bar{L}} \left(\frac{\rho_s}{\rho_f}\right)^{1/2}$$

Physically, τ is the finger formation "period", normalized by a parameter having units of time formed from maximum finger length and densities of vapor and liquid. A rearrangement as below shows the physics more clearly

$$\tau = \left(\frac{U_s^2 \rho_s}{(\bar{L}/\Delta T)^2 \rho_f}\right)^{1/2}$$

$\bar{L}/\Delta T$ can be interpreted as a "deformation velocity" for the fingers. The numerator is the square root of dynamic pressure of the vapor flow acting on the finger, and the denominator is a measure of the deformation stress upon the

liquid finger.

The other nondimensional parameter here used is Weber number where

$$We_s = \frac{\rho_s U_s^2 \bar{L}}{\sigma} \tag{5.5}$$

In this case We_s is the ratio of the driving vapor dynamic pressure to the stabilizing surface tension stress for the finger. Plots of τ vs. We_s for various film Reynolds numbers, are shown in Fig. 5.14. The peak in τ is reduced, and the corresponding value of We_s also increases, as Re_f is increased to $Re_f \cong 8.4$. For higher Re_f, no peak in τ occurred. Rather it increased smoothly with increasing Re_f. Thus, surface tension appears more important for low than high Re_f, as would be expected.

Another important length parameter, mentioned earlier, is the finger wave-length, λ_f, i.e., the average distance between fingers. It was measured by counting the number of fingers, N observed in individual Fastax frames, and dividing the transversal distance along the trailing edge by N. Plots of N vs. time are shown in Figs. 5.15-5.17. In general, the number of fingers was found to increase with steam velocity.

Corresponding finger wave lengths, λ_f, are plotted in Fig. 5.18 as a function of steam velocity. λ_f ranges between 3 and 13 mm for the whole experimental range. Finger wave-lengths decreases for increasing steam velocity, except for highest steam velocity, indicating a minimum

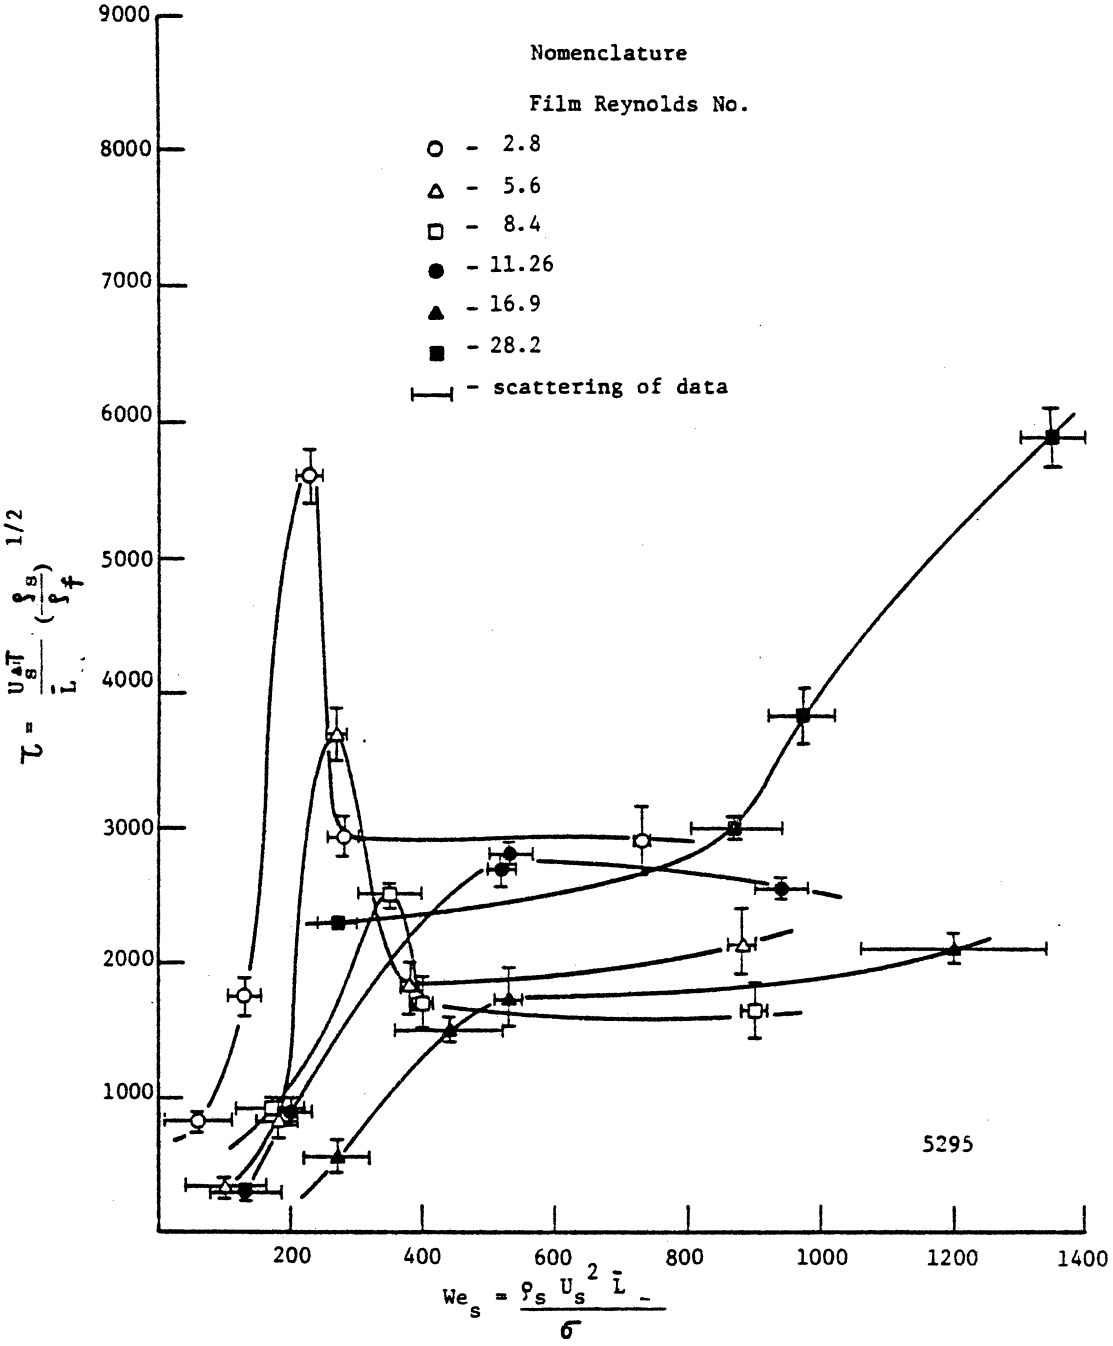

Fig. 5.14 Non-Dimensional Time and Weber Number for Finger

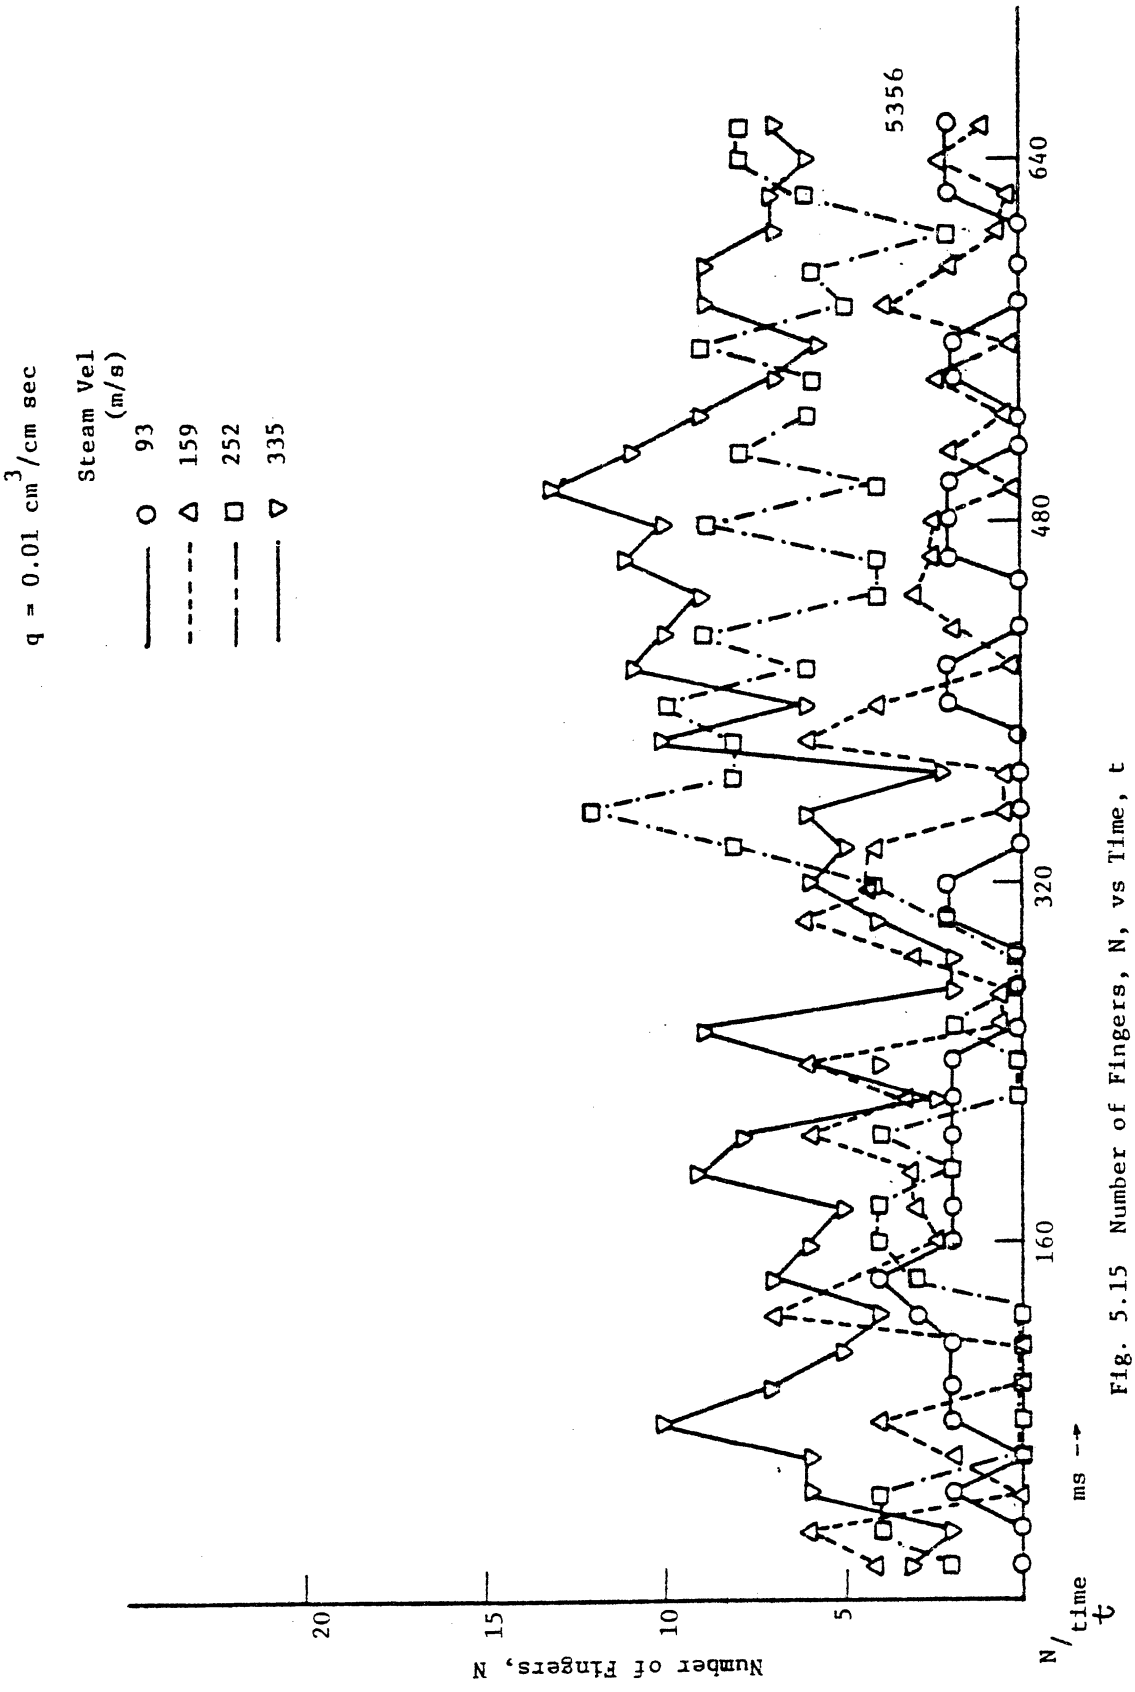

Fig. 5.15 Number of Fingers, N, vs Time, t

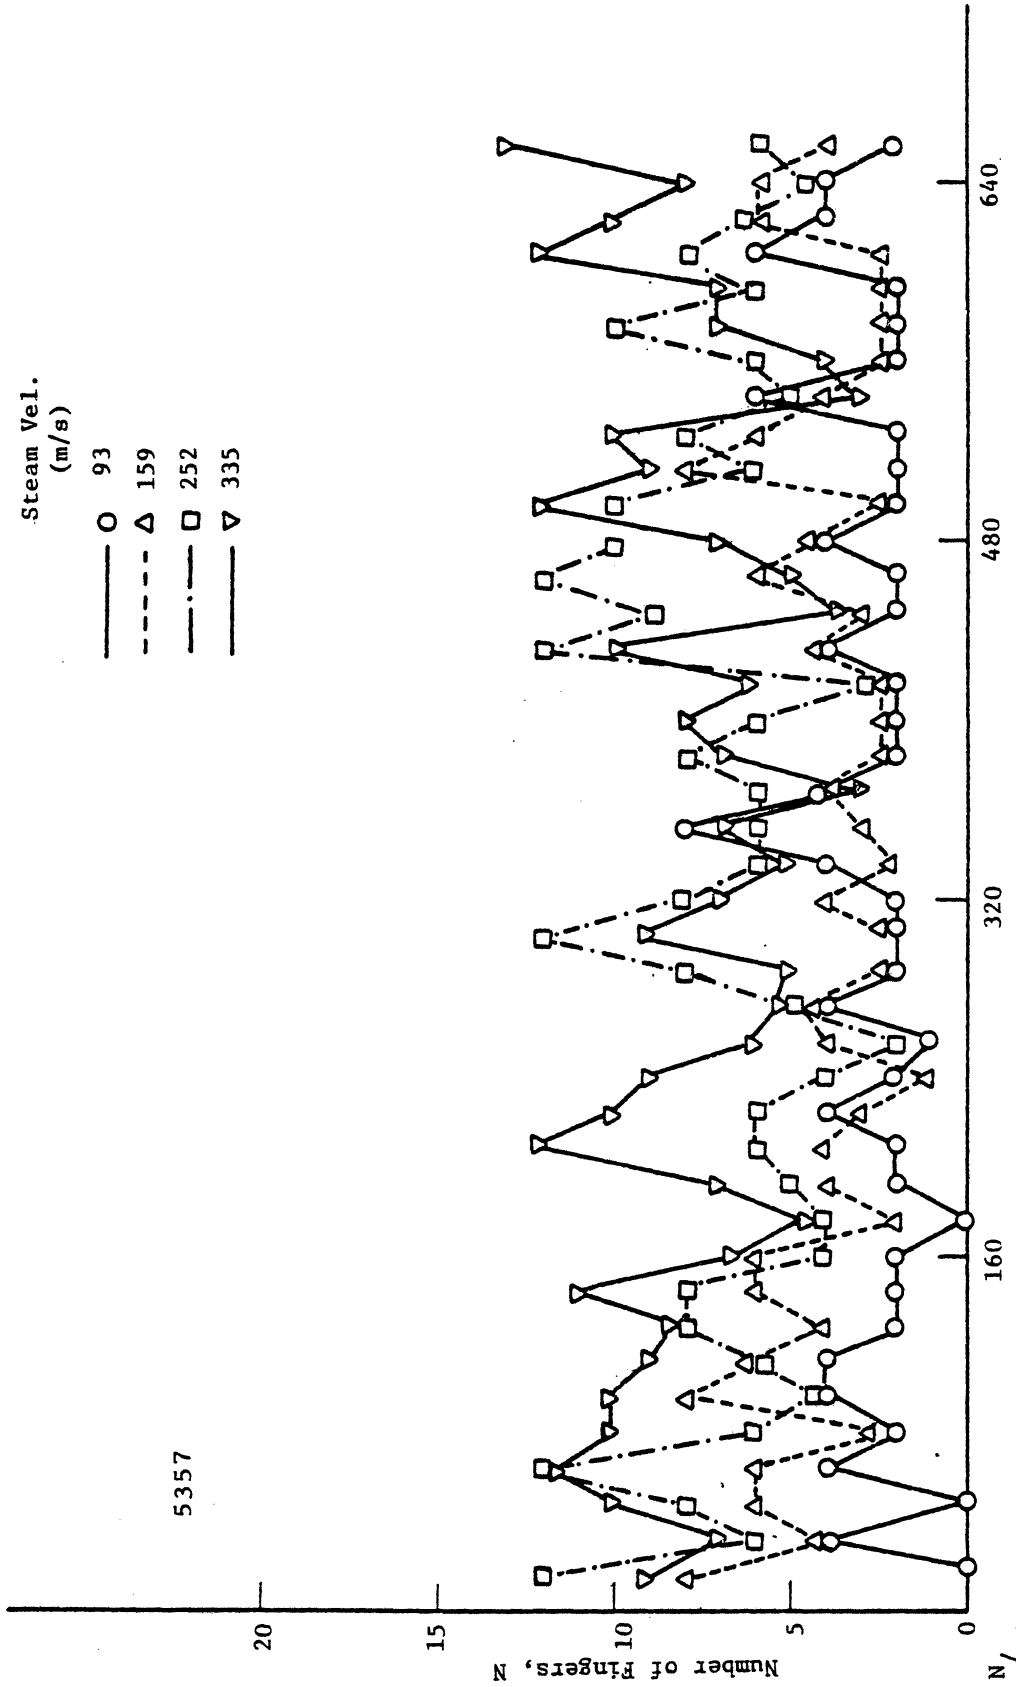

Fig. 5.16 Number of Fingers, N, vs Time, t

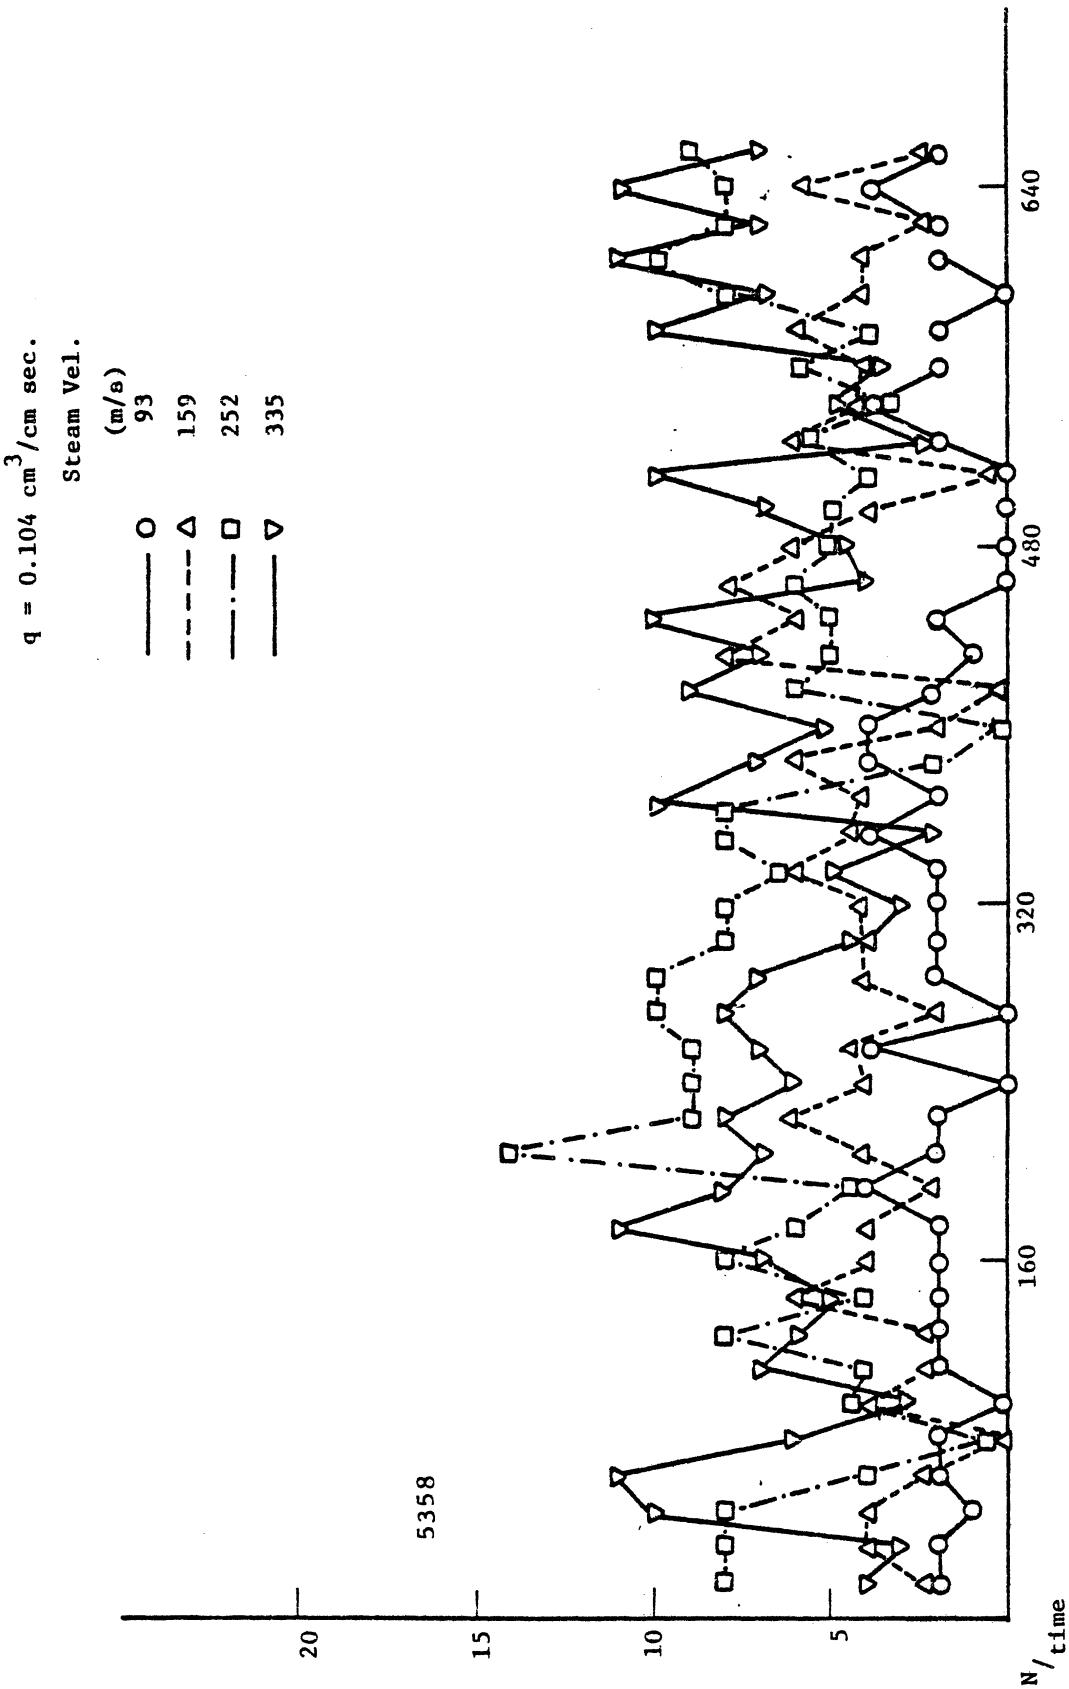

Fig. 5.17 Number of Fingers, N, vs Time, t

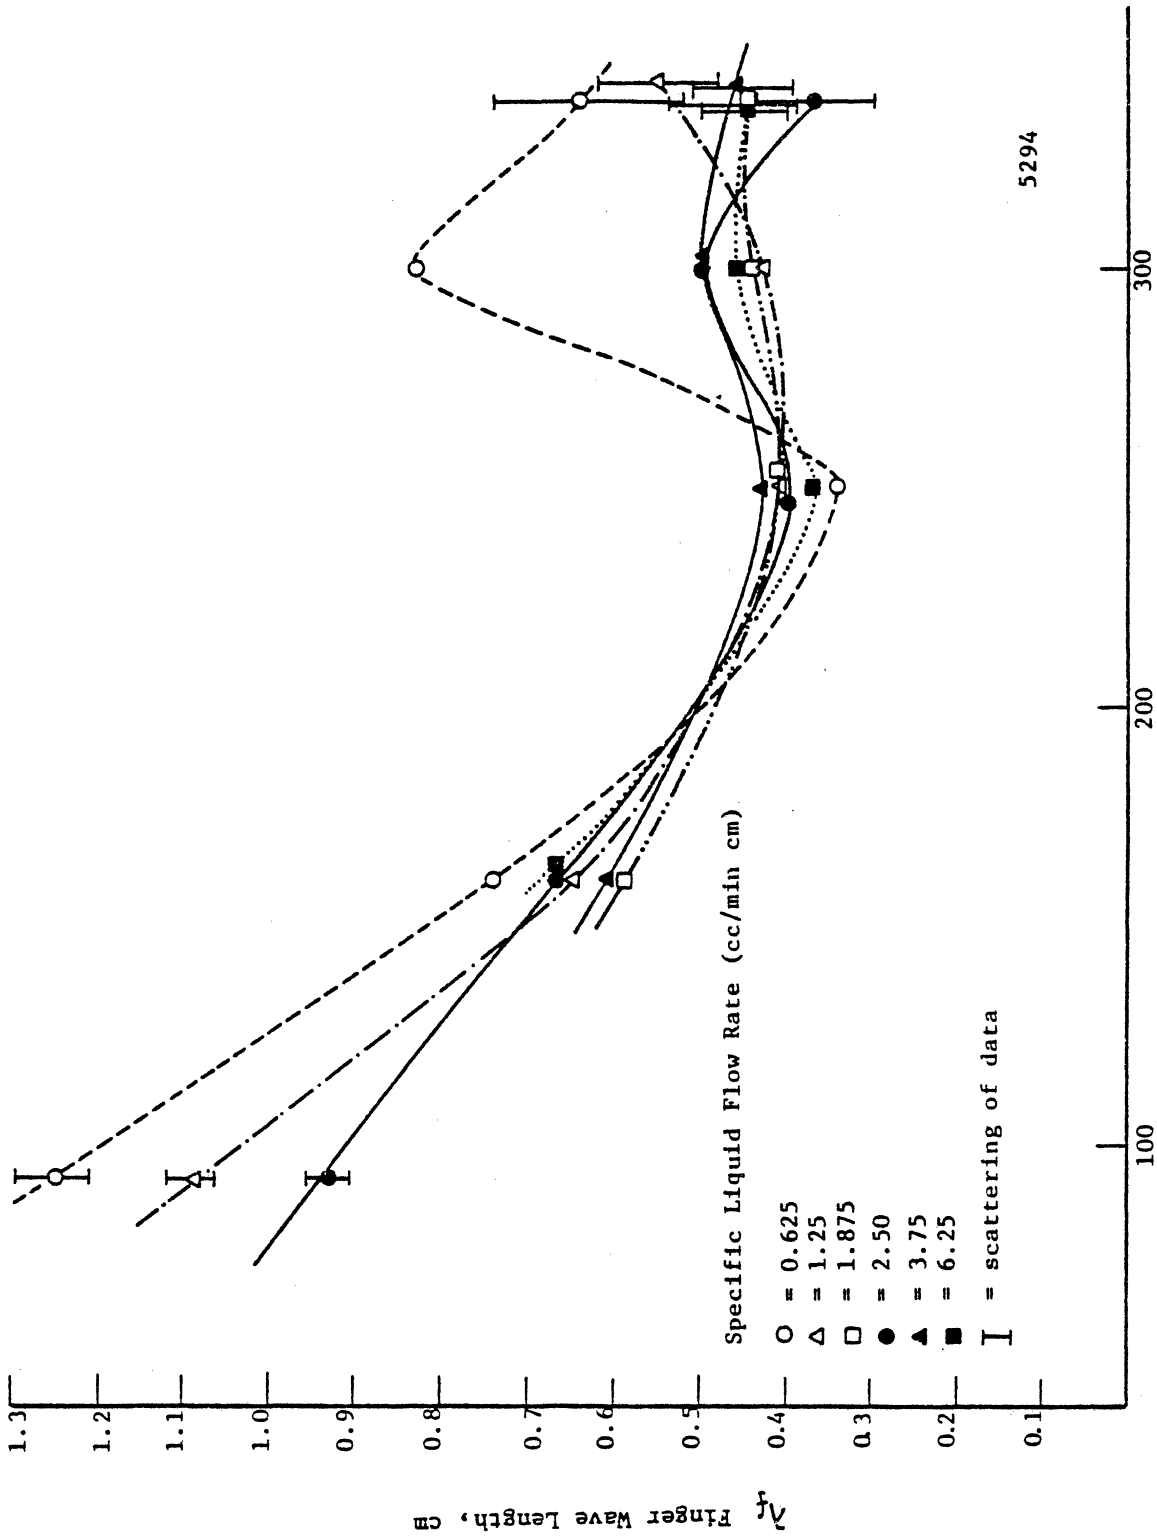

Fig. 5.18 Finger Wavelength vs Steam Velocity

with steam velocity. It is likely that the fingers become increasingly unstable, attaining smaller widths, as steam velocity is increased. This may result primarily from steam turbulence.

A non-dimensional finger length, L* is here defined as:

$$L^* = \frac{\bar{L}}{\lambda_f} \tag{5.6}$$

i.e., a ratio between average finger length and transversal distance between fingers. In general L* increases with Re_f at fixed Re_s (Fig. 5.19). Fluctuations with increasing Re_s are similar at each Re_f. These may be due to overall facility resonances depending upon steam velocity.

All finger formation parameters are listed in Table 5.2. Complete raw data and parameters are also available in our previous reports,[N9,T6,B10,B11] all done under author's supervision.

No results similar to author's current observations appear to exist in the literature, so that no comparisons with other data are possible. Thus author has made a "first attempt" which has obtained comprehensive experimental data. Later investigators will hopefully provide more complete theoretical understanding than obtained here, using this data as a basis.

B. SECONDARY DROPLET MOTION

Due to drag forces from the vapor flow in the trailing edge wake, the "secondary" droplets detached from the fingers are rapidly accelerated. From the viewpoint of turbine blade erosion, direct measurement of droplet acceleration in the wake region is most important. As the droplets approach steam velocity, their normal impact velocity, important for erosion, upon the next rotating blade row will be reduced. (See Fig. 1.6).

For higher steam velocities, many of the larger drops were observed shattered into much smaller droplets, within a distance of 4 cm downstream from the trailing edge. Droplet size distribution data as a function of position is also very important for erosion, defining the probable upper limit of droplet size reaching the next rotating row.

Droplet break-up time, t_b, is here defined as the time-span between droplet formation from the liquid fingers and their disintegration.

1. DROPLET ACCELERATION

Using frame by frame studies of the Fastax pictures (as for the finger formation data) the trajectories of large liquid droplets were recorded under various steam and liquid flow conditions. Droplet size and position from the trailing edge were recorded every 5 frames (every 1 ms). Values of the second time derivative of position were determined using the following equation,

$$\left(\frac{\Delta^2 x}{\Delta t^2}\right)_i = \frac{x_{i+1} + 2x_i - x_{i-1}}{(\Delta t)^2} \qquad (5.7)$$

The "second divided difference" (here used) is the best approximation for the second derivative, if differences of higher order are not known.(D6,W13) This procedure allows identification of those position values containing significant errors. The second divided difference can then be recalculated neglecting the questionable data points. When position values are thus neglected, the time intervals are not equal. The second divided difference can then be written:

$$\left(\frac{\Delta^2 x}{\Delta t^2}\right)_i = \frac{\dfrac{x_{i+1} - x_i}{t_{i+1} - t_i} - \dfrac{x_i - x_{i-1}}{t_i - t_{i-1}}}{\dfrac{t_{i+1} + t_{i-1}}{2}} \qquad (5.8)$$

The steam and liquid flow conditions for which data on accelerations and break-up time were obtained are listed in Table 5.3. All data on droplet size and position were stored on the computer tape. Details of computer programs used and output obtained are found in Appendix C.

The time-averaged accelerations of droplets under various steam and liquid flow conditions are listed in Table 5.3. and plotted in Fig. 5.20 . Observed droplet accelerations range from $\sim 3 \times 10^4$ to $\sim 3.5 \times 10^5$ cm/sec^2 ($\sim$30 to 350 "g"), and increase with steam velocity, as would be expected.

Considering the nature of the phenomena observed, a sta-

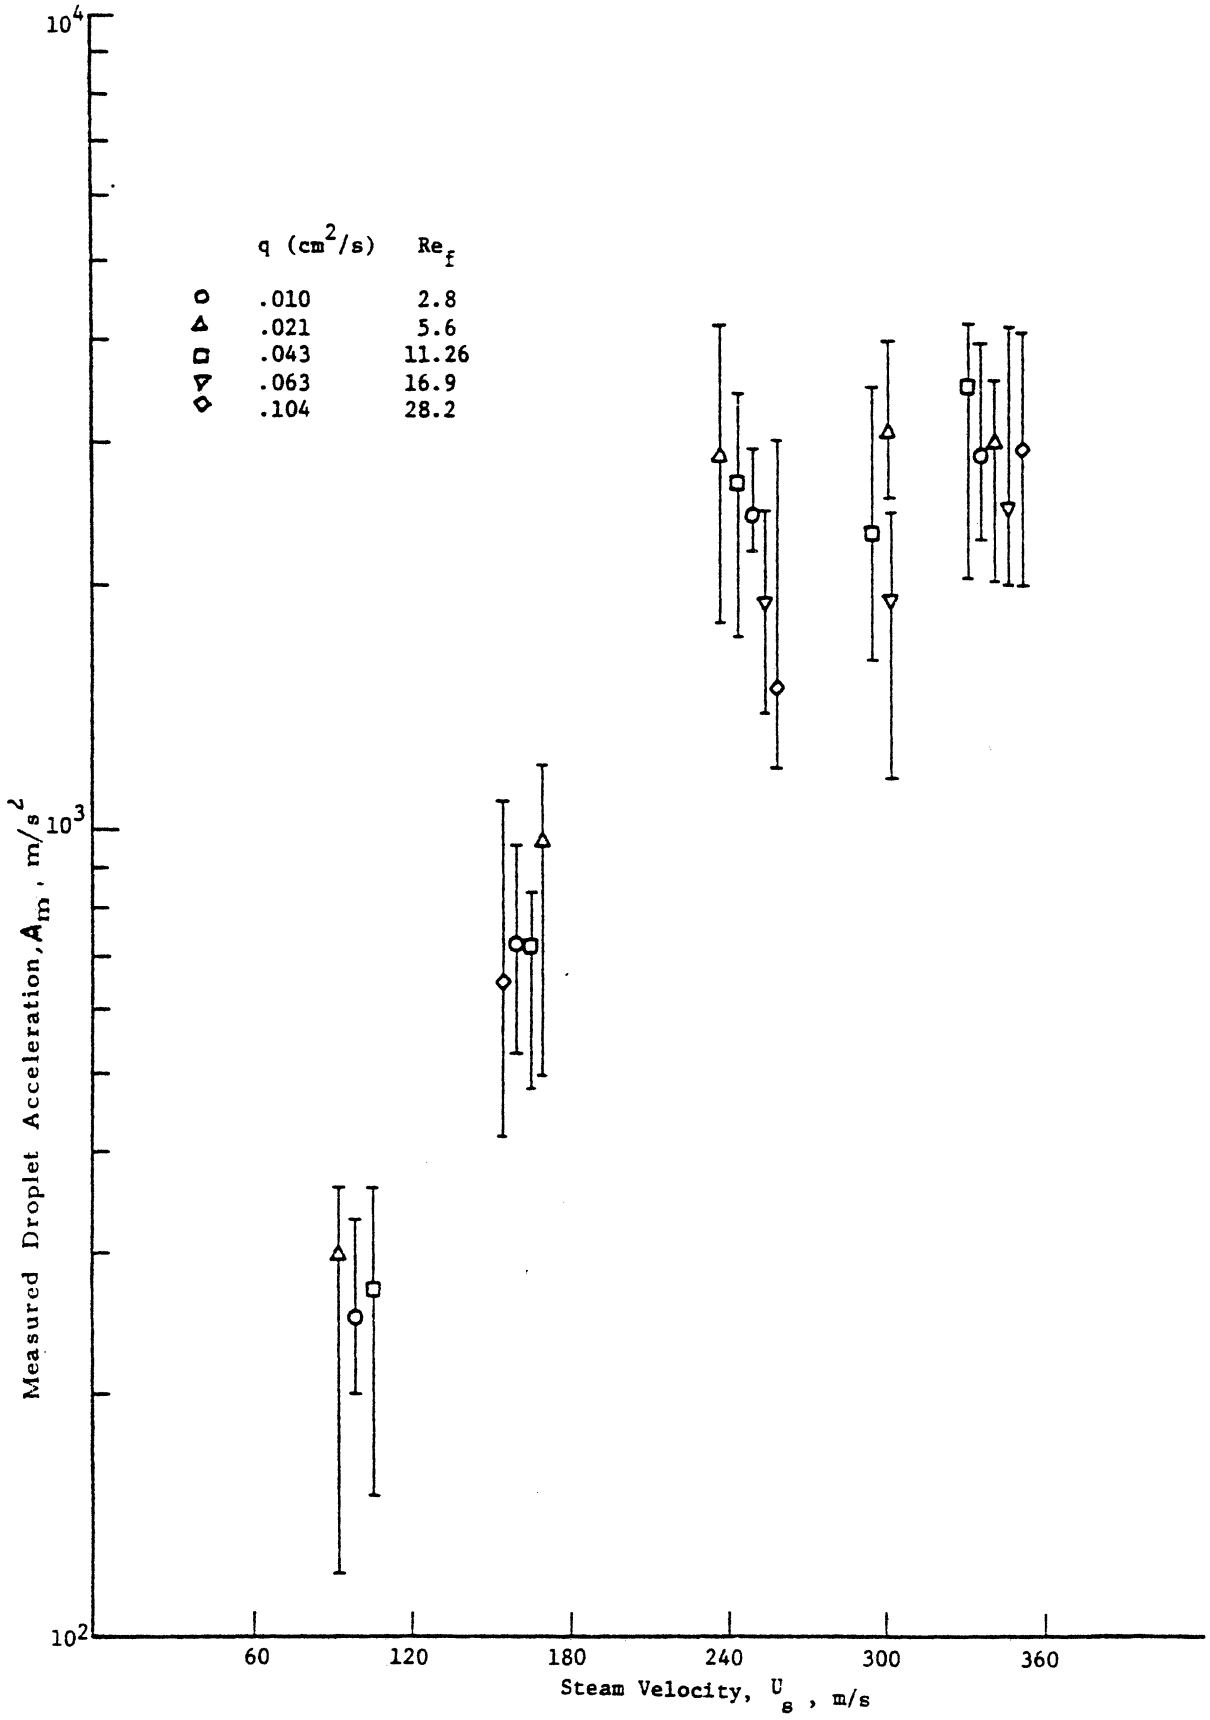

Fig. 5.20 Measured Droplet Acceleration as a Function of Steam Velocity

tistical method of data reduction was necessary and desirable. Thus a linear regression analysis was conducted. Full details of the analysis are given elsewhere (M14). The full output of the statistical analysis is given in Appendix D. An important result of this analysis is that droplet accelerations are largely unaffected by changes of liquid flow rate for all steam velocities. This is particularly true for low velocities. (Fig. 5.21)

THEORETICAL CONSIDERATIONS

Three important assumptions were needed to obtain an analytical expression for droplet acceleration. First, spherical drops were necessarily assumed, though many are severely distorted. An equivalent droplet diameter was defined as that of a disc of the same area perpendicular to the flow direction.

Next, the local vapor velocity was assumed to be the mean steam velocity at the blade exit plane.

Finally, the only force upon the droplets was assumed to be steam drag. One then obtains the following equation,

$$\rho_f \mathcal{V}_c \frac{dU}{dt} = C_D A_D \frac{\rho_s U_r^2}{2} \qquad (5.9)$$

where,

ρ_f = density of liquid droplet

ρ_s = density of vapor

$\mathcal{V}_c$ = volume of droplet $(= \frac{\pi D^3}{6})$

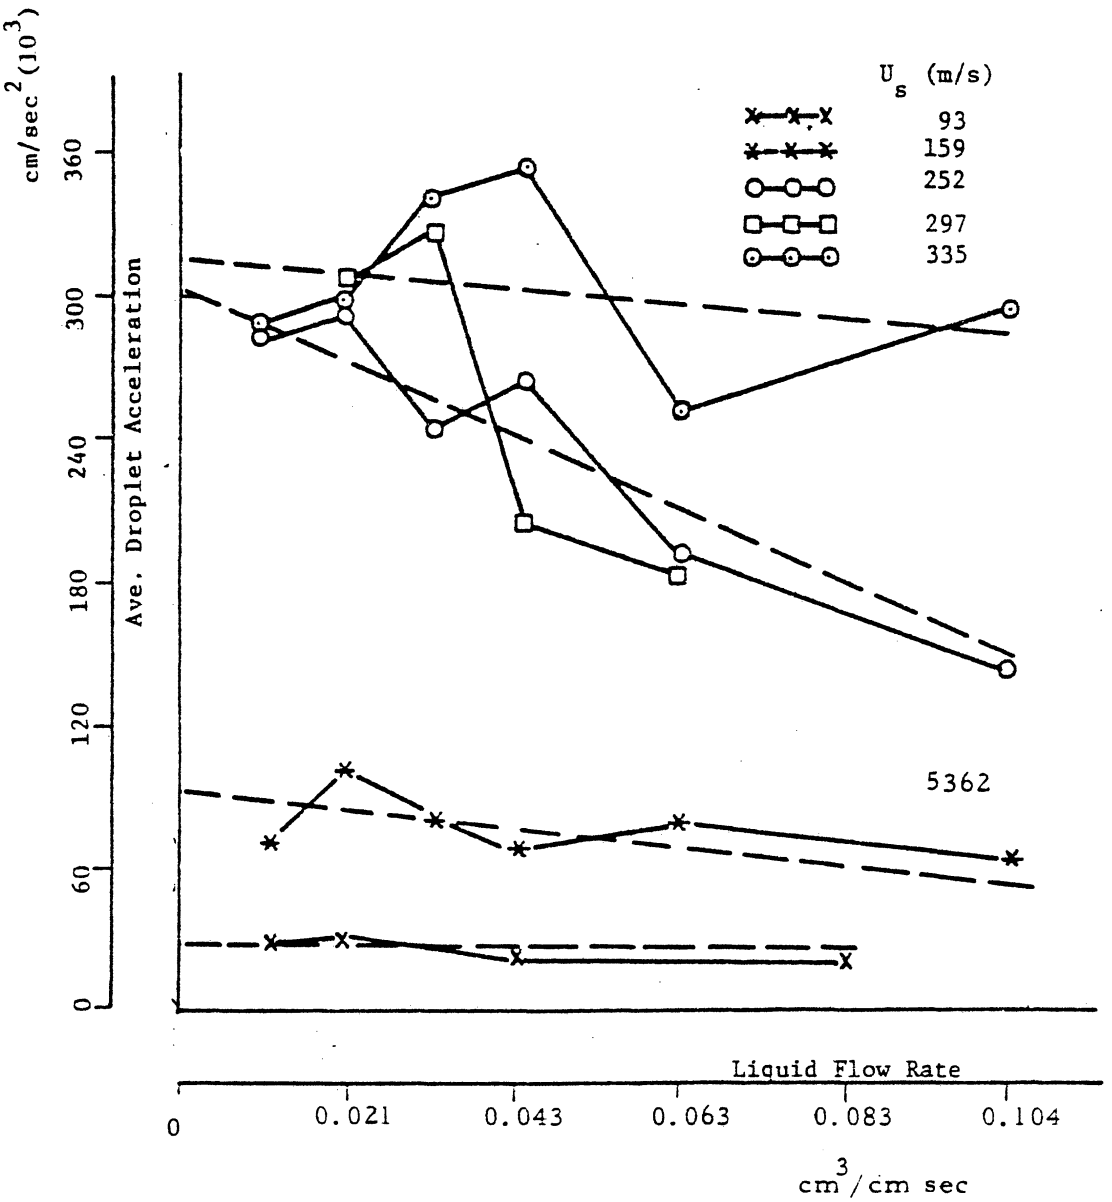

Fig. 5.21 Average Observed Droplet Acceleration versus Liquid Flow Rate at Various Steam Velocities. Dotted lines show regression analysis results. Note: Slopes of regression lines were not found to be significantly different than zero. See Statistical Analysis.

$\frac{dU}{dt}$ = droplet acceleration

C_D = Drag Coefficient

A_D = Projected area of droplet in the axial direction ($= \frac{\pi}{4} D^2$)

U_r = Relative velocity of droplet ($= U_s - U$)

Rearranging Eq. (5.9), droplet acceleration for drops of equivalent diameter, D, is $\frac{dU}{dt} = \frac{3}{4} \frac{\rho_s}{\rho_f} \frac{C_D}{D} U_r^2$ (5.10)

Many empirical results are available for C_D. As stated in Chapter II, all calculations of C_D were based on droplet acceleration due to uniform flow around a single droplet. No direct measurements of droplet acceleration in the wake region (as in the author's case) were found in the literature.

Author's wake-droplet regime is complicated by the presence of many droplets together. Because of spontaneous condensation in the "Wilson zone" combined with secondary droplets formation, a droplet size distribution exists in the wake. The drag for a given droplet will be influenced by other droplets. Such droplet "shielding" should thus be considered for a more precise analysis.

The drag coefficient shield effect was apparently first considered by Tam[T2]. He derived a statistical formula for the drag exerted on a cloud of spherical particles of given

size distribution. He concluded that the individual particle drag depends significantly only on the first three moments of the distribution function. However, no experimental verification yet exists. Tam's solution is not used by present author, because it is applicable only to very low Reynolds numbers.

Instead three different already published [C14,A1,S6] empirical correlations were compared with author's data. These are:

$$1) \quad C_D = \frac{24}{Re_D}\left(1 + \left(\frac{Re_D}{60}\right)^{5/9}\right)^{9/5} \tag{5.11}$$

$0 < Re_D < 3000$ (Churchill & Usagi [C14])

$$2) \quad C_D = 0.292\,(1 + 9.06/\sqrt{Re_D})^2 \tag{5.12}$$

$0 < Re_D < 5000$ (Abraham [A1]),

and

$$3) \quad C_D = \frac{24}{Re_D}\,(1 + 0.17\,Re_D^{2/3}) \tag{5.13}$$

$0 < Re_D < 6000$ (Serafini [S6]),

where droplet Reynolds number, Re_D, is defined as

$$Re_D = \frac{U_r\,D}{\nu_s} \tag{5.14}$$

These three empirical correlations were substituted into Eq. (5.9), and comparisons with author's data made.

(Appendix E). Calculated accelerations, using Eqs. (5.11 - 5.13) were compared with those measured (Fig. 5.22). For low acceleration, i.e., low steam velocity, the differences between measured and calcualted accelerations, using any of the C_D correlations are small. However, for higher steam velocities, the calculated accelerations using any of the C_D correlations are larger than those measured. The Serafini correlation fits best the present data. Therefore it alone has been used in the following.

2. Observed Droplet Decelerations

Author defines an acceleration ratio, R,

$$R = \frac{A_m}{A_s} \tag{5.15}$$

where A_m is measured acceleration and A_s that calculated from Serafini's C_D correlation (Eqn. 5.13). Time averaged results ($\bar{R}$) are listed in Table 5.3. One finds $\bar{R} < 1$ for high liquid flow rates ($q \geq 0.043$) and for the highest steam velocity (U_s = 335 m/s) for any value of q. For fixed flow conditions, abrupt oscillations in R with respect to time are found (Appendix C and Figs. 5.23 and 5.24). The wake droplets are not continuously accelerated, but actually decelerate at times and exhibit "back-flow" moving against the mean vapor flow. Several of our high-speed movies show this intermittent droplet directional change. To be more explicit, droplets detaching from a liquid finger move a short distance ($\sim$ 2 cm) down stream, then reverse

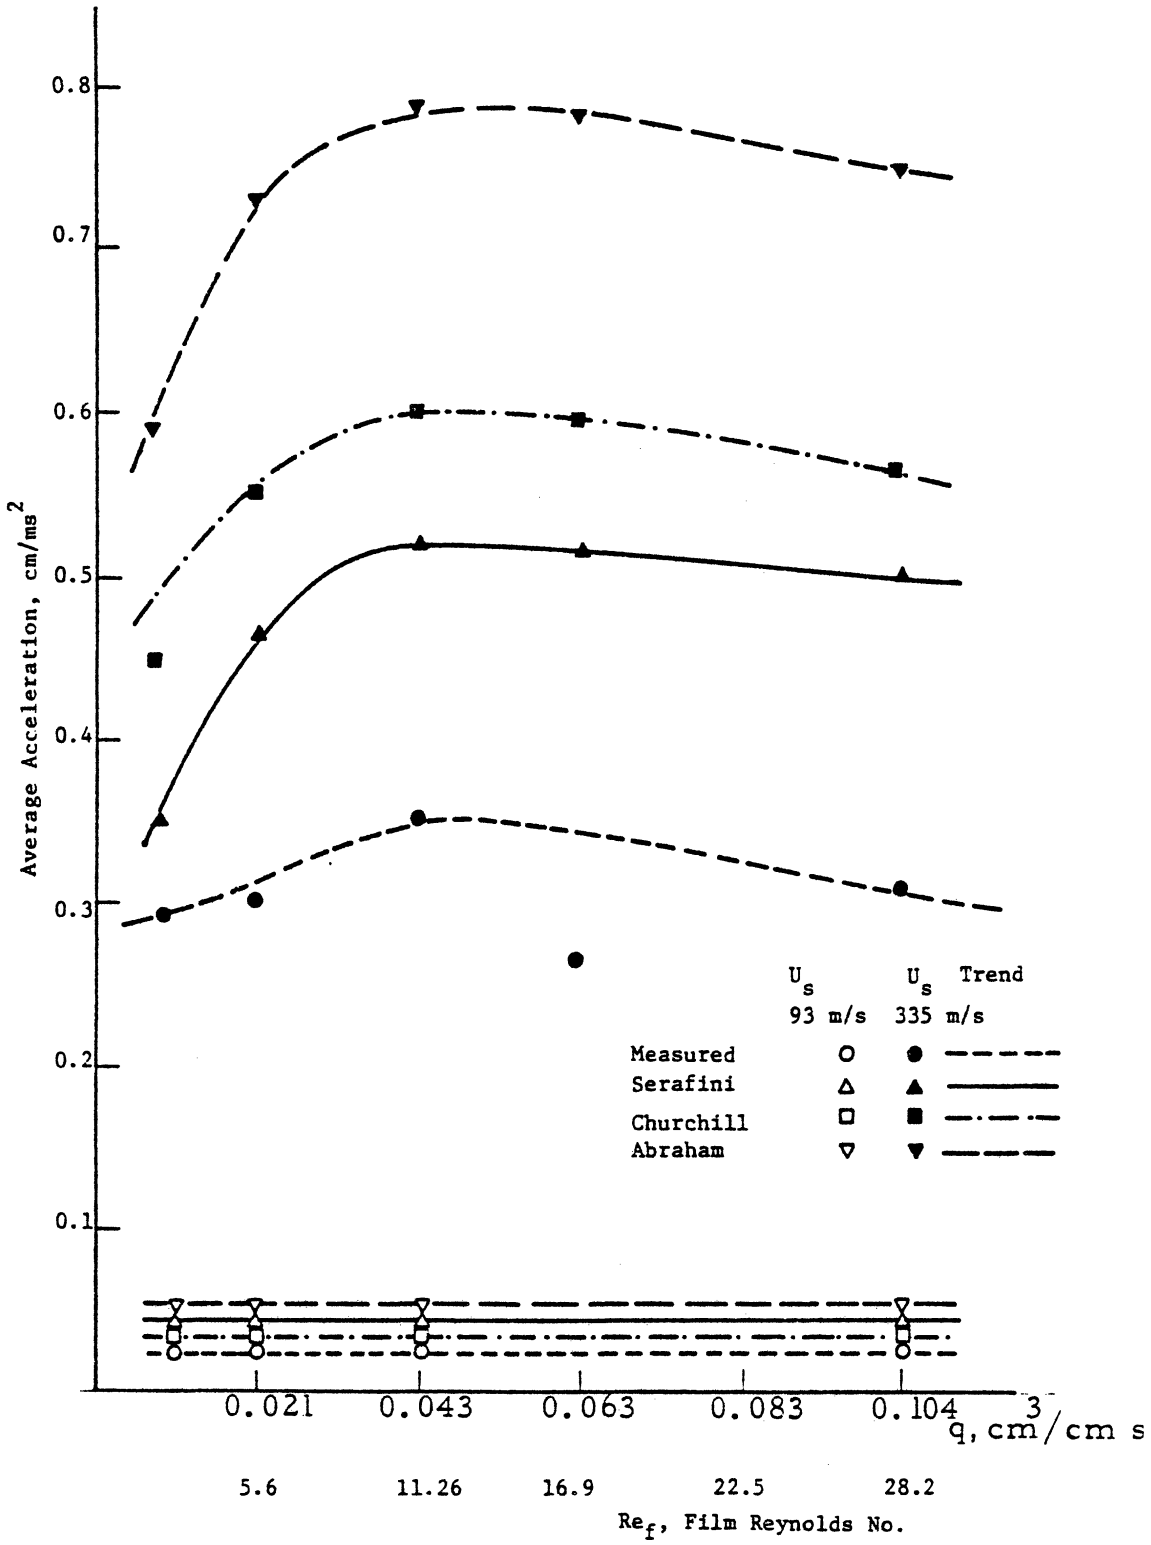

Fig. 5.22 Comparison of Average Measured Acceleration and those using other Correlations of C_D

direction, moving a short distance (~2 cm) upstream. These negative accelerations are shown in Figs. 5.23 and 5.24 .

The only plausible mechanism for this droplet deceleration and motion reversal appears to be periodic vortex shedding from the relatively blunt blade trailing edge. Figure 5.25 is a schematic of the hypothesized flow pattern. If an individual vortex is not aligned precisely with a droplet center (see lower portion of Fig. 5.25), then such a droplet will experience an additional (upstream or downstream) relative velocity and drag due to the velocity field of that particular vortex. For such upstream relative velocity, it would be momentarily decelerated. Even though this hypothesized mechanism is consistent with author's data, vortex measurements have not been possible. Nevertheless it does appear the only plausible explanation for the observations.

Some related parameters can be deduced. Average time interval Δt between decelerations, calculated from the R vs. t curves (Figs. 5.23 and 5.24), is a measure of the vortex shedding frequency. A calculation of Δt was possible only for low steam velocities (U_s = 93 and 159 m/s). For higher steam velocity, the droplets disintegrated too rapidly for accurate measurements of this type. Values of Δt and related parameters are listed in Table 5.4. Two non-dimensional parameters(S_B and Re_D) were selected to correlate the droplet deceleration frequency. These numbers are defined below.

$S_{B_{v_f}}$: ($\frac{B}{\Delta T V_f}$)

Table 5.4: Parameters Concerning the Periodic Deceleration of Droplet in the Wake Region.

$$S_B = \frac{B}{U_s \Delta t} \qquad \text{Strouhal number} \qquad (5.16)$$

$$Re_D = \frac{D\, U_s}{\nu_s} \qquad \text{Droplet Reynolds Number} \qquad (5.17)$$

where B is blade thickness, Δt periodicity of deceleration, and D effective droplet diameter.

S_B is plotted against Re_D in Fig. 5.26. Although data scatter is large, the solid lines show the general trends. S_B decreases as U_s increases from 93 to 159 m/s. This is due to the increase in both U_s and Δt. (Average Δt = 3.1 ms for U_s = 9.3 m/s and 3.8 ms for U_s = 159 m/s).

For a given steam velocity, S_B increases with increasing Re_D, remaining roughly constant at a higher Re_D. The present observation of droplet wake deceleration is apparently the first such reported. Thus no comparison with other experimental or theoretical results is possible.

3. Disintegration Time for Droplets

For high steam velocities, many of the large droplets were observed to undergo initial acceleration and then disintegrate into a mist of much finer particles. Break-up time, t_b, is here defined as the time between droplet formation (from the liquid fingers) and droplet disintegration into either an amorphous mass or numerous smaller droplets.

One of these disintegration processes is "disc" disintegration. Analogous behavior has been observed in shock tubes.(L8, H8, H15, J1, N8, W8) An intially almost

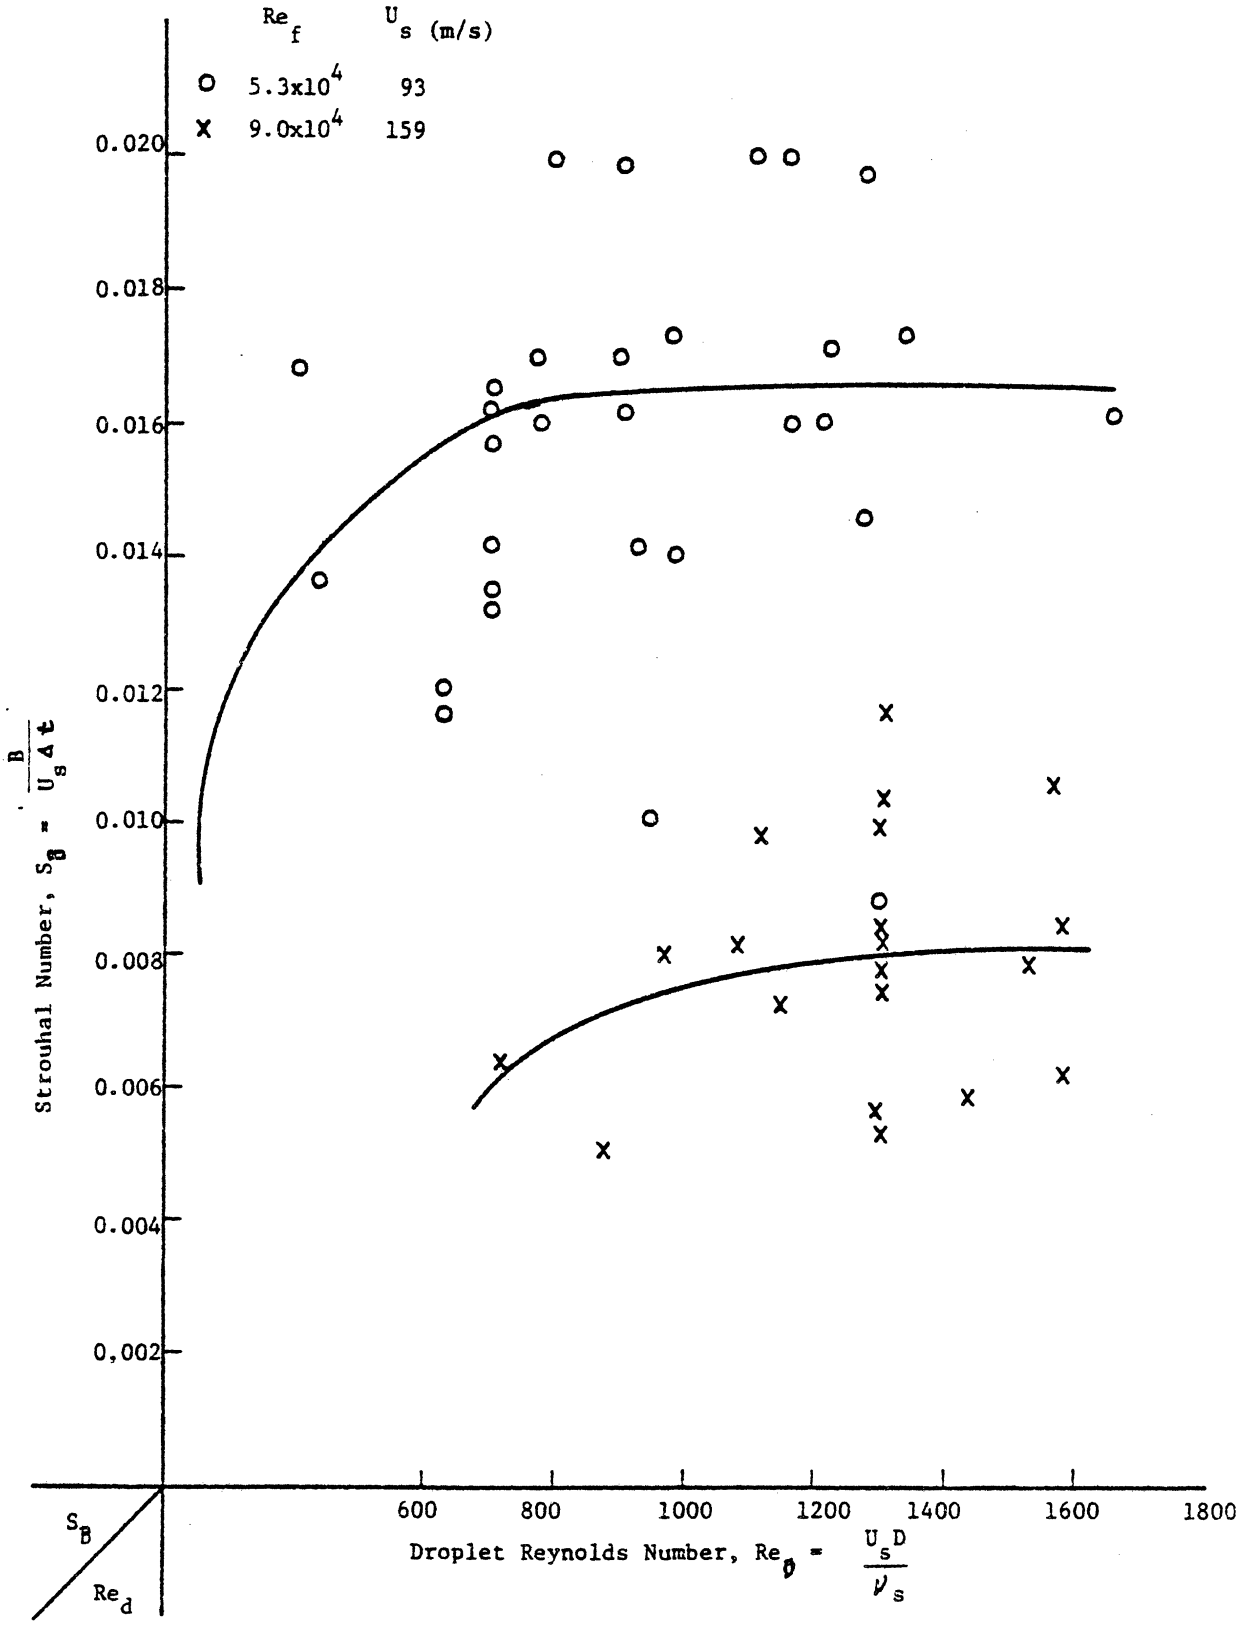

Fig. 5.26 Strouhal Number, S_B, versus Droplet Reynolds Number, Re_B

spherical droplet assumes a disc shape with axis parallel to flow direction. Upon further acceleration, it breaks into several smaller droplets.

Another disintegration mode here observed is the "club" or "claviform" process[H16, K11]. A droplet is formed around and behind a long liquid jet ("club" or "claviforn"). Break-up of the "club" then occurs with the residual droplets also quickly disintegrating. Further details are provided elsewhere[H16, K11].

In the case of supersonic aircraft rain-erosion, two additional modes of droplet break-up have been suggested[A4, R4, E1, K12, W9, W10, R5, B8] involving shock effects. Passing through a shock wave, droplets are either flattened (normal to the axis), with smaller droplets stripped from the circumference, or almost instantly torn apart.

Generally these other investigators use geometries different from author's. Liquid droplets of known size are often injected perpendicular to the flow. Shock waves may or may not occur. Author's droplets are formed from the liquid fingers previously discussed and shock waves are not involved (M<1).

Author's droplet disintegration data have been described using the following non-dimensional variables;

(1) Weber number, We_b, i.e. the ratio between steam dynamic liquid surface tension effects, here defined as,

$$We_b = \frac{\rho_s \, Ur^2 \, D_o}{\sigma}$$

Steam density, ρ_s, and velocity, U_r, relative to the droplet, are used. D_o is the original droplet diameter and σ the liquid surface tension.

(2) A non-dimensional break-up time, T_b, i.e., droplet lifetime before break-up, normalized to consider droplet size and both droplet and steam densities. T_b, used previously (A4, W9,W10,R5,B8), is defined:

$$T_b = \frac{U_r\, t_b}{D_o} \left(\frac{\rho_s}{\rho_f}\right)^{1/2} \tag{5.19}$$

where t_b is the pre-disintegration droplet lifetime. ρ_f and ρ_s are liquid and steam densities. The square of T_b is the ratio of dynamic steam pressure to a deformation droplet stress. This concept was discussed for finger formation.

(3) Q is non-dimensional flow around a droplet, already defined elsewhere (A4,B8,R5,W9,W10). It is the ratio of dynamic steam pressure on the droplet surface to upstream dynamic steam pressure, and is defined:

$$Q = \frac{\rho_g\, U_g^2}{\rho_s\, U_s^2} \tag{5.20}$$

Here ρ_g and U_g are local steam density and velocity and ρ_s and U_s the corresponding upstream values. Here $\rho_g \simeq \rho_s$. Then Q becomes:

$$Q = \left(\frac{U_g}{U_s}\right)^2 \tag{5.21}$$

Since Q is a locally varying quantity, a characteristic Q_m is its maximum. For low to moderate subsonic flows over a sphere, potential flow gives for a maximum, $Q_m = 9/4$ (see Arts. 92-96 in Ref. L6 and Section 15.30-15.53 in Ref. M13).

However, for high subsonic velocities as in some of author's cases, empirical results are required. A simple empirical expression for Q_m [R5], is

$$Q_m = 0.78 + \frac{1.47}{1 + 2.1\ M^{3.4}} \quad ; \quad 0 \lesssim M \lesssim 3.5 \qquad (5.22)$$

where M is steam Mach number.

Combining Eqs. 5.19 and 5.21, non-dimensional time, T_b, can be modified [W10, R5, B8] as in the following:

$$T_b\ Q_m^{1/2} = \frac{U_r\ t_b}{D_o} \left(\frac{\rho_s}{\rho_f}\right)^{1/2} \frac{U_g}{U_s} \qquad (5.23)$$

Then with the assumption that $U_r \tilde{=} U_s$, valid for the present tests, Eq. (5.23) becomes:

$$T_b\ Q_m^{1/2} = \frac{U_g t_b}{D_o} \left(\frac{\rho_s}{\rho_f}\right)^{1/2} \qquad (5.24)$$

The modified non-dimensional break-up time, (Eq. 5.2) can be physically interpreted as the square root of the ratio of maximum local dynamic pressure on the droplet surface to the accompanying droplet deformation stress.

$T_b Q_m^{1/2}$ is plotted against We_b in Figs. 5.27 - 5.30, and is found to be roughly inversely proportional to We_b. The proportionality constants increase with increasing steam velocity.

Experimental data obtained elsewhere in shock tubes [N8, H16, H17, A4, R5, B8] shows the non-dimensional break-up time, Eq. (5.19) or (5.24), to be approximately proportional to $We_b^{-1/4}$.

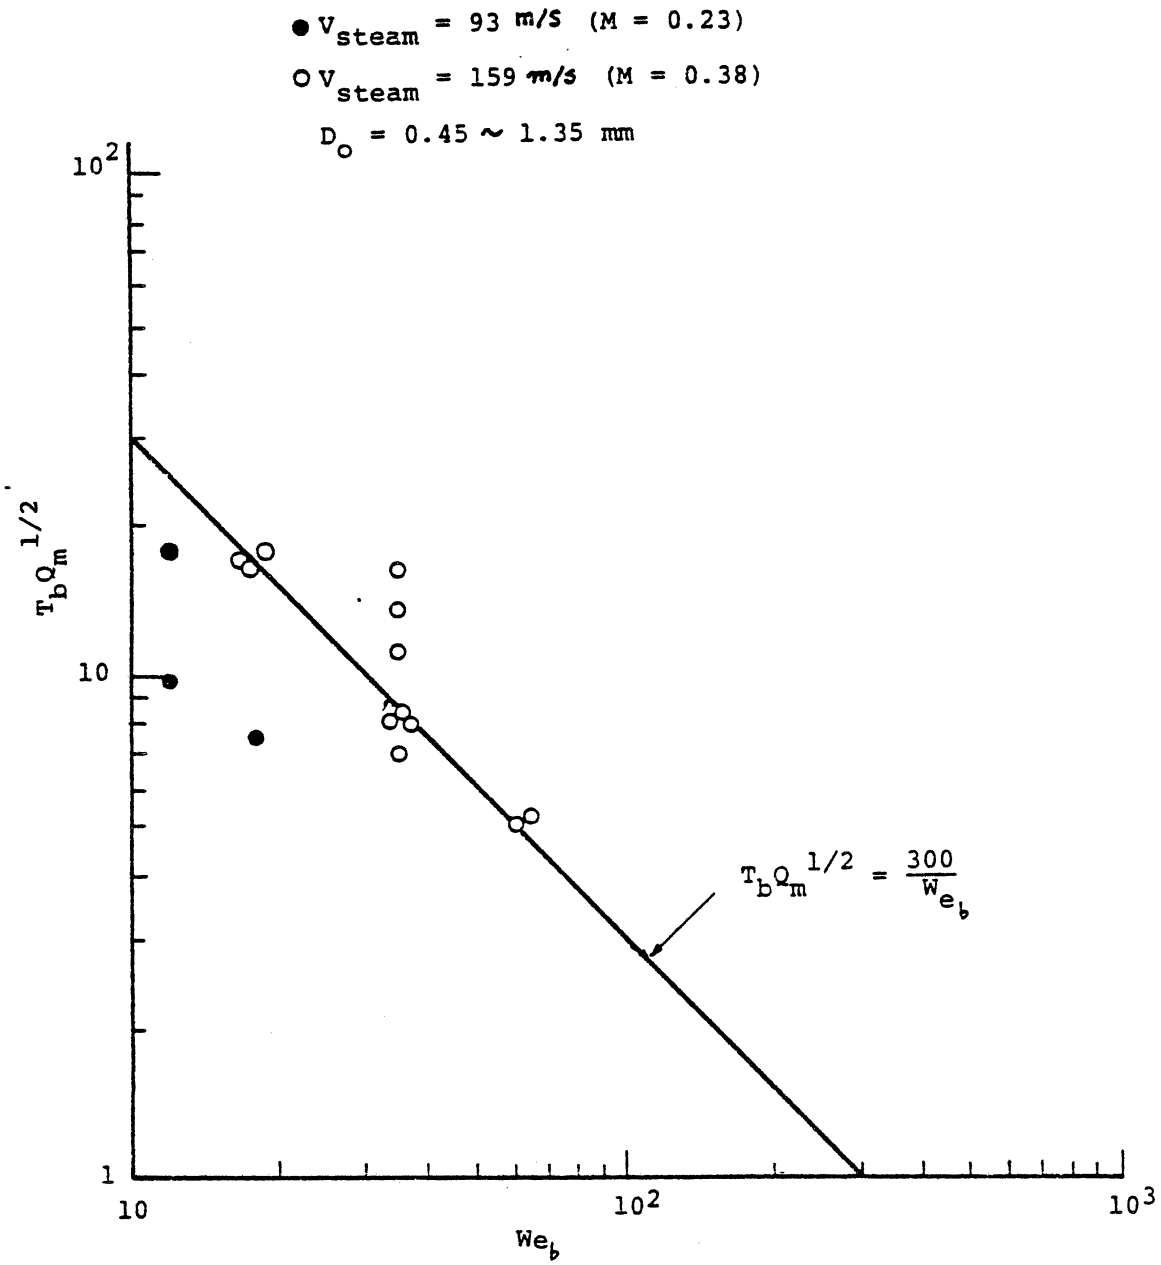

Fig. 5.27 Nondimensional Drop Breakup Time vs Droplet Weber No.

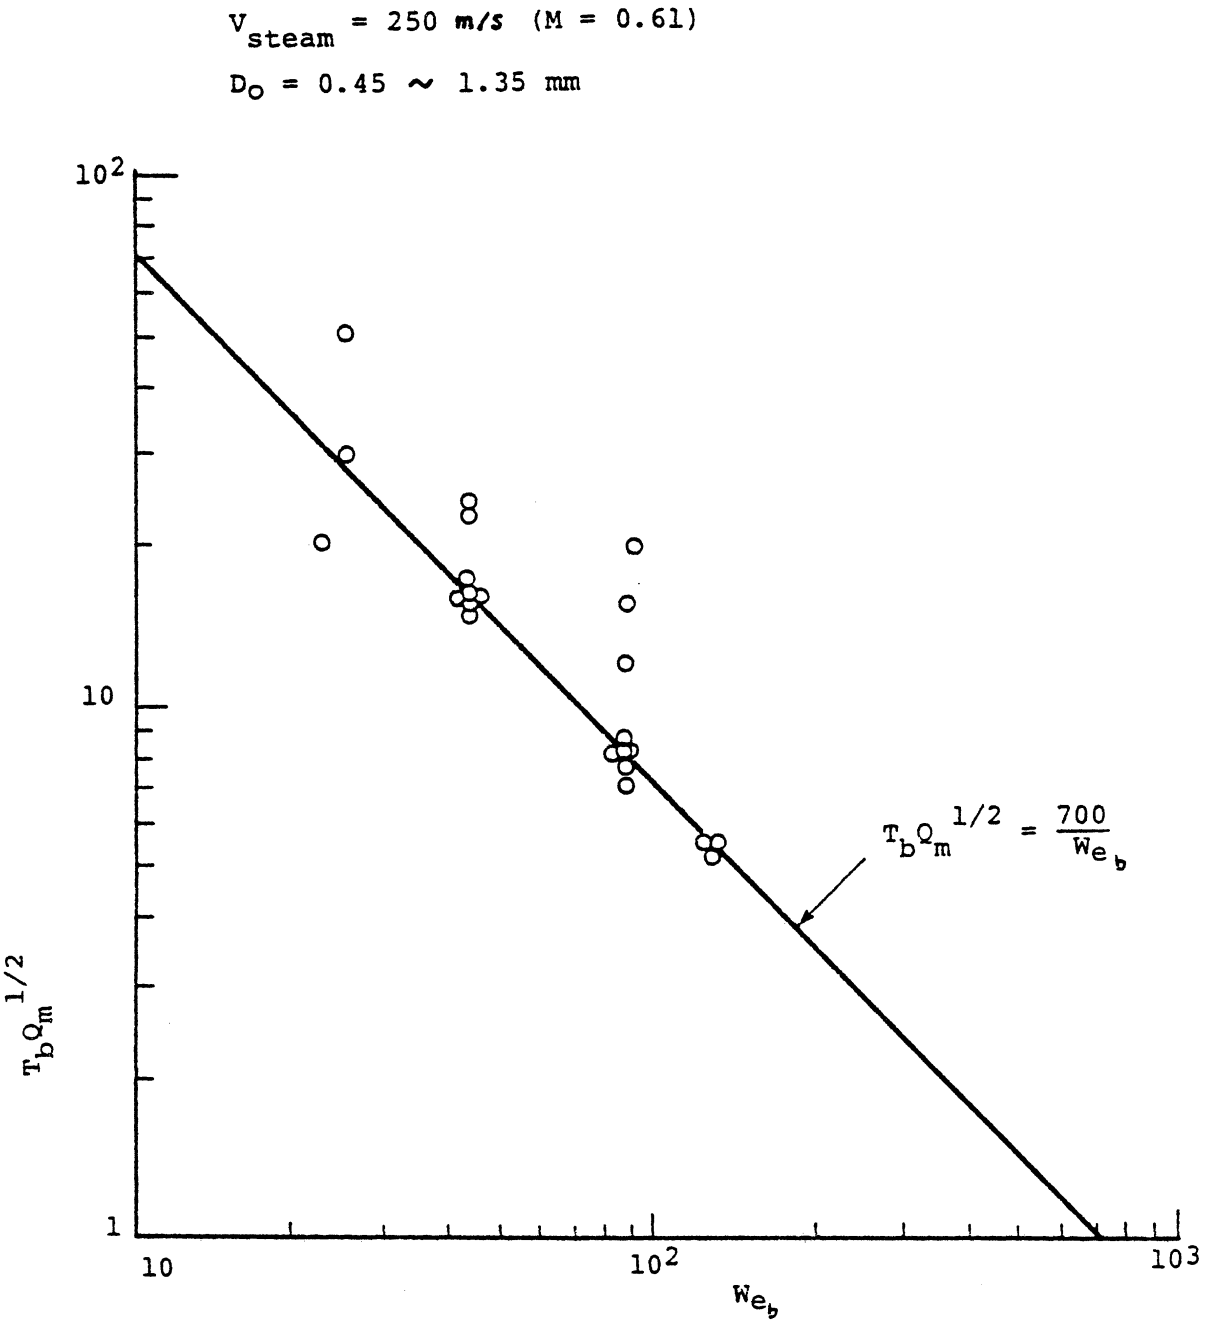

Fig. 5.28 Nondimensional Drop Breakup Time vs Droplet Weber No.

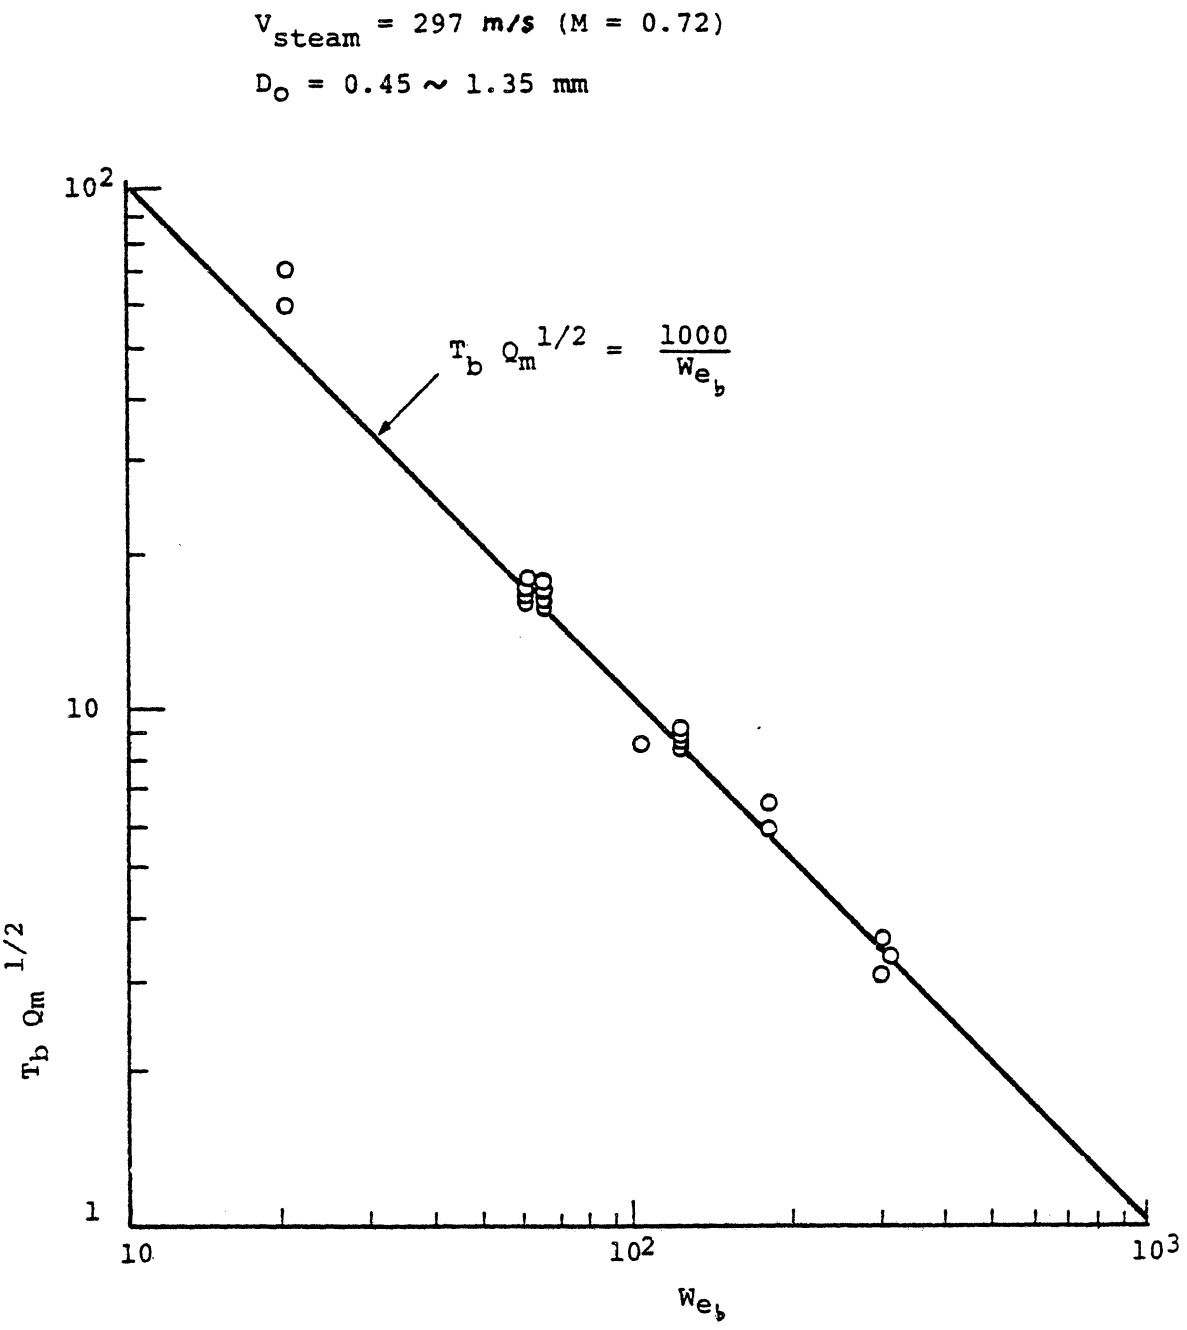

Fig. 5.29 Nondimensional Drop Breakup Time vs Droplet Weber No.

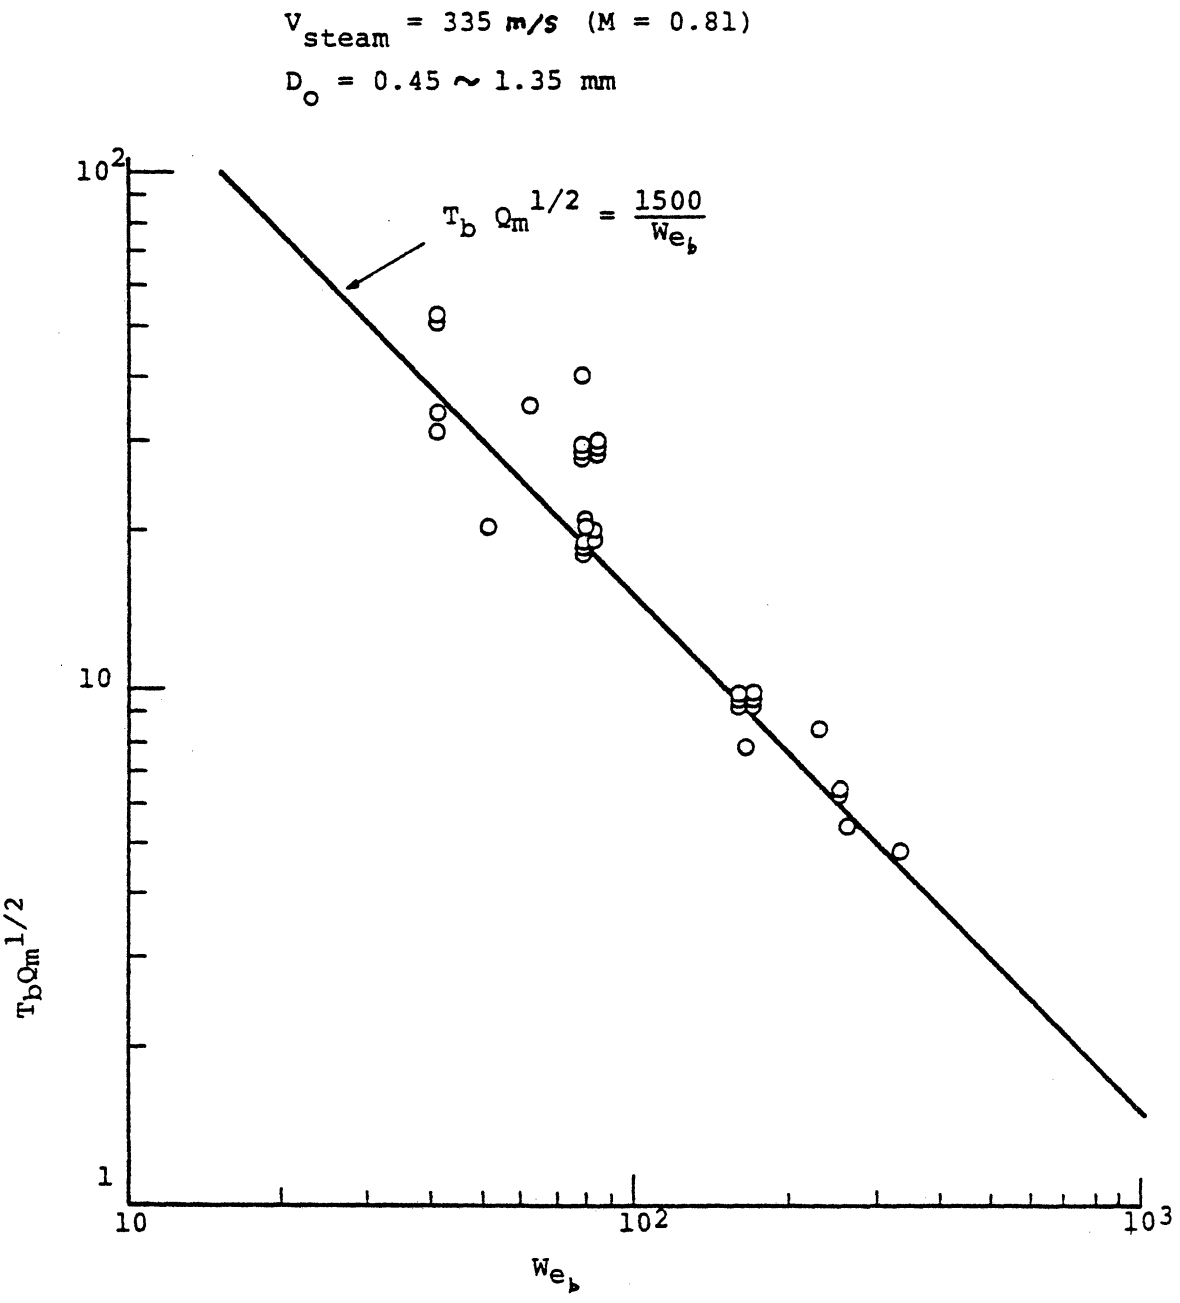

Fig. 5.30 Nondimensional Drop Breakup Time vs Droplet Weber No.

Figure 5.31 compares the shock tube data with that of present tests. The solid line is a previously proposed[R5] empirical correlation of the shock tube data. Author's data are shown as circles.

The exponent difference in droplet Weber number dependence can be explained by considering the wave growth model on the droplet surface proposed by previous investigators.[B8,R5] It is therefore concluded that an inverse We_b dependence (as found by author) is primarily due to a Kelvin-Helmholtz instability [C17,L6] near the equator of the droplet. A $We_b^{-1/4}$ dependency (from shock tube data) is due to the prevailing Rayleigh-Taylor instability [C17,L6] near the pole of the droplet.

Details of the wave growth analyses originally suggested by previous researchers [617,L6,R5,B8] are given in Appendix G.

(Comparison between shock tube experimental data and author's data)

CHAPTER VI

CONCLUSIONS

Phenomena leading to large steam turbine blading erosion have been investigated experimentally. These include the behavior of thin liquid films, and their subsequent break-up into droplets and fingers at the trailing edge of a stationary blade, here modelled by a thin flat plate.

Based primarily on photographic results, a film "Transition Map" for various flow regimes has been made. Three different film flow regimes were observed: rivulet, wavy films, and an entrainment regime corresponding to more vigorous wave action.

Liquid film thicknesses were measured as a function of time and position using electrical conductivity microgages. A best empirical correlation for author's film thickness data is: $h^+ = 0.6\ Re_f^{1/2}$, where h^+ is a non-dimensional film thickness and Re_f film Reynolds number. Few previous correlations for this very thin film range exist. However, an extrapolation of Hughmark's thick-film correlation[H6] along with some data from Collier-Hewitt[C13] give a prediction higher than author's correlation for given Re_f. Film entrainment at author's high steam velocities may be partially responsible for this discrepancy.

The author obtained the critical conditions for rivulet flow experimentally. Comparison with existing theoretical analyses shows that the wetting contact angles required in the analyses are much smaller than measured for static

or one curvature condition. Modifications of these analyses are suggested based on author's observations. First, the flow geometry around the filament or dry spot stagnation points should be considered in more detail. Author's photographs show that there is an abrupt bulge in the film near the stagnation point, instead of a smooth decrease in film thickness from upstream as had been previously assumed.

Also, film wave characteristics should be more carefully considered. Photographs from the present study show that some waviness always exists in the rivulet flow regime. These wavelets will certainly affect the dynamic forces causing film separation.

For the usual thick film analysis, the contribution of pressure perturbations to film instability with respect to wave generation is usually dominant, and that of shear perturbations negligible. For thin films (author's case) shear perturbations[C10] become relatively more important as film thickness decreases. Since author's photos always show some waviness even in the rivulet flow regime (which corresponds to the thinnest films), it is believed that the thin film shear perturbation mechanism is most important for author's case.

Measured two-dimensional wave propagation speed has been compared with Wurz's[W14] model, which well correlates author's high subsonic data. However this is not true for low subsonic data. All the two-dimensional wave celerity data is better explained by the classicial capillary-gravity

wave model.

For the film entrainment regime, both experimental and theoretical criteria are found. Liquid film entrainment was photographically observed to involve a rapid acceleration, lifting, and then shattering of small complex "wavelets" at the crests of larger waves. There is a limiting liquid flow rate below which no surface entrainment occurs ($\lesssim 0.07$ $cm^3/sec.cm$).

Based on author's thickness measurements, a correlation for critical entrainment conditions is found. This correlates the horizontal duct data better, including author's, than previous correlations.[I2] However, confidence in author's correlation is limited by the present lack of detailed information on actual shapes of larger waves, and the present inability to accurately calculate pressure variations over waves of arbitrary shape and size.

At the trailing edge, liquid finger length, L, and finger wavelength, λ_f, have been measured photographically. The upper limit of L for all time-spans decreases as steam velocity is increased. Also "dead" periods, while no finger is forming, are observed. Finger shedding frequency decreases with increasing steam velocity, U_s, and increases with an increase of liquid flow rate. The dependence of shedding frequency on U_s is explained by boundary layer thinning with increasing shear stress. It has been found that Karman vortex-shedding in the steam is not a controlling factor in finger formation.

A peak in nondimensional finger shedding period, τ, was found for lower film Reynolds number ranges. The peak value of τ is reduced, and the corresponding values of We_s is increased as Re_f is increased up to an intermediate value, $Re_f = 8.4$. For higher Re_f, no such peaks were observed. Rather τ then increases smoothly with increasing We_s.

Non-dimensional finger length, L*, normalized by transverse finger wavelength, λ_f, was found to increase with Re_f at fixed Re_f. These fluctuations could be due to various overall system resonances, which may themselves depend upon steam velocity. Since author's finger formation observations are apparently the first reported, no comparison with other related studies is possible.

Measured droplet accelerations were compared with those calculated using Serafini's empirical drag coefficient. However, author's wake-droplet behavior is complicated by the presence of many droplets together, i.e., significant "shielding" may exist.

Deceleration of droplets which sometimes reverse direction completely and move against the main stream, was observed. This phenomenon can be explained by the reverse velocity field induced by vortex shedding in the steam. A Strouhal number, S_B, considering the periodicity of deceleration, increases with increasing drop Reynolds number, Re_d, remaining roughly constant at higher Re_d. This general behavior is consistent with most vortex-shedding observations.

Disintegration time for the larger range of drops observed was measured along with characteristic droplet disintegration shapes (disc and "club" forms). Non-dimensional break-up time, T_b, is found to be proportional to We_b^{-1}. However, shock-tube data shows $T_b \propto We_b^{-1/4}$. These dependencies are explained using surface wave growth theory.

APPENDIX A

DESIGN, CALIBRATION AND GENERALIZED CHARACTERISTICS OF 'ELECTRICAL CONDUCTANCE FILM THICKNESS GAGES

The behavior of thin film is of considerable interest because the gas-liquid interface is often the controlling feature for heat-mass transfer. The most important parameter for the investigation in this line of interest is the thickness of film and variation of its values with respect to time.

Various techniques to measure film thickness have been developed before i.e., hold-up measurement,[T3] radioactive absorption and emission, conductance probe, needle contact method. Light absorption and Fluorescence-Spectrometer method and so on. An extensive review on film thickness measurement technique was provided by Collier and Hewitt.[C13]

Among many possible techniques, an electrical conductance gage was employed at the University of Michigan Steam Tunnel facility. The unique feature of the gage is that no part of it protrudes into either the liquid or the gas. The gage has been successfully utilized to study the interface wave characteristics and the thickness of a liquid film flowing over a horizontal plate with a high-speed vapor flow over the liquid face.

The gage consists of 3 concentric parts; i.e., a center conducting electrode of radius r_1, an insulating ring of outside radius r_2, and finally a conducting infinite plate. (Figs. A1 and A2). Electrical connections are made to the center electrode and the plate.

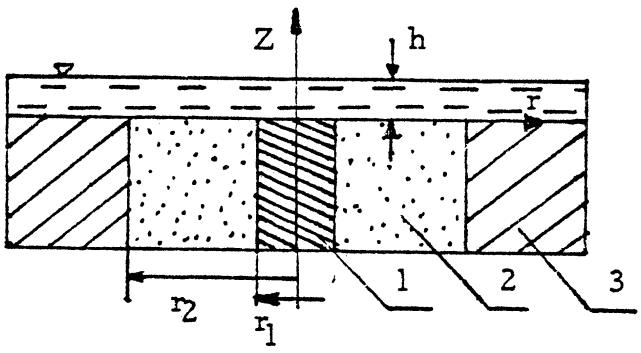

Fig. A1 : Schematic Representation of Conductance Probe

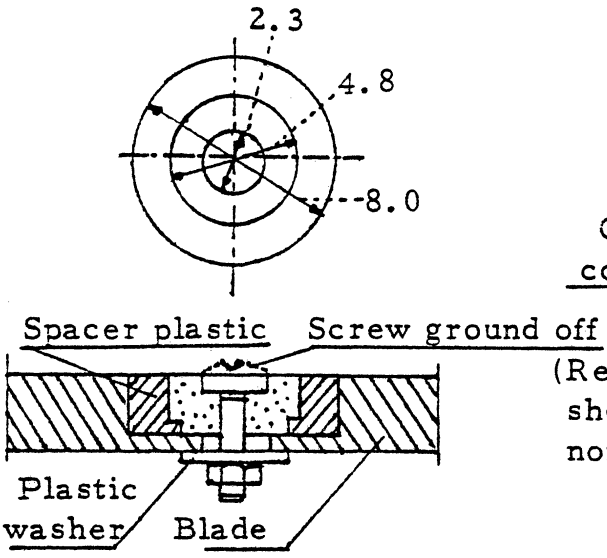

Fig. A2: Design Drawing of Gauge

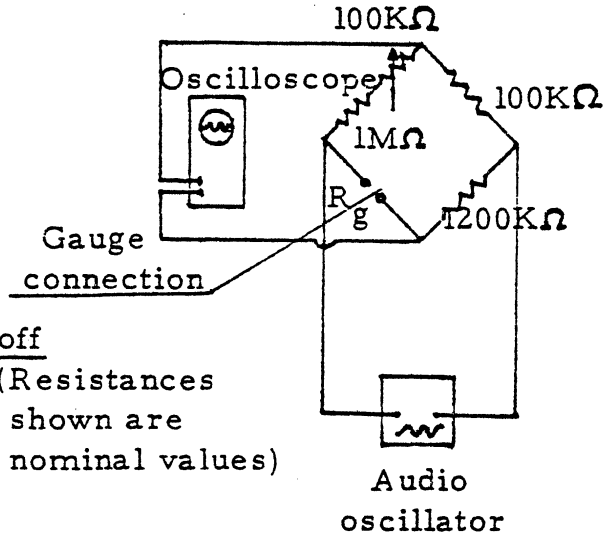

Fig. A3: Wheatstone Bridge and Related Equipment

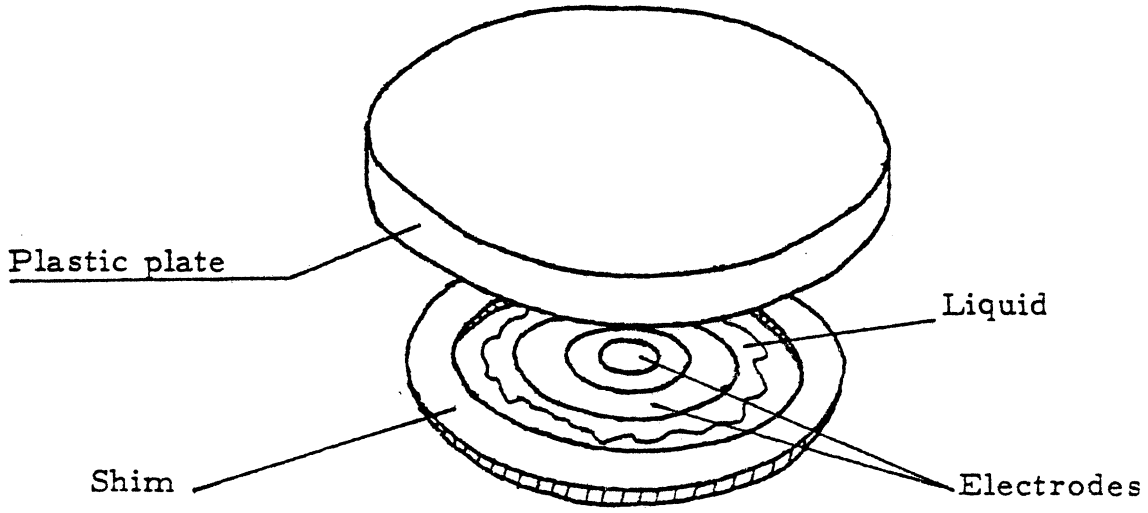

Fig. A4: Schematic of Calibration Method

Mikielewicz and Hammitt,[10] sovling Laplace equation for electrical potential distribution in the film, concluded that,

$$i = C_g\, h\, \sigma\, \Delta u \qquad (A.1)$$

where,

$i = \pi\, \sigma r_1^2 j$ - electric current

σ - specific conductivity of liquid

j - density of electrical current flow

C_g - geometric constant of the gage

h - film thickness

Δu - electrical potential difference between r_1 and r_2

Based on the experimental results of Collier and Hewitt,[C13]

$$C = 2.918\, \sigma\, h \qquad (A.2)$$

where C is the film conductivity between the probe electrodes, they assumed the following relation for this range of thickness.

$$C = C_g\, \sigma\, f(h) \qquad (A.3)$$

where f(h) is unknown function of film thickness, which can be easily established experimentally by calibrating the gages.

The design of our gage is shown in Fig. A2 . Collier and Hewitt (1964) pointed out the importance of gage size. As the gage is reduced in size, the local sensitivity is increased while the maximum measureable thickness is decreased. They suggested that electrode spacing should be about 10 times the maximum expected film thickness. Thus the diameter of the center electrode was chosen to be 2.3 mm, and the outside diameter of insulating ring 4.8 mm.

Measurements were conducted using an out-of-balance Wheatstone bridge (Fig. A3), excited by an A-C audio oscillator. Frequency of 1 KHz was used, producing a sinusoidal wave amplitude of 10 volts. The bridge output voltage was fed to an oscilloscope. The output voltage was a function of the film resistance. Known film thicknesses were obtained by placing a pre-measured circular shim around the gage (Fig. A.4), putting a few drops of water on the gage, and finally setting a circular non-conducting plate over fixed shims, trapping the water over the gage, and squeezing to the desired shim thickness. Measurements were made with distilled water and 0.05% salt (by mass) addition. This solution strength was necessary to avoid variations in water conductivity, at the different temperatures required, ranging from 70° to 150°F. (~ 21 to 66°C).

Typical calibration curves are shown in Fig. A.5 . The function, f(h), depending only on film thickness for a given gage, was found using values from calibration curves. The resulting function f(h), along with the dependence upon the factor C_g versus temperature, are presented in Figs. A.6 and A.7 . The small scatter of data points shown on Figs. A.6 and A.7 indicates the general precision level of calibration, and the realism of the calculating procedure used. Function f(h) is general for all gages, but the factor C_g is different for various gages.

One can obtain the thickness of liquid film, using the generalized characteristic curves of Fig. A.6 and A.7 .

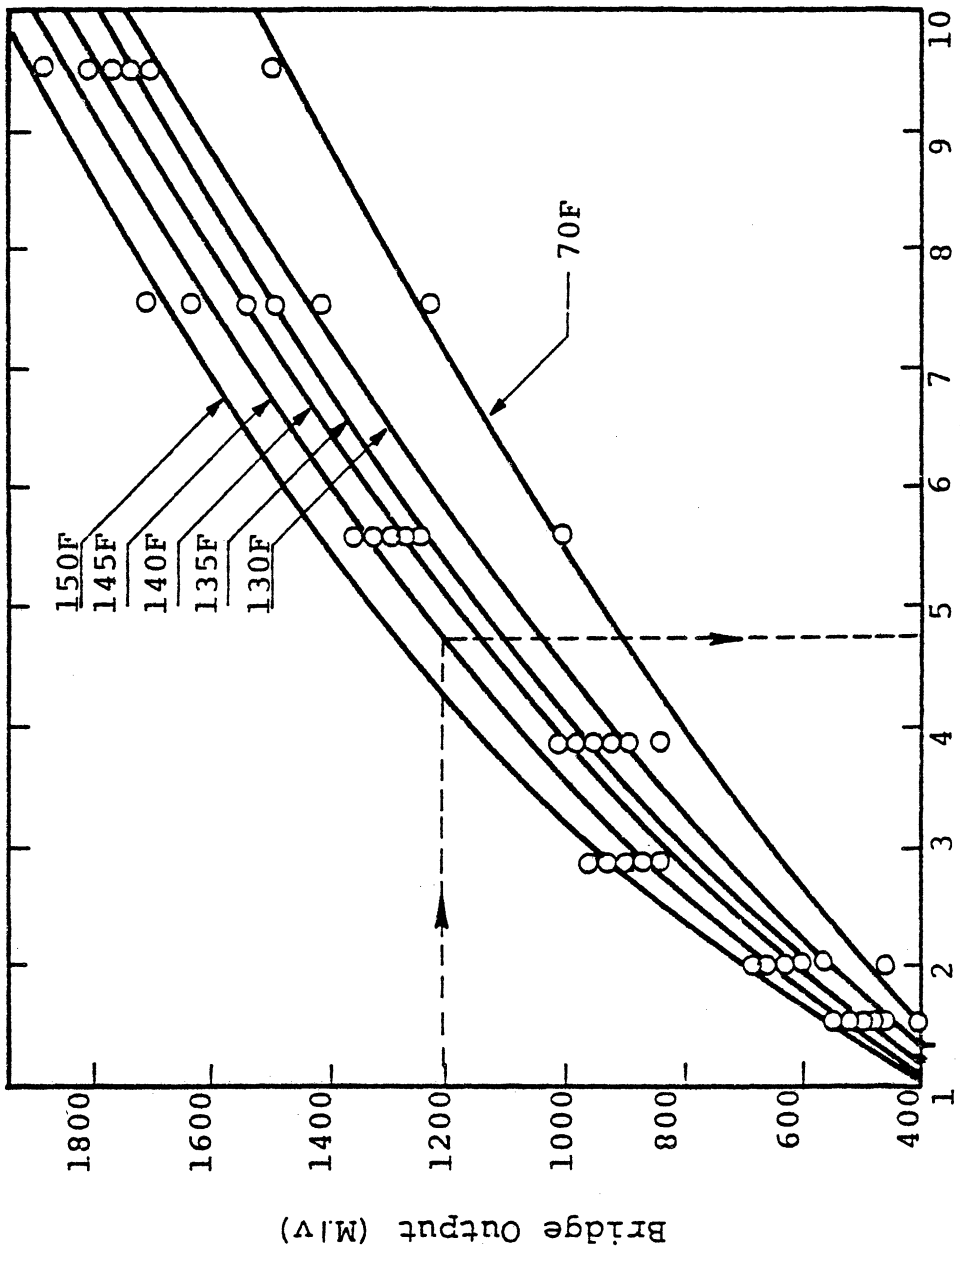

Fig. A5 Typical Calibration Curves (Gauge No. 1)

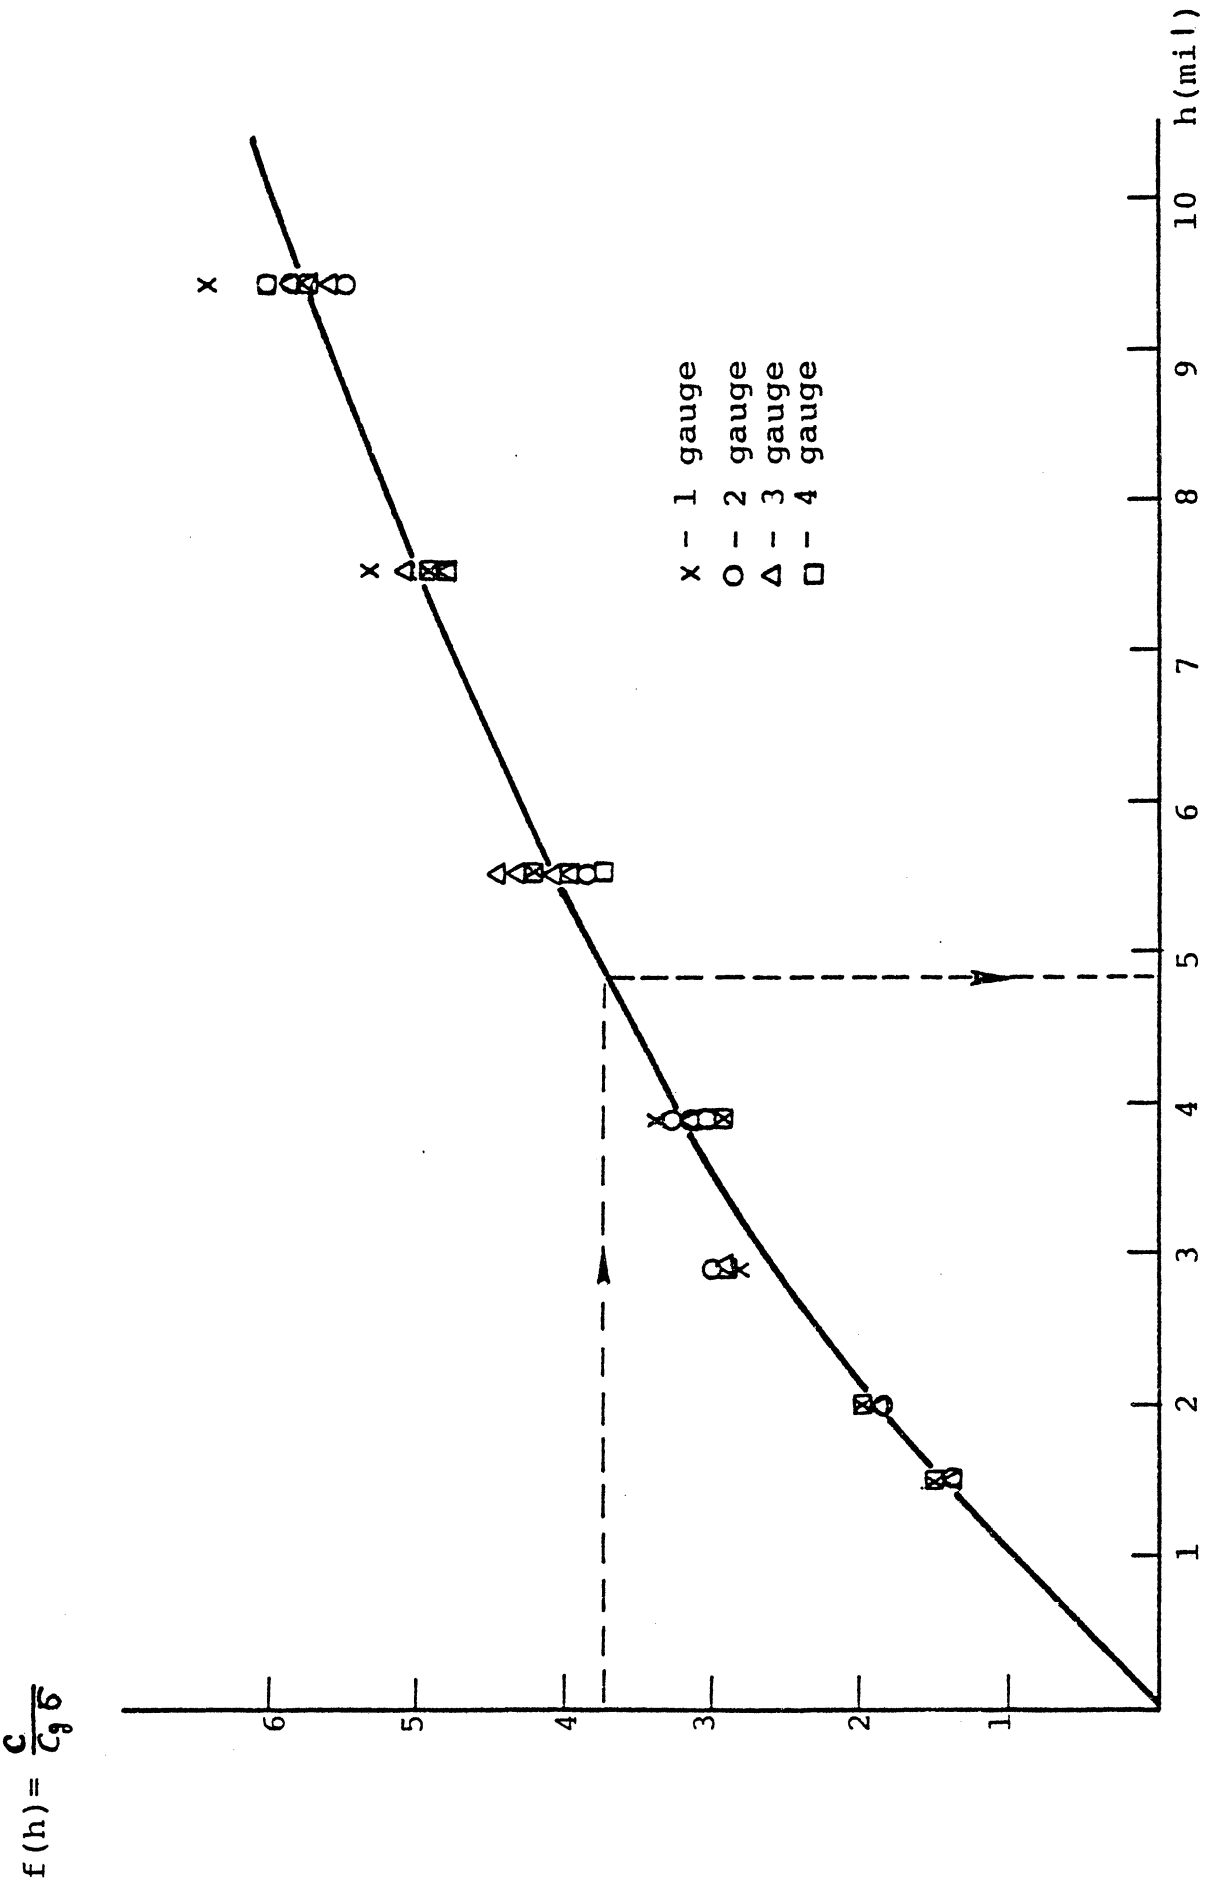

Fig. A6 Dependence of f(h) on Film Thickness, h for Gauges No. 1,2,3,4

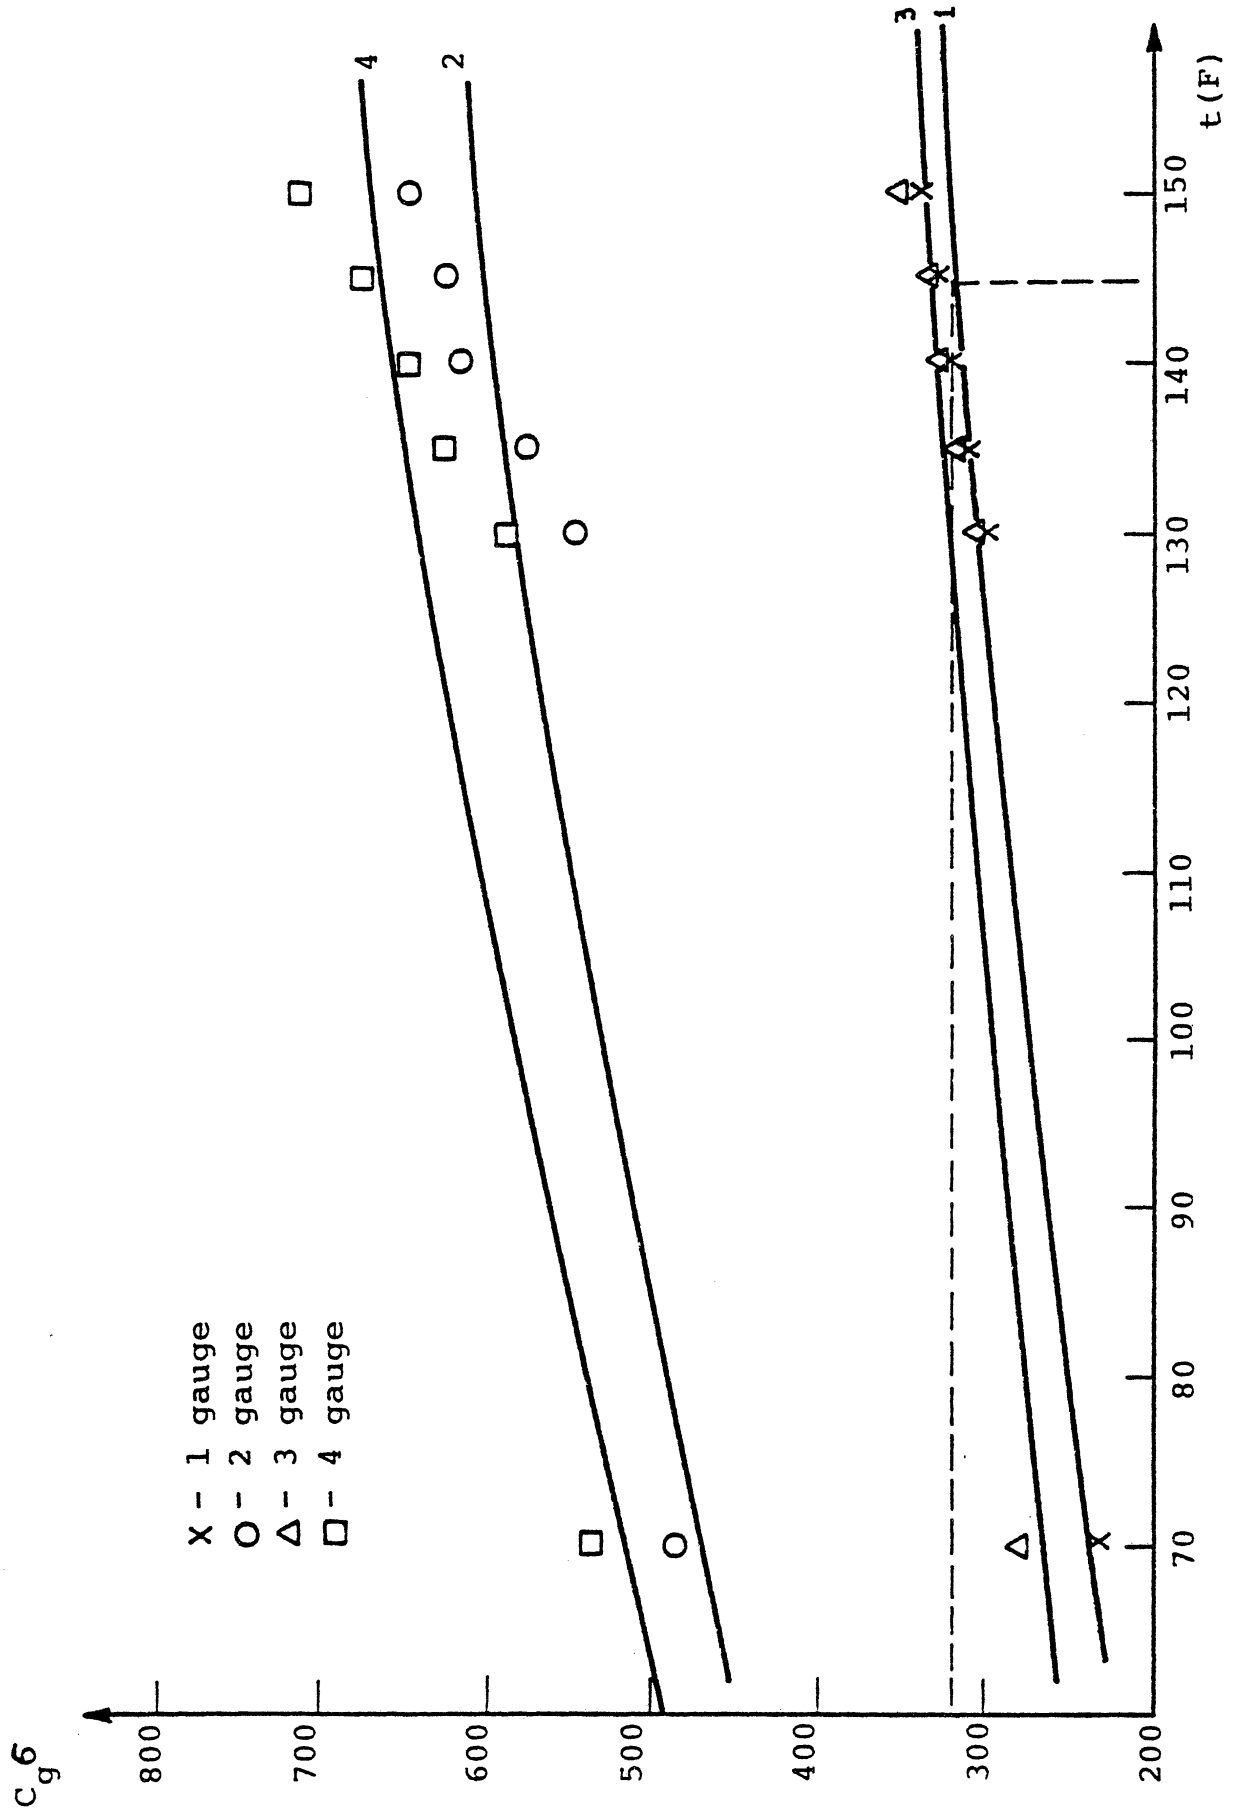

Fig. A7 Dependence of Product of Geometric Factor and Water Conductance on Temperature for Gauges No. 1,2,3, and 4.

For example, if the output of the Wheatstone bridge is 1200 mV and the temperature of the film is 145°F (63°C), one can find directly from the calibration curve (Fig. A.5) the thickness of the film, 4.75 mils (≈ 121 μm).

The same result can be obtained using the generalized characteristic. For film temperature of 145°F, the corresponding factor C_g (Fig. A.7) is 320. Dividing output of bridge (1200 mV) by value of factor C_g (320), one can find the value of the function f(h), and the measured thickness of the film equals about 4.75 mils (Fig. A.6). The procedure is shown by the dotted lines on Figs. A.6 and A.7 . Using this generalized characteristic, one can easily see the influence of temperature on the thickness measurement.

Error of correlating experimental data of film thickness is given in Table A.1 .

Thickness μm	Predicted measured value of $f_t(h)$	Minimum measured value of $f_m(h)$	Maximum measured value of $f_m(h)$	Range of error $\frac{f_t - f_m}{f_t}$ %
39.37	39.37	38.1	40.64	+ 3.1
50.80	50.80	48.26	53.34	∓ 5.0
73.66	69.85	69.85	78.74	0, ∓ 12.6
99.06	86.36	76.20	88.90	-11.8, +14.6
140.97	107.95	96.52	116.84	-10.6, +8.3
191.77	132.08	121.92	137.16	-7.7, +3.8
240.03	147.32	142.24	154.94	-3.4, +5.2

Table A1. Error of Thickness Gage Calibration

APPENDIX B

CALCULATION OF NORMAL AND TANGENTIAL PERTURBATION STRESSES UPON WAVY FILM

Estimates of normal and tangential perturbation stresses upon the wavy films from the parallel gas phase flow is extremely important for author's present data on wavy film characteristics.

Based on the Benjamin's analysis[B4], Craik[C10] simplified the expression for perturbation stresses. Author's wavy film data has been compared with Craik's[C10] theoretical analysis.

Introducing normal II, and tangential Σ, perturbation stress parameters, he solved the "Orr-Sommerfeld" equation for perturbation velocity stream function.

$$II = \frac{2\alpha}{Re_f f_i} [I - \sqrt{3}S + i(f_i - s)] \tag{B.1}$$

$$\Sigma = \frac{(4\beta . I)}{\sqrt{3} f_i} e^{i\pi/3} \alpha^3 (\alpha Re_f)^{-4/3} \tag{B.2}$$

where,

$$I = \int_o \left(\frac{U}{U_o}\right)^2 e^{-\alpha Y} d(\alpha y) = 2\int_o^{H/2h} \left(\frac{2yh}{H}\right)^{2/\eta} e^{-\alpha y} d(\alpha y) \tag{B.3}$$

$$s = 0.644\ I \tag{B.4}$$

$$\Delta = \frac{21}{f_i} \left(\frac{\mu_s}{\mu_f}\right)^{2/3} (\alpha Re_f)^{-2/3} \alpha^2 \tag{B.5}$$

$$\frac{4\beta}{\sqrt{3}} = 2.744 \left(\frac{\nu_s}{\nu_f}\right)^{2/3} \left(\frac{\rho_s}{\rho_f}\right)^{1/3} \tag{B.6}$$

$\alpha = kh = \frac{2\pi h}{\lambda}$ Nondimensional wave number

$Re_f = \frac{V_f h}{\nu_f} = \frac{2q}{\nu_f}$ Film Reynolds number

f_i	Friction coefficient estimated in Section B of Chapter IV
I	Integral representing the effect of turbulence gas velocity profile using $1/\eta$ rule
h	film thickness
H	Height of the channel ($\cong$ 4 cm)

Subscript s and f represent steam and liquid properties used. Finally he obtained wave growth rate and wave propagation velocity as follows:

$$\alpha C_i Re_f = \frac{(\alpha Re_f)^2}{3}[II_r + \frac{3\Sigma_i}{\alpha} - T\alpha^2 - G] \tag{B.7}$$

$$C_r - 1 = -\frac{\frac{7}{8}(\alpha C_i Re_f) - \alpha Re_f II_i + \frac{3}{2}(Re_f \Sigma_r)}{3 + \frac{27}{5}\alpha^2 + \frac{12}{5}(\alpha C_i Re_f)} \tag{B.8}$$

where,

$$T = \frac{\sigma}{\rho_f V_f^2 h}$$

$$G = \frac{gh}{V_f^2}$$

and subscript r and i indicate real and imaginary part respectively. Critical (or cut-off) wave number can be obtained by setting $\alpha C_i Re_f = 0$. List of computer program and output are as follows,

APPENDIX C

COMPUTER PROGRAM FOR DATA REDUCTION ON ACCELERATION AND BREAK-UP TIME OF DROPLETS

WATERDROP is a computer program developed to analyze liquid droplet behavior as observed in steam tunnel. The size, orientation and kinematics of a droplet are determined by analyzing four basic parameters in a film frame of movie film. The equations used in the program are developed and presented in section B.1, Chapter V. The experimental results physically define the particle in each observation frame. The experimental and analytical accelerations calculated are compared in the program to determine if the theoretical relations can be used to predict the actual acceleration for a specific particle size and steam velocity.

A basic understanding of the program requires a knowledge of how it categorizes experimental data. Each data point belongs to three interrelated groups or sets as shown in Fig. C1 . In general, each point is classified to be in a set. A set includes all of the data taken at a specific liquid flow rate and steam velocity. The next major

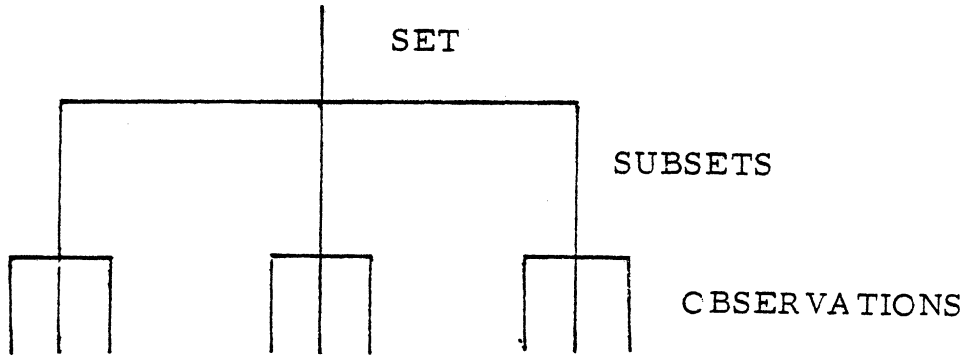

Fig. C1 WATERDROP Data point categories

classification is a subset. A subset includes all of the data points describing a specific particle motion from the time it was first observed until it either disintegrates or vanishes from view. The last group is the observation. The instantaneous size and position of a particle in a reference frame is recorded.

SUBSET RESULTS

A sample listing of these results are given. Each subset has experimental results printed under the twelve headings at the top of the computer printout. The metric CGS units used in the program are listed below each heading. The first six columns define the particle postion and size, while the last six columns define its motion.

The second set of headings lists the calculation results and the comparison between experimental and analytical accelerations according to Serafini correlations[S6]. The last four columns allow a direct comparison of the experimental and analytical accelerations in three ways. First, the experimental acceleration is reprinted directly after the theoretical to allow a comparison at each observation. Second, the difference between these accelerations is printed. Third, a ratio between them is printed to allow an order of magnitude comparison.

Statistics of the subset experimental accelerations are printed next. The arithmetic mean, the mean deviation, and the standard deviation of all accelerations in a subset show an average value and how it varies. The arithmetic mean of

the acceration ratio is also printed to show the average value for the subset.

Information in the last four lines of the subset results define the operating conditions for the subset. Steam flow rate and velocity are given in both metric and English units for clarity. Particle density, steam density, and the kinematic viscosity of the steam are printed to further define the flow conditions. Movie film framing rate and a data conversion factor are given to show the equivalence factors necessary to convert the raw laboratory data into usable results. The last line describes the particle stability, and the elapsed time and position of the observation.

SET RESULTS

The program determines an average value for experimental acceleration and acceleration ratio for each flow and velocity condition. A sample listing from these printouts are also listed. The arithmetic mean, mean deviation,* and standard deviation are calculated for the average experimental accelerations of each subset. In addition, the arithmetic mean of all average acceleration ratios from each subset is printed. The average experimental accelerations from all subsets are printed to keep all the average values on a single page.

---

*Mean deviation = $\dfrac{|X_1-\bar{X}| + |X_2-\bar{X}| + \ldots + |X_n-\bar{X}|}{n}$

WATERDROP VARIABLE AND SUBSCRIPTS LIST

Variable Name	Description of Variable
ABAR(II)	Average acceleration for each subset
ACCEL(J)	EXperimental accelerations from three successive film observations
ARATIO(J)	Ratio of experimental to analytic acceleration for each observation
AREA(J)	Water particle area at each observation
ARR(II)	Average ratio of experimental acceleration ratios of a subset
ARSUM	Sum of all experimental acceleration ratios of a subset
ASUM	Sum of all experimental accelerations in a subset
ATOT	Total sum of experimental acceleration for a subset
ATOTB	Average experimental acceleration of a set
CD(J)	Analytic drag coefficient at each observation
CON	Equivalence factor for converting feet to centimeters
CONFAC	Equivalence factor for converting film measured quantities to centimeters
DELA(J)	Change in acceleration in four consecutive observations
DELV(J)	Change in velocity in three consecutive observations
DELX(J)	Change in displacement between two consecutive observations
DIA(I)	Diameter of the particle at each observation
DTAVG	Average change in time in experimental acceleration calculation

Variable Name	Description of Variable
DVM	Mean deviation of experimental acceleration calculation
FILMV	Velocity of the film
FN(I)	Number of film frames between observations
K1	A test point to determine whether a particle was observed to split
MASS(J)	Mass of the particle at each observation
MEANDV	Mean deviation of experimental acceleration for each subset
N	Total number of data points in a subset
NPL	One less than the total number of data points
NP2	Two less than the total number of data points
P14	One-fourth of the constant
Q	Steam flow rate
QCHECK	Test point to determine the equality of two flow rates
RBAR	Average acceleration ratio for a set
RE(J)	Reynolds number for each observation
RHOS	Steam density
RHOW	Water density
RSUM	Sum of acceleration ratios for a set
SD	Absolute value of the difference between average experimental accelerations of a set and of a subset
SFLOW	Steam flow rate
SIGMA	Standard deviation of experimental acceleration for each subset
SMD	Sum of the differences between experimental and average acceleration for each set

Variable Name	Description of Variable
SMD2	Square of the sums of the experimental and average acceleration difference for each subset
STDV	Standard deviation of the experimental acceleration for each set
SUMDIF	Absolute value of the difference between the average and experimental acceleration in each subset
SUMD2	Square of the sum of the experimental and average acceleration difference for each subset
SUMMD	Sum of the experimental and average acceleration difference for each subset
SVEL	Steam velocity
T(I)	Water particle thickness
TD(J)	Elapsed time between observations
TOTHRD	A constant, 0.6666...
TTOL	Total particle observation time
UDOTW(J)	Analytic Acceleration
V	Steam velocity
VCHECK	A test point to determine the equality of two steam velocities
VEL(J)	Velocity between two consecutive observations
VISNU	Kinematic viscosity of the steam
VOL(J)	Volume of an observed particle

Subscript Character	Description of Subscript
I	Input reading iteration
II	Set calculation iteration
J	Subset calculation iteration
JJ	Average set calculation iteration
K	Output printing iteration

APPENDIX D

STATISTICAL LINEAR REGRESSION ANALYSIS OF DROPLET ACCELERATION

Due to the nature of the physical phenomenon under consideration and the large amount of experimental data collected, certain statistical tools were used to better understand the experimental results. Reduction of the initial raw data (Appendix C) resulted in 855 droplet accelerations for the flow conditions outlined in Table 5.3 . These 855 cases were broken into 327 subsets for which average droplet accelerations were obtained.

When performing a first-order regression of E.A. (Experimental Acceleration) on Q the 327 data set was arranged into the following cases corresponding to constant steam velocity, U_s, and stored in data file "AVGACCEL";

Cases	U_s (ft/sec)
1-45	305
46-129	520
130-185	825
186-246	975
247-327	1100

In a similar manner the "327" data set was rearranged in order to perform a first-order regression of E.A. on U_s with liquid flow rate, Q, being held constant. These are stored on data file "QACCEL".

Cases	Q (cm^3/min)
1-3	0
4-58	5
59-130	10
131-198	15
199-250	20
251-294	30
295-302	40
303-327	50

MIDAS "REGRESSION" command was used to perform the regression analyses mentioned throughout the test.

From the MIDAS results, it is found that E.A. is not affected by changing Q. However, it is seen that E.A. is strong function of U_s. For example, "goodness of fit," R-SQR shows that for Q = 15, there is a variation of 76% in E.A., which can be explained by the variation in U_s. Full details of this analysis is available from on of our previous reports.(M14) Regression analysis output is followed.

APPENDIX E

COMPARISON OF EXPERIMENTAL DROPLET ACCELERATIONS WITH THOSE USING SERAFINI, ABRAHAM AND CHURCHILL'S EMPIRICAL CORRELATIONS FOR THE DRAG COEFFICIENT, C_D

VARIABLE NAME	DESCRIPTION OF VARIABLE
AA(M)	Analytical acceleration as calculated by Abraham
AABAR	Average of all Abraham accelerations for a particular steam velocity and flow rate
AASM	Sum of all Abraham accelerations for a particular steam velocity and flow rate
ABAR(M)	Average of the measured accelerations for one droplet
AC(M)	Analytical acceleration as calculated by Churchill
ACBAR	Average of all Churchill accelerations for a particular steam velocity and flow rate
ACCSM	Sum of all the measured accelerations for a particular steam velocity and flow rate
ACEL(J)	Measured acceleration of one droplet for three successive film readings
ACSM	Sum of all the Churchill accelerations for a particular steam velocity and flow rate
AS(M)	Analytical acceleration as calculated by Serafini
ASBAR	Average of all measured accelerations for a particular steam velocity and flow rate
ASUM	Sum of all the measured accelerations for one droplet
CDA(M)	Abraham's expression for the drag coefficient
CDC(M)	Churchill's expression for the drag coefficient
CDS(M)	Serafini's expression for the drag coefficient
CON	Constant conversion factor, 30.48, the number of cm/sec in one ft/sec.

VARIABLE NAME	DESCRIPTION OF VARIABLE
CONFAC	Constant conversion factor, .45, the number of centimeters in one measured screen unit
DELV(J)	The difference between two consecutively measured velocities
DELX(J)	The difference between two consecutively measured distances
DIA(J)	The diameter of the water droplet for a particular observation
DPBAR	The average of all the diameters for a particular steam velocity and flow rate
DPSM	The sum of all the diameters for a particular steam velocity and flow rate
DPSUM	The sum of all the diameters observed for a particular droplet
DRPU(M)	The average of all diameters observed for a particular droplet
DTAVG	The average time between each successive observation
FILMV	The film speed at which the pictures were taken
FIVNIN	Constant, which equals 5/9.
FN(I)	Number of frames between each successive observation
IM2	The number of observations in a set minus two
M	A counter which checks how many different cases were observed for each steam velocity and flow rate
Q	Flow rate of water entering the test section
QCHECK	A control that is used to see if the flow rate has changed
RA(M)	The ratio of measured acceleration to Abraham acceleration, for a particular water droplet
RABAR	The average of all measured/Abraham acceleration ratios for a particular steam velocity and flow

VARIABLE NAME	DESCRIPTION OF VARIABLE
	rate
RASM	The sum of all measured/Abraham acceleration ratios for a particular steam velocity and flow rate
RBAR	The average of all measured/Serafini acceleration ratios for a particular water droplet
RC(M)	The ratio of measured acceleration to Churchill acceleration for a particular water droplet
RCBAR	The average of all measured/Churchill acceleration ratios for a particular steam velocity and flow rate
RCSM	The sum of all measured/Churchill acceleration ratios for a particular steam velocity and flow rate
RE(M)	Reynolds number for a particular water droplet
REBAR	The average of all Reynolds numbers for a particular steam velocity and flow rate
RESUM	The sum of all Reynolds numbers for a particular steam velocity and flow rate
RHOW	Density of water
RS(M)	The ratio of measured acceleration to Serafini acceleration for a particular water droplet
RSUM	The sum of all measured/Serafini acceleration ratios for a particular steam velocity and flow rate
SEBAR	Average of all Serafini accelerations for a particular steam velocity and flow rate
SVEL	Steam velocity in cm/sec.
T(I)	Thickness of the water droplet for a particular observation
TD(J)	Elapsed time between observations
TOTHRD	Constant, which equals 2/3
TTOL	Total time that observations on a particular

VARIABLE NAME	DESCRIPTION OF VARIABLE
	drop were made
V	Steam Velocity
VEECK	A control which checks if the steam velocity has changed
VEL(J)	Measured velocity of one droplet for two successive film readings
X(I)	Distance an individual particle was away from the edge of the blade

APPENDIX F

COMPUTER PROGRAM AND OUTPUT OF DROPLET BREAK-UP TIME DATA REDUCTION LIST OF VARIABLES

VARIABLES NAME	DESCRIPTION OF VARIABLE
DIA(I)	Diameter of an individual droplet at a particular observation
DIST	The distance that the particle travelled since the last observation
DRPF	Final observed diameter of a particular droplet
DRPI	Initial observed diameter of a particular droplet
FN(I)	Number of frames between each successive observation
Q	Flow rate of water in the test section
QM	Ratio of dynamic pressure
QMTB	Square root of the dynamic pressure ratio times dimensionless break-up time
RE	Reynolds number for a particular particle
SMACH	Mach number of the steam through the test section
T(I)	Thickness of an individual droplet at a particular observation
TB	Dimensionless break-up time
THKF	Final observed thickness of a particular droplet
THKI	Initial observed thickness of a particular droplet
TIME	Real time measured between observations
V	Steam velocity in the system
VEL	Droplet velocity across the test section
WE	Weber number for a particular particle
X(I)	Distance of an individual droplet from the edge of the blade at a particular observation.

BREAK-UP TIME ANALYSIS PROGRAM

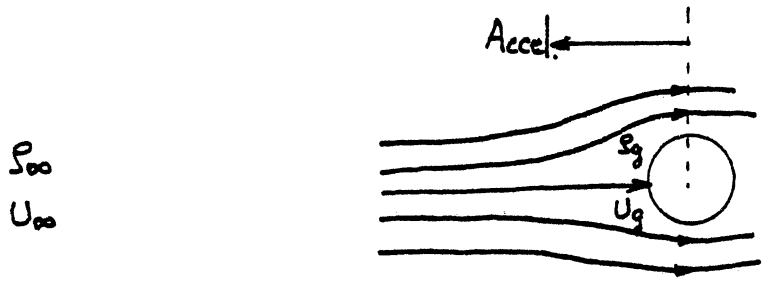
APPENDIX G

WAVE GROWTH THEORY ON LIQUID DROPLET SURFACE

To understand the droplet break-up mechanism, the use of unstable wave growth theory has been suggested.(B8,R5) A summary of these theories is presented here.

Considering the moving liquid droplet as the frame of reference, the following schematic describes droplet motion.



The gas-liquid interface is assumed smooth and potential flow to exist in the gas. Then wave displacement can be expressed,

$$Y = Y_o + \eta = y_o + \eta_o e^{i(kx-\sigma t)} \tag{G.1}$$

From the solution of Lamb(L6) or Chandrasekhr(C17)

$$\frac{\sigma}{k} = \frac{\rho_f U_f + \rho_g U_g}{\rho_f + \rho_g} + \left(-\frac{\rho_f \rho_g (U_g - U_f)^2}{(\rho_f + \rho_g)^2} + \frac{(\rho_f - \rho_g)\frac{g}{k} + KS}{\rho_f + \rho_g} \right)^{1/2} \tag{G.2}$$

Replacing

$$\frac{\rho_f U_f + \rho_g U_g}{\rho_f + \rho_g} = V \tag{G.3}$$

and

$$g = -A \tag{G.4}$$

where,

$$\rho_f \frac{4}{3} \pi \left(\frac{D_o}{2}\right)^3 A = C_D \left(\frac{\pi}{4} D_o^2\right) \frac{\rho_g U_\infty^2}{2}$$

$$\therefore \quad A = \frac{3}{4} C_D \left(\frac{\rho_g}{\rho_f}\right) \frac{U_\infty^2}{D_o} \tag{G.5}$$

Equation (G.2) becomes,

$$\frac{\sigma}{k} = V + \left(- \frac{\rho_f \rho_g (U_g - U_f)^2}{(\rho_f + \rho_g)^2} - \frac{(\rho_f - \rho_g) A}{(\rho_f + \rho_g) k} + \frac{kS}{\rho_f + \rho_g} \right)^{1/2} \qquad (G.6)$$

(1) (2) (3)

If the sum of terms within the square root is negative, the wave will become unstable and grow. Each term in Eq. (G.6) can be interpreted as follows:

(1) Relative velocity term between gas and liquid on the drop (Kelvin-Helmholtz term)

(2) Acceleration term due to drag (Rayleigh-Taylor term)

(3) Surface tension term

Here (1) and (2) are destabilizing factors, while (3) is stabilizing. Since $\rho_f >> \rho_g$ ($U_g >> U_f$),

$$\frac{(2)}{(1)} \cong \frac{\rho_f}{\rho_g} \frac{A}{k} \frac{1}{(U_g - U_f)^2} = \frac{\rho_f}{\rho_g} \frac{3}{4} C_D \frac{\rho_g}{\rho_f} \frac{U_\infty^2}{D_o} \frac{\lambda}{2\pi} \frac{1}{U_g^2}$$

$$\therefore \frac{(2)}{(1)} \cong \frac{3}{8} \frac{C_D}{\pi Q} \frac{\lambda}{D_o} \qquad (G.7)$$

where,

$$Q = \frac{\rho_g U_g^2}{\rho_g U_\infty^2} = \frac{\text{Dynamic pressure of gas at drop surface}}{\text{Dynamic pressure of gas ahead of drop}} \qquad (G.8)$$

$$\frac{(3)}{(1)} = \frac{2\pi}{\lambda} \frac{S}{(\rho_f + \rho_g)} \frac{(\rho_f + \rho_g)^2}{\rho_f \rho_g (U_g - U_f)^2} \cong \frac{2\pi}{\lambda} \frac{S}{\rho_g U_g^2}$$

$$\therefore \frac{(3)}{(1)} = \frac{2\pi}{\lambda} \frac{S}{\rho_g U_\infty^2 D_o} \frac{D_o}{U_g^2 / U_\infty^2} = \frac{2\pi}{\lambda} \frac{D_o}{We_b Q} \qquad (G.9)$$

where $$We_b = \frac{\rho_g U_\infty^2 D_o}{S} \qquad (G.10)$$

For unstable case, from Eq. (G.6),

$$\sigma - kV = iU_g \sqrt{\frac{\rho_g}{\rho_f}} \frac{2\pi}{\lambda} \left[1 + \frac{1}{Q}\left(\frac{3}{4}\frac{C_D}{D_o}\frac{\lambda}{2\pi} - \frac{2\pi}{\lambda}\frac{D_o}{We_b}\right)\right]^{1/2} \qquad (G.11)$$

Rearranging Eq. (G.11) the dimensionless time, T_σ is

$$T_\sigma = \frac{i2\pi}{\sigma - kV}\frac{U_\infty}{D_o}\sqrt{\frac{\rho_g}{\rho_f}} = \frac{\lambda}{D_o} Q^{-1/2}\left[1+\frac{1}{Q}\left(\frac{3}{4}\frac{C_D}{D_o}\frac{\lambda}{2\pi} - \frac{2\pi}{\lambda}\frac{D_o}{We_b}\right)\right]^{-1/2}$$

$$\cong \frac{\lambda}{D_o}\left(Q + \frac{3}{4}\frac{C_D}{2\pi}\frac{\lambda}{D_o} - \frac{2\pi}{We_b}\frac{D_o}{\lambda}\right)^{-1/2} \qquad (G.12)$$

The fastest growing wave length, λ_f, is obtained by setting,

$$\frac{\partial T_\sigma}{\partial \lambda} = 0$$

Then

$$\frac{\lambda_f}{D_o} = \frac{8\pi}{3C_D} Q \left[\left(1 + \frac{9}{4}\frac{C_D}{Q^2 We_b}\right)^{1/2} - 1\right] \qquad (G.13)$$

Also the critical (or cut-off) wavelength, λ_c is obtained by setting, $T_\sigma \longrightarrow \infty$

then

$$\frac{\lambda_c}{D_o} = \frac{4\pi Q}{3 C_D}\left[\left(1 + \frac{3 C_D}{Q^2 We_b}\right)^{1/2} - 1\right] \qquad (G.14)$$

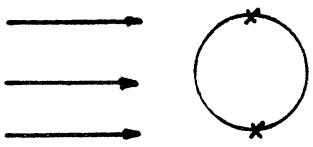
For large vaues of We_b, two limiting cases can be obtained as,

i) $Q = 0$ (1)

$$\frac{\lambda_c}{D_o} = \frac{2\pi}{Q We_b}$$

$$\frac{\lambda_f}{D_o} = \frac{3\pi}{QWe_b}$$

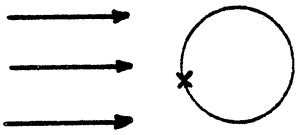
$$T\sigma_f = \pi\left(\frac{3}{Q}\right)^{3/2} We_b^{-1}$$



ii) $Q^2 << We_b$

$$\frac{\lambda_c}{D_o} = \frac{4\pi}{\sqrt{3C_D We_b}}$$

$$\frac{\lambda_f}{D_o} = \frac{4\pi}{\sqrt{C_D We_b}}$$



$$T\sigma_f = \frac{4\pi}{C_D^{3/4} We_b^{1/4}}$$
