Are neighbourhood characteristics associated with depressive symptoms? A review of evidence

C Mair, A V Diez Roux, S Galea

ABSTRACT
A review of published observational studies of neighbourhoods and depression/depressive symptoms was conducted to inform future directions for the field. Forty-five English-language cross-sectional and longitudinal studies that analysed the effect of at least one neighbourhood-level variable on either depression or depressive symptoms were analysed. Of the 45 studies, 37 reported associations of at least one neighbourhood characteristic with depression/depressive symptoms. Seven of the 10 longitudinal studies reported associations of at least one neighbourhood characteristic with incident depression. Socioeconomic composition was the most common neighbourhood characteristic investigated. The associations of depressive symptoms/depression with structural features (socioeconomic and racial composition, stability and built environment) were less consistent than with social processes (disorder, social interactions, violence). Among the structural features, measures of the built environment were the most consistently associated with depression but the number of studies was small. The extent to which these associations reflect causal processes remains to be determined. The large variability in studies across neighbourhood definitions and measures, adjustment variables and study populations makes it difficult to draw more than a few general qualitative conclusions. Improving the quality of observational work through improved measurement of neighbourhood attributes, more sophisticated consideration of spatial scale, longitudinal designs and evaluation of natural experiments will strengthen inferences regarding causal effects of area attributes on depression.

The notion that environmental features may be related to psychological well-being and mental health has a long history. As far back as 1959, Faris and Dunham found that schizophrenia and substance abuse rates were highest amongst individuals living in socially disorganised Chicago neighbourhoods. In My Name is Legion, published in 1959, Alexander Leighton explored how the expression of mental illness was shaped by local context and concluded that processes underlying the sociocultural disintegration of neighbourhoods may be shaping patterns of mental health and psychiatric disorder.

In recent years, there has been an explosion of interest in the peer-reviewed medical and public health literature about the ways in which neighbourhoods and residential environments may affect a variety of health outcomes, including mental health and depression. This interest has been spurred by theoretical discussions of the ecologic determinants of health as well as by the growing popularity and availability of multilevel analysis, a statistical technique that has been used to assess the relation between neighbourhood context and health after controlling for potential individual-level confounders.

There are many theoretical reasons why neighbourhood environments may be particularly relevant to mental health, and specifically to depression and depressive symptoms. Features of neighbourhoods such as lack of resources, disorder, violence, inadequate housing, and lack of green spaces may function as stressors. Neighbourhood features may also act as buffers of individual-based sources of stress related to mental illness. For example, physical and social features of neighbourhoods may affect social connections and the levels of social support experienced by residents. Social support may in turn affect residents’ vulnerability to stress and depressive symptoms.

Despite some theoretical rationale for neighbourhood effects on depressive symptoms, the results of the literature in this area are still somewhat mixed. In this review we take stock of the published observational studies of neighbourhoods and depression and depressive symptoms in order to identify future directions for the field. We summarise the main research questions, study populations, neighbourhood definitions, neighbourhood measures, depressive symptom measures, study designs, analytic techniques and results from these studies. The review concludes by discussing the remaining gaps in our knowledge about the relationship between neighbourhood context and depression, and suggests future research directions. This review complements a prior review of neighbourhoods and mental health by focusing specifically on the more narrow outcomes of depression and depressive symptoms, extending the review to also encompass articles published from 2004 to 2007 (a time of increasing publications in this area), and focusing on observational studies and their limitations.

METHODS
Studies were primarily identified using a biomedical database (PubMed) and two databases of psychological literature (PsycINFO and PsycARTICLES). The search terms “depression,” “depressive symptoms,” or “psychological distress” were entered together with “neighbourhood” or “neighbourhood characteristics”. These terms were selected since we were interested in any type of neighbourhood effect on either depression or depressive symptoms. These searches retrieved 79 articles in PubMed and 168 articles in...
Five of the studies excluded men from analyses, whereas distribution across most studies was relatively evenly balanced. Their populations varied from 117 to 56,428 subjects. Some of the studies restricted their populations to specific racial/ethnic groups or age categories, whereas others included a wide range of demographic characteristics. Twenty-nine studies examined the contextual effect of neighbourhood-level variables on depression, and 28 examined both neighbourhood structural characteristics and social processes. The majority of studies were conducted in metropolitan or urban areas: only 14 studies included non-urban dwelling subjects in their populations. 22–26 41 45 47 57 55 54 56 and one study used circular buffers of varying sizes around residences to define neighbourhoods. 36

The nine studies conducted in the UK used government-defined areas as proxies for neighbourhood, ranging from British electoral wards (mean population about 5500) to larger regional units, such as the 22 regional unitary authorities of Wales (mean population 122,880). 29–34 45–50 Studies conducted in Canada and the Netherlands also used administratively defined areas (census tracts in Canada 29 and boroughs in Amsterdam). 35

Neighbourhood features
The neighbourhood characteristics investigated fell into two categories: structural characteristics—such as neighbourhood socioeconomic and racial/ethnic composition, residential stability, and the built and service environments—and measures of social processes—such as neighbourhood disorder, social cohesion and ties with neighbours, and perceived exposure to crime, violence, drug use and graffiti. Structural characteristics were the most common features examined (35 out of the 45 studies). Twenty-five studies examined the contextual effect of neighbourhood socioeconomic position (after accounting for compositional differences) 2 11 15 17 19–21 28–34 37 39 40 42 43 46 48–50 and nine included measures of both type of neighbourhood socioeconomic characteristic. 21 28–30 32–34 46 50 Racial/ethnic composition (examined in 10 studies) 13 16 17 20 23 40 45 46 50 56 and residential mobility (examined in eight studies) 11 15 16 20 23 45 46 were the other two structural characteristics most commonly examined. Four studies investigated the role of the built environment 27 35 36 and one study examined the available service environment. 13

Twelve-five of the 45 studies examined the association between neighbourhood social processes and depressive symptoms. 11 15 16 19–22 25 31 37 39 40 44 47 48 51–57 Of these, 10 examined neighbourhood disorder and related domains, 11 24 44 45 47 49 51 52 56 57 6 16 examined social interactions between neighbours 13 19 22–24 31 37 39 41 42 47 52 54–57 and 12 investigated exposure to violence and other hazardous conditions. 18 19 22 25 26 41 42 44 52–54 56

Twelve studies examined both neighbourhood structural characteristics and social processes. 11 15 20 31 37 39 40 44 51 55 57 Nine of the 12 studies looked at both neighbourhood socioeconomic characteristics and social processes. 11 15 20 31 37 39 40 44 57

Measurement of neighbourhood features
Neighbourhood characteristics were measured using a variety of techniques. Census-derived neighbourhood variables were the most common measures used (16 studies). 2 16 17 21 25–30 32–34 40 45 46 48 50 followed by self-reports of neighbourhood characteristics by study participants (14 studies). 22–26 36 37 41 45 47 52–54 56 Ten studies included both census-derived measures and participant self-reports. 11 13 16 20 39 42 51 55 57 A small number of studies created measures by using objective raters who did not live in the neighbourhoods 22 35 36 or by using resources such as phone books to construct neighbourhood measures, and investigated the measures so constructed either on their own or in combination with census measures.

<td>Anehensel et al, 2007</td>
<td>Are depressive symptoms in older individuals associated with low SES, high concentration of ethnic minorities, low residential stability and low proportion of residents aged 65+ in urban neighbourhoods?</td>
<td>3442 individuals aged &gt;70 years living in urban areas in the USA, from AHEAD</td>
<td>Census tracts</td>
<td>Socioeconomic disadvantage, affluence, racial/ethnic composition (proportion of African-American residents, proportion of Hispanic residents), residential stability, proportion of persons &gt;65 years (all from census)</td>
<td>Eight-item version of CES-D</td>
<td>Cross-sectional</td>
<td>Multilevel analysis</td>
<td>Y and N: depressive symptoms are associated with residential stability (p (SE) 0.72 (0.27)) after controlling for individual-level characteristics, but not with any of the other neighbourhood characteristics</td>
</tr>
<tr>
<td>Anehensel et al, 1996</td>
<td>Are adolescents’ experiences of their neighbourhood as threatening or cohesive associated with their mental health?</td>
<td>877 adolescents aged 12–17 from Los Angeles County</td>
<td>Census tracts, grouped using cluster analysis into eight clusters</td>
<td>Participant-reported subjective neighbourhood measures (ambient hazards, social cohesion), neighbourhood stability</td>
<td>CDI</td>
<td>Cross-sectional</td>
<td>Single-level linear regression</td>
<td>Y: Adolescents’ perceptions of ambient hazards (p (SE) 0.022 (0.001)) and negative social cohesion (p (SE) −0.1220.032) are both associated with depressive symptoms.</td>
</tr>
<tr>
<td>Berke et al, 2007</td>
<td>Is there an association between neighbourhood walkability and depressive symptoms in older adults?</td>
<td>740 adults aged 65+ from King County, Washington</td>
<td>Circular buffers of radius 100, 500, and 1000 m around each subject’s home</td>
<td>Neighbourhood walkability, measured by the WBC. Greater walkability was assessed, on a scale of 0 to 100, according to the probability of meeting the CDC guidelines of 150-minutes per week of physical activity versus none</td>
<td>CES-D</td>
<td>Cross-sectional</td>
<td>Single-level logistic regression</td>
<td>Y: for men, there was an association between neighbourhood walkability and depressive symptoms (OR for the interquartile range of walkability score = 0.31–0.33 for the buffer radii, p = 0.02) after adjustment for key individual-level factors. This association was not significant in women (p&gt;0.68).</td>
</tr>
<tr>
<td>Caughy et al, 2003</td>
<td>Is there an association between how well a parent knows their neighbours and their child’s internalising behaviours? Does this association differ by neighbourhood SES context?</td>
<td>200 African-American families with a child aged 3–4.5 in Baltimore</td>
<td>Census block groups</td>
<td>Neighbourhood poverty (from census), general sense of community, how well one knows one’s neighbours (participant reported)</td>
<td>CBCL internalising problems score</td>
<td>Cross-sectional</td>
<td>Single-level linear regression</td>
<td>Y: Low sense of community was associated overall with higher levels of internalising problems (κ (SE) 3.61.9). In wealthy neighbourhoods, knowing neighbours decreases internalising problems; in poor neighbourhoods knowing neighbours was associated with increased internalising problems</td>
</tr>
<tr>
<td>Christie-Mizell et al, 2003</td>
<td>Are the subjective appraisal of the neighbourhood and living in an urban versus rural area associated with maternal psychological distress? Does this differ by race?</td>
<td>2204 women with at least one child from NLSY</td>
<td>Participant-defined neighbourhoods (for the subjective appraisal) and type of neighbourhood subjects lived in, as defined by the census (central city vs urban vs rural area)</td>
<td>Living in a SMSA, perceived neighbourhood disorder (participant reported)</td>
<td>Seven-item version of CES-D score</td>
<td>Longitudinal</td>
<td>Single-level linear regression with change in CES-D as outcome</td>
<td>Y: Across all racial groups, neighbourhood perceptions influence maternal distress (κ (SE) 0.17 (0.02)). Also, objective neighbourhood location influences how mothers perceive their neighbourhoods</td>
</tr>
<tr>
<td>Cutrona et al, 2005</td>
<td>Are women who reside in poor and/or dangerous neighborhoods 0.33–0.33 more likely to experience episodes of major depression than those in safe, affluent ones, after controlling for individual-level risk factors?</td>
<td>720 women from FACHS (large-scale study of African-American families who live outside large metropolitan inner cities in the USA)</td>
<td>Census block groups</td>
<td>Economic disadvantage index (from census), neighbourhood-level social disorder (combination of community dilapidation and community deviance scales)</td>
<td>UM-CIDI</td>
<td>Cross-sectional and longitudinal</td>
<td>Multilevel analysis</td>
<td>Y: neighbourhood disadvantage/social disorder was associated with recent onset of depression, after controlling for individual-level risk factors (OR 1.92, 1.04 to 3.52). However, neighbourhood disadvantage and disorder did not predict onset of depression at a later date</td>

<td>Cutrona et al, 2000</td>
<td>What is the effect of neighbourhood context on psychological distress among African-American women? Does community context interact with individual-level risk factors in the prediction of distress?</td>
<td>733 African-American women from the FACHS who were the primary caregiver for a 10–12-year-old child</td>
<td>Census neighbourhood block group areas</td>
<td>Neighbourhood cohesion and disorder (participant reported), community economic disadvantage (from census)</td>
<td>General distress and anxious arousal, two subscales from the mini-mood and anxiety symptom questionnaire (similar to UM-CIDI)</td>
<td>Cross-sectional</td>
<td>Multilevel analysis</td>
<td>Y: neighbourhood disorder ($\beta = 0.38, p &lt; 0.05$), but not cohesion or economic disadvantage, was associated with level of distress, after controlling for individual-level characteristics. There were significant interactions between some neighbourhood- and individual-level characteristics in the prediction of distress</td>
</tr>
<tr>
<td>Dupére and Perkins, 2007</td>
<td>Is there variation at the block level in well-being and depression? Do community-level environmental stressors and social resources affect well-being and depression?</td>
<td>412 residents from 50 neighbourhoods in a large city in the Mid-Atlantic region of the USA</td>
<td>Census blocks</td>
<td>Neighbourhood disorder, fear of crime, formal participation, informal ties with neighbours (participant-reported)</td>
<td>The 6-item depression factor of the CES-D scale</td>
<td>Cross-sectional</td>
<td>Multilevel analysis</td>
<td>N: There was no significant variation at the block level for depression, although there was significant variation at the block level for well-being. The community-level stressors and resources had no impact on mental health over and above individual and block socio-economic characteristics</td>
</tr>
<tr>
<td>Fitzpatrick et al, 2005</td>

*Although difficult to distinguish between neighborhood constructs and neighborhood measures in some studies, so they have been combined for the purposes of this table.*
Depression measures

The most common outcome measure examined was the CES-D (Center for Epidemiologic Studies Depression) scale (either full or modified) (19 out of 45 studies). Nine studies relied on measures approximating DSM-IV (Diagnostic and Statistical Manual of Mental Disorders) criteria, a measure of clinical depression. The SF-36 (Mental health index of the Short Form Health Survey) was used in two studies and a question from a general health survey (Behavioural Risk Factors Surveillance System) was used in one study.

Study designs

The majority of the studies (55) were cross-sectional in nature. Only 10 of the 45 studies used any type of follow-up or prospective analysis. Thirty-two studies had multilevel designs in that they included data on individuals nested within neighbourhoods and collected data at both levels. Thirty-two studies had multilevel designs in that they included data on individuals nested within neighbourhoods and collected data at both levels. Only 10 of the 45 studies used any type of follow-up or prospective analysis. Twenty-five of the 37 social processes (68%) examined in the studies were significantly associated with depression/depressive symptoms. All but one of the nine studies that assessed whether individual perceptions of the conditions and disorder in one’s neighbourhood affected risk of depression concluded that these factors were associated with depressive symptoms.

Analytical techniques

Twenty-one of the studies used linear or logistic multilevel models to investigate the relationship between depression or depressive symptoms and area-level characteristics. The remaining studies used single-level linear or logistic regression, or tests of significance of the difference in prevalence rates between groups. The four studies that contrasted results from multilevel analysis with an analysis ignoring the multilevel structure reported similar results with both approaches. Individual-level confounders, most commonly age, gender, marital status, ethnicity, education, employment status, financial strain, and number of current physical health problems, were included in models in all 45 studies.

Study results

Thirty-seven of the 45 studies found support for an association between neighbourhood characteristics and depression or depressive symptoms after controlling for a variety of individual-level characteristics, usually a combination of race/ethnicity, age, gender, marital status, education and income. When categorised by study design six of the seven purely longitudinal studies were significantly associated with depression/depressive symptoms in 30 out of 34 studies.

Differences based on neighbourhood characteristics and definitions

Study results differed depending on which neighbourhood characteristics were being studied. Overall, 24 of the 46 different structural characteristics (52%) examined were significantly associated with depressive symptoms/depression. Thirteen of the 25 studies that examined the effect of neighbourhood socioeconomic position on depressive symptoms found evidence to support the presence of an association after adjustment for individual-level characteristics. Four of the eight studies that examined the association between depression and residential mobility found evidence of an association. Only four of the 10 studies that examined racial/ethnic composition of neighbourhoods found support for the association between neighbourhood context and depression. All four studies that looked at the association between depressive symptoms and the built environment (specifically the internal and external built environment, the quality of housing areas, the walking environment and a negative neighbourhood environment, identified by factors such as violence, abandoned buildings and homeless people on the streets) found an association with depressive symptoms.

Twenty-five of the 57 social processes (68%) examined in the studies were significantly associated with depression/depressive symptoms. All but one of the nine studies that assessed whether individual perceptions of the conditions and disorder in one’s neighbourhood affected risk of depression concluded that these factors were associated with depressive symptoms.

Eleven out of 16 studies found positive social interactions between neighbours to be a protective factor against depression.

Exposure to violence and hazardous conditions was found to be associated with depressive symptoms in six out of 12 studies.

Both of the studies that systematically compared results for different scales found no consistent evidence that results differed systematically by neighbourhood size, although one study suggested that small scales (smaller than electoral ward in the UK) may be most relevant to depression. Study results differed somewhat in the USA and in the UK. Regardless of how they defined neighbourhood, UK studies found evidence for associations between neighbourhood environments and depression in only two-thirds of the studies (6 out of 9), whereas studies in the USA, independent of the size or definition of neighbourhood, found associations between at least one neighbourhood characteristic and depression in 30 out of 34 studies.

Heterogeneity in the effects of neighbourhood-level variables

It is often hypothesised that the effect of neighbourhood context on depression may vary by gender, age, racial/ethnic group or socioeconomic position. Of the nine studies that reported results either stratified by gender or with interaction terms between gender and neighbourhood characteristics, two found that neighbourhood characteristics were more strongly associated with depressive symptoms in women and one found a stronger association in men, whereas others had mixed results or found no difference between genders. Although the number of studies of children or of older people was generally small, there was limited evidence of more consistent associations in children or older people: four of the five studies that restricted their populations to older people and of the 10 studies of children aged 18 and under found evidence of an association between neighbourhood characteristics and depressive symptoms, compared with 24 of 50 studies of adult populations. Very few studies have investigated heterogeneity...
by race/ethnicity.\textsuperscript{37} In a Baltimore study, community cohesion was associated with less depression amongst White people, but was not associated with depression amongst African-Americans.\textsuperscript{46} One study found Mexican-Americans had better mental health in areas with high concentrations of Mexican-Americans, whereas another study found that African-Americans had worse mental health in areas with higher concentrations of African-Americans, although this association disappeared after adjustment for individual-level variables.\textsuperscript{17,20}

Five studies examined interactions of neighbourhood characteristics with individual-level socioeconomic position. Three of these studies found no interaction,\textsuperscript{40,48,49} whereas two found a significant interaction between individual-level economic status and neighbourhood conditions.\textsuperscript{46,50} Wealthy individuals living in areas with high income inequality had higher levels of mental disorders than those living in more equal areas, but the opposite was true for poor individuals.\textsuperscript{46} Living in a poverty area was only associated with worse mental health outcomes among the unemployed in another study.\textsuperscript{50} Other sets of interactions have also been examined in a small number of studies: knowing one’s neighbours was more strongly associated with higher levels of childhood anxiety and depression in poverty area neighbourhoods than in wealthy neighbourhoods;\textsuperscript{29} parents’ use of inductive reasoning was a protective factor for African-American teenagers’ levels of depressive symptoms only for those living in disordered neighbourhoods;\textsuperscript{44} and residential stability was associated with lower levels of depressive symptoms in wealthy neighbourhoods and higher levels in poor neighbourhoods.\textsuperscript{45}

**Longitudinal studies**

Ten of the 45 studies used some type of follow-up or prospective analysis.\textsuperscript{20,21,24,28,44,49,51,53,54} Two studies had 1 year or less of follow-up time,\textsuperscript{24,34} six studies had 1–2 years of follow-up,\textsuperscript{20,28,44,49,51,53} one study had 7–8 years of follow-up\textsuperscript{24} and one study followed subjects for 10 years.\textsuperscript{21} Nine of the 10 studies had two waves of data,\textsuperscript{20,21,24,28,44,49,51,53,54} whereas one study used three waves of data collection.\textsuperscript{20} Four studies defined incident depression/depressive symptoms as subjects who did not have depression or fell below a certain cut-off level of depressive symptoms at baseline, but who did have depression or were above the cut-off level at follow-up time(s).\textsuperscript{21,28,34,49} One study used a change score,\textsuperscript{31} and five studies simply used the level/presence of depressive symptoms at follow-up, with three of these controlling for baseline levels in their models.\textsuperscript{20,24,44,53,54} Four studies restricted their populations to children\textsuperscript{20,44,53,54} and two to women,\textsuperscript{49,51} whereas the remainder enrolled representative adult populations.\textsuperscript{21,24,25,34} Each of these studies used a different definition of neighbourhood: New York City community districts, census block groups, clusters of census block group areas, British electoral wards, clusters of multiple census tracts, poverty areas/non-poverty areas and participant-defined neighbourhoods. Five of these studies focused on measures of neighbourhood socioeconomic position and disadvantage,\textsuperscript{20,21,24,34,49} and two of these additionally examined social cohesion and neighbourhood disorder as predictors.\textsuperscript{20,49} Four of the five studies that examined the association between neighbourhood socioeconomic status and development of depressive symptoms found evidence of an association,\textsuperscript{20,21,24,49} after controlling for combinations of age, education, sex, race/ethnicity, income, stressors, marital status, number of children, receiving government assistance, perceived health status, body mass index, smoking and alcohol consumption, whereas one found no association.\textsuperscript{44} Neighbourhood disorder was prospectively associated with depressive symptoms in four out of five studies.\textsuperscript{24,45,51,53} Neighbourhood cohesiveness was associated with depressive symptoms in two\textsuperscript{20,53} of the three studies that examined this process.\textsuperscript{20,24,54}

**DISCUSSION**

Of the 45 studies reviewed, 37 reported associations of at least one neighbourhood characteristic with depression or depressive symptoms after controlling for individual-level characteristics. The percentage of positive results was similar in cross-sectional (52%) and longitudinal (70%) studies. The associations of depressive symptoms/depression with structural features were less consistent (52% significantly associated) than with social processes (68%). Among the structural features, measures of the built environment appeared to be more consistently associated with depression than socioeconomic deprivation, residential stability or race composition, although only a few studies to date have investigated the built environment.

Although a wide variety of area definitions were investigated, very few studies systematically compared area definitions and no clear pattern emerged from the comparison of studies using different-sized areas. Controlling for individual-level confounders often reduced the magnitude of the association between neighbourhood characteristics and depression/depressive symptoms, although the association rarely disappeared altogether. Interactions were investigated in only a small number of studies making it difficult to draw any conclusions about vulnerable groups, although there was some evidence of stronger effects in children and older people than in adult populations. The studies varied widely in neighbourhood definitions, in the neighbourhood-level variables investigated and in the individual-level covariates examined, making it impossible to conduct a meta-analysis of study results. Increasing comparability across studies in the geographic areas, the variables and the outcomes examined to conduct systematic reviews is an important need in the field.

Current limitations in this body of literature include limited theory about how neighbourhoods may influence depression and depressive symptoms; the lack of consistency in the definitions of neighbourhoods and the measures of neighbourhood-level properties examined; the possibility of reporting bias, reverse causation and residual confounding; the dearth of studies exploring different spatial scales; and the relative lack of longitudinal studies. Five important research directions emerge from the reviewed works. These research directions are (1) developing theory on the processes through which specific area features may affect mental health, including theories on the most vulnerable groups; (2) improving the measures of neighbourhood or area-level factors necessary to test these theories empirically; (3) investigation of a broad range of areas (or spatial scales) and neighbourhood–person interactions; (4) addressing issues of reporting bias, reverse causation and residual confounding; and (5) increasing the use longitudinal designs and quasi-experimental or experimental designs.

Developing theory on the processes through which area features may be associated with depression and depressive symptoms and empirically testing specific predictions derived from these theories is fundamental to strengthening causal inference. Empirical investigations of the processes linking neighbourhood characteristics to depression will require the measurement of the specific neighbourhood attributes involved. To date, the majority of studies have used measures of the socioeconomic composition of areas as a proxy for the more
specific area attributes that may be relevant. A growing number of studies have attempted to measure specific attributes of neighbourhoods such as the built environment, social cohesion disorder or crime. It is interesting to note that findings have generally been more consistent for studies focusing on specific neighbourhood attributes than those focusing on aggregate measures of socioeconomic position or deprivation. However, the measures used across studies have varied widely, making comparisons difficult. Developing standardised measurement instruments that can be applied across studies so that findings can be systematically compared will be an important advancement. One methodology that could potentially be explored further involves the use of geographic information systems (GIS) to construct measures of the built environment and the physical layout of neighbourhoods hypothesised to be related to mental health or to create synthetic geographical areas with optimised homogeneity of social characteristics.

There is little consensus on what spatial scales (ranging from the immediate built environment of the home to broader regional characteristics) may be relevant to depression or depressive symptoms in different population groups. The development of hypotheses on relevant spatial definitions will require more sophisticated theory on how persons interact with and are affected by spatial contexts. In the absence of clear theory on the spatial scale relevant to a particular process, researchers can conduct sensitivity analyses to determine the effects of different definitions of “neighbourhoods” on the results of their research. The definition and size of a neighbourhood varied widely across the studies in this review and few studies have examined sensitivity of results to the use of measures corresponding to different-sized areas. The use of spatial analytic methods is another promising arena that has not yet been extensively used in this body of literature. These methods can be used to investigate the spatial patterning of health outcomes without relying on arbitrary defined boundaries. This spatial patterning can provide information on the spatial scale at which the relevant processes may be operating.

An important methodological challenge in investigating neighbourhood effects on depression is reporting bias (sometimes also referred to as same-source bias). Reporting bias may arise for example if people who are already depressed report lower levels of social cohesion and a worse external environment because of their depression. Many of the studies in this review measured neighbourhood conditions from the same sample of people from whom they took measurements on depressive symptoms. The association between social cohesion and depressive symptoms, for example, might exist because depressed people feel more alone, even though their neighbourhood, objectively, does not have low social cohesion. A growing body of work on ecological measurement has begun to develop alternative ways to use survey data or objectively collected data on the built environment (though publicly available data or systematic social observation) to characterise neighbourhood environments in ways that avoid same-source bias. Greater use of these methods in the area of neighbourhood characteristics and depression is needed.

Reverse causation and residual confounding by individual-level variables are two additional methodological problems. Reverse causation would arise if people who are depressed tend to stay in or move into deprived neighbourhoods. In this case the exposure to the neighbourhood condition is a consequence of (and not a cause of) depression. All cross-sectional studies are vulnerable to the problems of reverse causation. Longitudinal designs are necessary to rule out reverse causation as an explanation for cross-sectional associations. As in other neighbourhood effects research, the possibility of residual confounding by individual-level variables is an important limitation of observational studies of neighbourhoods and depression. Most studies in this review attempted to address this issue by controlling for a variety of individual-level variables, but there is no consensus on what the key confounders are likely to be, or on the sensitivity of results to plausible amounts of residual confounding. Other approaches sometimes used to control for multiple confounders such as propensity score analysis have not been used in research on neighbourhoods and depression.

The majority of existing studies of neighbourhoods and depression are cross-sectional. As noted above, longitudinal studies are necessary to rule out reverse causation. They are also needed to investigate time lags and cumulative effects of neighbourhoods on depression. Short of the ideal randomised experiment, natural experiments or quasi-experimental designs may also provide opportunities to examine causal effects of neighbourhood or area attributes on depression avoiding some of the pitfalls of observational studies. For example, a study could examine changes in depressive symptoms over time in a neighbourhood in response to some source of exogenous variation such as the inauguration of a new public space, or the implementation of a new community policing approach. These interventions, which are “naturally occurring” in neighbourhoods all the time, provide valuable but as yet untapped opportunities to investigate area or neighbourhood effects on depression. In summary, existing observational evidence supports a role of neighbourhood conditions in the development of depression and depressive symptoms. However, more refined observational work (including the study of natural experiments) is needed to determine whether the associations observed are causal and what the relevant neighbourhood-level attributes and mediating variables might be.

We summarise and review existing work on neighbourhoods and depression or depressive symptoms and find that the majority of published studies on this topic (37 of 45 studies) reported associations of at least one neighbourhood characteristic with depression or depressive symptoms after controlling for individual-level characteristics. The percentage of positive results was similar in cross-sectional (82%) and longitudinal (70%) studies. The associations of depressive symptoms/depression with structural features were less consistent than with social processes. Measures of the built environment appeared to be more consistently associated with depression that socioeconomic deprivation, residential stability or race composition.
We identify five important research directions: (1) developing theory on the processes through which specific area features may affect mental health, including theories on the most vulnerable groups; (2) improving the measures of neighbourhood or area-level factors necessary to test these theories empirically; (3) investigation of a broad range of areas (or spatial scales) and neighbourhood–person interactions; (4) addressing issues of reporting bias, reverse causation and residual confounding; and (5) increasing the use longitudinal designs and quasi-experimental or experimental designs.

The confirmation of causal neighbourhood effects on depression would suggest that strategies to prevent depression should take residential context into consideration.
