PET imaging is an exciting and rapidly growing area of research in which short-lived radionuclides, such as carbon-11 and fluorine-18, are generated in a cyclotron and used to label small molecules. The resulting radiopharmaceuticals find widespread application in the noninvasive examination of biochemical processes in living human subjects (Figure 1).

Radiopharmaceuticals can range from the small and simple (e.g., small molecules, sugars, peptides, amino acids) to the large and complex (e.g., taxol, large peptides, proteins, antibodies) and can be custom-synthesized for applications in, for example, neurology, oncology, and cardiology. Radiochemistry is the process by which such molecules are tagged with a radioisotope. Owing to the high levels of radiation involved, it is frequently not a trivial process. In the last two or three decades, a broad range of ingenious radiochemical reactions and automated hardware solutions have been developed to simplify the process. A detailed discussion of these developments is beyond the scope of this Highlight; however, the subject has received much attention in recent review articles in the mainstream organic chemistry literature, most noticeably in a comprehensive article by Miller et al.

The scope of PET imaging is perhaps endless, especially when one considers how many biochemical processes are occurring in the human body (or elsewhere in nature) at any given time. Therefore, future applications in, for example, genomics and stem-cell research are expected and eagerly anticipated. Despite this potential, and echoing the opinion of Miller et al., PET imaging is currently underexploited because of the limited availability of pertinent radiopharmaceuticals. Access to radiopharmaceuticals is in turn restricted by the arsenal of labeling reactions at the radiochemist’s disposal. This problem is exacerbated by the fairly small number of radiochemists developing new reactions. The slow process of reaction development is often hindered further when forced into second place behind increasing clinical-production demands. However, the growing numbers of traditional organic chemists entering the radiochemistry arena worldwide, a trend reflected by the recent flurry of review articles, offers a promising solution to these problems. Many innovative organic chemistry techniques (e.g., solid-phase synthesis, fluorous technology, microfluidics) and reactions (e.g., the Huisgen cycloaddition (click chemistry), palladium-catalyzed cross-coupling reactions) are beginning to be adapted for radiochemical synthesis.

Carbon-11 is one of the most useful radioisotopes to work with owing to the ease with which it can be incorporated into many molecules without a significant effect on biological activity (in contrast to the detrimental effect on activity frequently encountered upon the addition of an [18F]fluoroethyl group to a promising pharmacological scaffold). At the same time, however, competing side reactions with environmental carbon-12 sources (e.g., atmospheric CO₂) and the 20 min half-life make high-specific-activity radiopharmaceuticals labeled with carbon-11 some of the most synthetically challenging to prepare. The radiochemical reactions have to be very fast (must typically occur within 5 min), high yielding, and clean enough that crude reaction mixtures can be purified rapidly (by semipreparative HPLC or solid-phase extraction (SPE) techniques) to provide pure radiopharmaceuticals as sterile, pyrogen-free isotonic solutions suitable for intravenous injection.

Carbon-11 is generated in the cyclotron target by a nuclear reaction with nitrogen-14: }

\[
^{14}N + p \rightarrow ^{11}C + n
\]

This reaction is typically monitored using a beta-scintillator to indicate the何时的时刻.

carbon-11 then reacts with trace amounts of a gas added intentionally to the nitrogen-14 cyclotron target gas, either oxygen or hydrogen, to produce $^{14}$CO$_2$ (1) or $^{14}$CH$_3$ (2), respectively. These compounds can be used directly, or, much more commonly, converted into more reactive species (typically $^{14}$CH$_3$I (3) or $^{14}$CH$_3$OTf (4)) through the use of one of a sophisticated array of automated reactions (for a selection, see Scheme 1).

The most common reactions in modern carbon-11 chemistry involve methylation of an appropriate precursor molecule (typically an amine or phenoxide precursor) with $^{14}$CH$_3$I (3). In the case of less active precursors, the more reactive methylating agent $^{14}$CH$_3$OTf (4) can be generated by passing $^{14}$CH$_3$I through a column of hot silver triflate.

Hostetler et al. from Merck saw an opportunity to exploit the reactivity of $^{14}$CH$_3$I in the palladium-catalyzed Suzuki reaction (Scheme 2). The lack of $\beta$ hydrogen atoms ensures that $\beta$ elimination, a common hindrance to the use of other alkyl halides in palladium chemistry, is not possible. The optimum catalyst/base combination was found to be [Pd(dppf)Cl]$_2$/K$_2$PO$_4$, and a number of $^{14}$C-labeled aryl species 6 were obtained in 49–92% decay-corrected yield (DCY) from the corresponding boronic acids 5.

One drawback of $^{14}$CH$_3$I is that a nucleophilic precursor suitable for methylation must be first generated. More-sensitive precursors containing other reactive functional groups can be difficult to handle and store, and are undesirable for long-term clinical-production needs. However, an interesting reversal of the reactivity profile was reported by Jacobson and Mishani.[8] $^{14}$CH$_3$I was treated with methylamine (7) to generate $[^{14}$C]dimethylamine 8, which was then used to generate PET biomarkers (e.g. 9 and 10) bearing the $[^{14}$C]dimethylamino functional group from the corresponding electrophilic alkyl halide precursors (Scheme 3). This reaction is expected to find widespread use in future carbon-11 chemistry.

Hooker and co-workers have devoted much research effort to the development of novel reactions for the enhancement of carbon-11 radiochemistry and have recently reported two useful examples.[9,10] Like the reactions described above, the first uses $^{14}$CH$_3$I as a starting point. It offers an improved, very mild and rapid method of generating $[^{14}$C]formaldehyde (13) (Scheme 4). The treatment of trimethylamine N-oxide (TMAO, 11) with $^{14}$CH$_3$I (3) provided 12, which underwent immediate decomposition into $[^{14}$C]formaldehyde 13. In a test reaction, the treatment of tryptamine (14) with $^{14}$CH$_3$O under acidic conditions provided labeled 2,3,4,9-tetrahydro-1H-$\beta$-carboline 15 in excellent radiochemical yield and with excellent specific activity (3.0–4.5 Ci mmol$^{-1}$).

The second reaction described by Hooker and co-workers is a novel one-pot method for the incorporation of $^{14}$CO$_2$ into carbamates (Table 1).[10] The above reactions require the conversion of $^{14}$CO$_2$ into $^{14}$CH$_3$I, followed by a labeling reaction. These two steps can take longer than 20 min and consume at least half of the starting radioactivity. Thus, one-pot reactions in which $^{14}$CO$_2$ is the reactive species are in
demand. Such reactions are uncommon because of the limited number of substrates that contain suitable motifs for labeling. Nonetheless, in view of the growing demand for new radiochemical reactions, this latest study by Hooker and co-workers is timely and of great interest to the field. Initially, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) was used to trap 11CO2: The authors propose the formation of 16. Compound 16 was treated with alkyl halides to generate intermediates 17, which then supplied [11C]carbamates 18 on treatment with an amine. The reaction yields are moderate (\%77\%), with scope for improvement, but do provide usable amounts of high-specific-activity (5 Ci\,\text{m}\text{mol}^{-1}) products. Furthermore, this new labeling strategy is tolerant of water; so much so that the spiking of reactions with 10 mg of water has a negligible effect on the reaction yield.

One significant obstacle occasionally encountered in radiochemistry is that reactions developed on simple test compounds do not translate well to complex radiopharmaceutical precursors. Thankfully, this was not the case with the method for carbamate preparation described by Hooker and co-workers. Relevance was demonstrated admirably in the production of [11C]metergoline 20, a PET ligand for serotonin (5HT) receptors (Scheme 5). Benzyl chloride was treated initially with the DBU\,11CO2 complex, and the resulting intermediate was quenched with the amino precursor 19 to provide [11C]metergoline in 32–40\% radiochemical yield (RCY). The designed simplicity and efficiency of this reaction should very quickly make it the method of choice for preparing related [11C]-labeled biomarkers.

In conclusion, to meet the growing demand for novel radiopharmaceuticals in nuclear medicine, it is imperative that new labeling methods in radiochemistry continue to be developed. Many research groups worldwide are actively pursuing such endeavors with a high degree of success, as the impressive selection of new [11C]-labeling reactions featured herein emphasizes. Such reactions in conjunction with the growing use of techniques such as solid-phase synthesis and fluorous technologies are greatly enhancing the art and science of radiopharmaceutical synthesis.
