(Received 4 February 1991; accepted for publication 15 March 1991)

Deflection of carbon dioxide and helium-neon laser beams has been used to measure plasma and neutral density gradients during the operating mode and after the shorting time of a long-pulse field-emission electron beam diode. Plasma density gradients of \((10^{14}-10^{15}) \text{ cm}^{-4}\) were observed throughout the diode during the final microsecond of the 2–3 \(\mu\)s electron beam pulse. The neutral density gradient was less than \(1\times10^{18} \text{ cm}^{-4}\) during the electron beam pulse. Upon diode shorting, neutral density gradients increased to \((10^{18}-10^{19}) \text{ cm}^{-4}\) over \(\sim 1 \mu\)s, and decayed over many microseconds. Plasma density gradients of \(\sim 10^{15} \text{ cm}^{-4}\) were also observed after shorting. These experiments demonstrate the value of carbon-dioxide laser and helium-neon laser deflection for diagnosing plasma and neutral particles in long-pulse electron beam diodes.

I. INTRODUCTION

Field-emission electron beam diodes can be used to provide long-pulse electron beams with energies of \(\sim 1\) MeV, pulse length \(\sim 1 \mu\)s, and multikiloampere currents. In a typical diode, an electric field of hundreds of kilovolts per centimeter is applied between parallel plates separated by a few centimeters. The cathode may be covered with felt or velvet to provide electric field enhancement at the tips of fibers. The application of the electric field initiates a series of events: (1) cathode turn-on in which plasma spots form on the cathode and coalesce into a plasma layer over several ns, providing an electron source; (2) operating mode, a time period on the order of 2 \(\mu\)s (for anode cathode gaps of several cm) during which electrons from the cathode plasma are accelerated towards the anode at energies \(\sim 1\) MeV, and the diode impedance drops towards zero; and (3) shorting, a high-current, low-impedance arc with decreased voltage between anode and cathode, during which the diode becomes filled with neutral particles and plasma.

The diode impedance during the operating mode is typically that of a vacuum diode whose anode-cathode separation decreases linearly with time at a velocity of several cm/\(\mu\)s. Researchers have frequently relied upon the time-dependent diode impedance to infer the diode properties. The impedance behavior has been ascribed to the diode impedance in the operating mode is 280 times as great as that of the He-Ne laser because of its longer wavelength (10.6 \(\mu\)m as opposed to 0.633 \(\mu\)m), while the deflection from neutral gradients has been previously observed using two-wavelength deflection measurements using carbon dioxide (CO\(_2\)) and helium-neon (He-Ne) lasers traversing nearly identical paths through a planar diode with anode-cathode separation of 8 cm. The CO\(_2\) laser deflection from plasma density gradients is 780 times as great as that of the He-Ne laser because of its longer wavelength (10.6 \(\mu\)m as opposed to 0.633 \(\mu\)m), while the deflection from neutral gradients are nearly the same (within 3%). As a result, increased sensitivity to plasma density gradients is provided by the CO\(_2\) laser, allowing observation of plasma throughout the diode.

In this article, we describe two-wavelength deflection measurements using carbon dioxide (CO\(_2\)) and helium-neon (He-Ne) lasers at the same location and time, both the plasma and neutral density gradients may be deduced. With this additional capability, density gradients after the shorting time, when both neutral and plasma species are present, have been determined.

With laser beams skimming the cathode, a cathode plasma density gradient was observed during the final \(\mu\)s of
the 2–3 μs electron beam pulse, peaking at \( \sim 1.5 \times 10^{15} \) cm\(^{-4}\) near shorting time. The neutral density gradient was less than \( 1 \times 10^{18} \) cm\(^{-4}\) during this time period. Upon shorting, a neutral density gradient indicative of cathode-produced neutrals was observed near the cathode, increasing to \( 6 \times 10^{18} \) cm\(^{-4}\) over \( \sim 1 \) μs, and decaying over many microseconds. The cathode plasma density gradient reverses direction at shorting time and disappears over the following μs, consistent with the cathode plasma being pushed away from the cathode by the expanding neutral cloud. Several μs later, plasma density gradients of several \( 10^{14} \) cm\(^{-4}\) appear, with density increasing away from the cathode.

Cathode plasma density gradients of \( \sim 1 \times 10^{14} \) cm\(^{-4}\) prior to shorting were observed with CO\(_2\) laser deflection at distances of 1.5 and 4.5 cm from the cathode. With the CO\(_2\) laser skimming the anode, a plasma density gradient of \( 2 \times 10^{14} \) cm\(^{-4}\) increasing towards the anode was observed during the final 0.5 μs preceding shorting.

II. APPARATUS

This experiment was performed using the Michigan Electron Long Beam Accelerator (MELBA), operated with parameters of peak voltage = \(-900\) kV, peak diode current = 50 kA, and pulse length of \( \sim 2 \) μs. This accelerator consists of a modified Marx generator, in which the voltage is compensated by a reverse-charged resistance-inductance-capacitance (RLC) ringing circuit.\(^9\) The cold cathode was an aluminum disk of 10 cm diameter covered with carbon felt, separated from the carbon anode plate by a distance of 8 cm. A shielded guard ring (o.d. = 14 cm) covers the edge of the fabric cathode, exposing 7.6 cm diameter of fabric. A current density of 30–125 A/cm\(^2\) was thereby produced. Voltage was measured with a resistive divider, while anode current was measured with wide-band current transformers (Pearson Electronics 110A) on four isolated current return paths.

A schematic of the experiment is shown in Fig. 1. A 5 mW He-Ne laser is directed through the diode, upon a 10.8 m path into a Faraday cage, through a He-Ne line filter, to a photodiode quadrant detector (Silicon Detector Corporation SD-380-23-21-051) with a very fast differential amplifier.\(^10\) With the resultant laser spot size (\( \sim 1 \) cm), the detector output is proportional to the laser spot position over a distance of \( \sim 1 \) cm, so that deflections up to \( \pm 0.5 \) mrad can be measured.

A 1–5 W CO\(_2\) laser provides a 7 mm beam for infrared laser deflection. The beam traverses 6 m, then is reduced and focused using a NaCl lens pair 2 m from the diode, with best focus in the diode. This provides a beam diameter of \( \sim 5 \) mm on its 7.6 cm path through the diode, which is nearly identical to the He-Ne path in the diode. Because of diffraction effects, the CO\(_2\) beam diameter cannot be significantly reduced over a 7.6 cm path length. The beam is then directed on a 11.3 m path to the Faraday cage, and focused onto a detector using a NaCl lens with 10 cm focal length. A knife edge bisects the beam (diam \( \sim 4 \) cm) as it exits this final lens. The detector used was a liquid-nitrogen-cooled Raytheon IR101 PbSnTe detector with Raytheon DA-20 preamplifier (bandwidth of 20 Hz to 4 MHz), filtered with a 10.6 μm line filter. The portion of the beam intersected by the knife edge changes with the laser spot position, so that the detector signal varies linearly with laser spot position over a distance of \( \sim 2 \) cm. Deflections up to \( \pm 1 \) mrad can thus be measured.

Response curves of the CO\(_2\) and He-Ne laser deflection systems are shown in Fig. 2. A position shift of 1 cm over the 10 m path from the diode to the detectors corresponds to a deflection of 1 mrad. Deflection signals were converted from mV to mrad using the slope of these curves at the initial laser spot position. Because the CO\(_2\) laser power varied from shot to shot, the curve in Fig. 2(a) was normalized to the laser power for each shot. Electrical noise upon the deflection signals was monitored during each data run by performing shots with the laser paths blocked.

III. THEORY

Laser deflection results from plasma and neutral density gradients \( \left( \frac{dn_e}{dz}, \frac{dn_n}{dz} \right) \) in the diode according to:

\[
\theta = -L \frac{dn_e}{dz} - L \left( K_e \frac{dn_e}{dz} + K_n \frac{dn_n}{dz} \right),
\]

where \( \theta \) is the deflection angle in radians, \( L \) is the path length through the diode (7.6 cm), \( z \) is the distance from the cathode to the laser path, \( \eta \) is the refractivity of the medium in the diode, \( K_e \) is the Gladstone-Dale constant for plasma electrons (in cm\(^3\)/electron), and \( K_n \) is the Gladstone-Dale constant for neutrals (in cm\(^3\)/atom). \( K_e \) and \( K_n \) have opposite signs, so that the laser is deflected in opposite directions by plasma and neutral density gradients. A deflection towards the cathode is positive. \( K_e \) equals \(-\left(2 n_e\right)^{-1}\), where \( n_e \) is the critical plasma density for the laser wavelength. \( K_n \) depends upon the laser wavelength as \( \lambda^2 \); \( K_n \) depends upon the neutral species composition, but has little dependence upon laser wavelength. \( K_e = -5.0 \times 10^{-24} \) cm\(^3\)/electron for the CO\(_2\) laser beam (\( \lambda = 10.6 \) μm), while \( K_e = -1.8 \times 10^{-22} \) cm\(^3\)/electron for the He-Ne laser beam (\( \lambda = 0.633 \) μm).\(^10\) Thus, the CO\(_2\) laser deflection is 280 times as sensitive to plasma deflections as to plasma electrons. For neutral carbon atoms, \( K_n = 6.25 \times 10^{-24} \) cm\(^3\)/atom for the CO\(_2\) laser and \( 6.4 \times 10^{-24} \) cm\(^3\)/atom for the He-Ne laser,\(^11\) a difference of only 3%. A summary of the laser deflection parameters is given in Table I.

From Eq. (1), we can write:

\[
\theta_{CO_2} = (7.6 \text{ cm}) \left(5.0 \times 10^{-30} \text{ cm}^3 \frac{dn_e}{dz} \right) - (6.25 \times 10^{-24} \text{ cm}^3 \frac{dn_n}{dz}),
\]

\[
\theta_{HeNe} = (7.6 \text{ cm}) \left(1.8 \times 10^{-22} \text{ cm}^3 \frac{dn_e}{dz} \right) - (6.4 \times 10^{-24} \text{ cm}^3 \frac{dn_n}{dz}).
\]
Multiplying Eq. (3) by 0.97 and subtracting it from Eq. (2) yields:

\[ \theta_{\text{CO}_2} - (0.97)\theta_{\text{HeNe}} = (7.6 \text{ cm})(5.0 \times 10^{-20} \text{ cm}^3) \frac{dn_x}{dz} \].

Equation (4) allows the plasma density gradient to be determined from the measured deflections. Similarly,

\[ \theta_{\text{HeNe}} - (0.0036)\theta_{\text{CO}_2} = (7.6 \text{ cm})(-6.4 \times 10^{-24} \text{ cm}^3) \frac{dn_x}{dz} \].

For CO₂ and HeNe deflection angles of the same order of magnitude, the CO₂ contribution to Eq. (5) is negligible, so that the HeNe laser deflection may be attributed to neutral density gradients. This is the case in our results. The CO₂ deflection minus 0.97 times the HeNe deflection is proportional to the plasma density gradient. Prior to diode shorting, the He-Ne deflection was not observable, so that the CO₂ deflection is proportional to the plasma density gradient.

IV. RESULTS

Observations with He-Ne and CO₂ laser beams simultaneously skimming the cathode have shown deflection angles of the same order of magnitude for both lasers. This indicates that the observed He-Ne deflection results from the neutral density gradient. In Fig. 3, we display data for laser beams skimming the cathode. The He-Ne deflection is not observable during the operating mode of the diode, indicating that the neutral density gradient is less than \(1 \times 10^{18} \text{ cm}^{-4}\). Upon shorting, cathode-produced neutrals produce a density gradient of carbon atoms building to \(6 \times 10^{18} \text{ cm}^{-4}\) over \(\sim 1 \mu s\), and decreasing over several microseconds. Similar He-Ne deflection signals were ob-
served in other locations near the cathode. When the He-Ne laser skimmed the anode, the deflection signal was similar but inverted, consistent with anode-produced neutrals.

Subtracting the neutral-produced He-Ne deflection from the CO₂ deflection signal yields the plasma-produced deflection, shown in Fig. 3(e). This is a bipolar signal indicating a cathode-plasma density gradient building to ~1.5 x 10¹³ cm⁻⁴ during the final microsecond of the operating mode. The deflection reverses direction at shorting time and builds to a comparable angle in the opposite direction, indicating that plasma density increases away from the cathode. This is consistent with the cathode plasma being pushed away by cathode-produced neutrals after the shorting time. A plasma density gradient of 5 x 10¹⁴ cm⁻⁴ increasing away from the cathode is observed 4 μs after shorting, showing the presence of plasma during the arc. On some shots, this feature was not observed, while other shots showed several plasma density gradient peaks during the arc.

At other locations within the diode, CO₂ laser and He-Ne laser deflection were performed on separate shots.

FIG. 4. Voltage pulse, anode current pulse, and CO2 laser deflection signals for five shots. (a) Laser positioned 1.5 cm from the cathode. (b) Laser positioned 4.5 cm from the cathode (3.7 cm from the anode). (c) Laser skimming the anode. (d) Laser positioned 1.5 cm from the cathode, for a shot with a transient arc preceding diode shorting. (e) Laser positioned 1.5 cm from the cathode, for a shot in which the voltage is crowbarred after 1 μs.
The He-Ne deflection was not observable (<0.05 mrad) during the operating mode, indicating that the neutral density gradient was less than $1 \times 10^{18}$ cm$^{-4}$. Upon shorting, the He-Ne deflection increased over $\sim 1$ μs, sometimes in an irregular fashion, and then gradually decreased over many microseconds. Near the cathode (anode), the neutral density increased in the direction of the cathode (anode). Shot-to-shot variability prevented a complete analysis of the post-shorting CO$_2$ signals, for which both plasma and neutral gradients contribute. However, the contribution from the neutral density gradient following shorting could frequently be identified as a slowly decreasing deflection, upon which larger deflections from plasma gradients were superimposed.

Figure 4 shows the CO$_2$ laser deflection signals for several shots at various positions within the diode. Prior to shorting, the deflection is proportional to the plasma density gradient. A plasma density gradient of $2.6 \times 10^{15}$ cm$^{-4}$ corresponds to a 1 mrad deflection. After shorting, the majority of the deflection is attributable to the plasma density gradient, summed with a smaller slowly decreasing neutral density gradient signal. For deflections attributable to plasma gradients, a scale for $dn/dz$ is shown in Fig. 4.

In Fig. 4(a), we display a signal with the CO$_2$ laser located 1.5 cm from the cathode. A deflection from a cathode plasma density gradient of $\sim 1 \times 10^{14}$ cm$^{-4}$ is observed prior to shorting, and develops into a bipolar plasma signal with peak plasma density gradients of $\sim 1 \times 10^{15}$ cm$^{-4}$. Compared with the bipolar signal observed with the probe skimming the cathode, this signal has about one-half the magnitude, occurs 1-2 μs later, and lasts nearly twice as long. Finally, a slowly-decaying neutral-produced gradient remains, with about one-fifth the magnitude observed skimming the cathode.

In Fig. 4(b), we display the CO$_2$ deflection at a position 4.5 cm from the cathode (3.7 cm from the anode). At this position near the center of the diode, several cm from cathode or anode, a deflection from a cathode plasma density gradient of $\sim 1 \times 10^{14}$ cm$^{-4}$ was observed 0.5 μs prior to shorting. To our knowledge, this is the first detection of plasma during the operating mode of a relativistic electron beam diode several cm from either electrode.

In Fig. 4(c), we display a signal with the CO$_2$ laser skimming the anode. When these data were taken, observations with the laser path blocked showed that negative-going electrical noise signals were associated with transient arcs during the first 2 μs of the pulse. Consequently, the first negative-going voltage pulse on the laser deflection signal is likely to be noise. During the final 0.5 μs of the pulse, a plasma density gradient of $2 \times 10^{14}$ cm$^{-4}$ is observed, with density increasing towards the anode. The anode surface energy deposition by accelerated electrons is expected to be $\sim 300$ J/g by this time. This is comparable to the absorbed dose of 530-500 J/g required for the observation of anode plasma from a graphite anode in an earlier study of relativistic electron beam diodes. Consequently, the plasma density gradient may result from anode-produced plasma. Alternatively, the observed plasma deflection may result from cathode-produced plasma which has flowed to the anode and stagnated. Upon shorting, the deflection reverses, and after 1 μs, only a slowly-decreasing signal associated with anode-produced neutrals remains. Three microseconds later, plasma deflection signals are again observed.

In Fig. 4(d), we display a signal with the CO$_2$ laser located 1.5 cm from the cathode, for a shot in which a transient arc precedes shorting. A cathode plasma pulse of Fig. 4(a) is observed, but there is no persistent signal from a neutral density gradient. This is consistent with observations that neutral ablation is prevented by voltage crowbarring.

In Fig. 4(e), we display a signal with the CO$_2$ laser located 1.5 cm from the cathode, for a shot in which the diode voltage is crowbarred at 1 μs. A pulse similar to the cathode plasma pulse of Fig. 4(a) is observed, but there is no persistent signal from a neutral density gradient. This is consistent with observations that neutral ablation is prevented by voltage crowbarring.

The data of Figs. 3 and 4 demonstrate the ability of CO$_2$ laser deflection to detect cathode plasma throughout the diode during the operating mode. In conjunction with simultaneous He-Ne deflection observations, the post-

FIG. 4. (Continued).
shorting deflection signals, which include deflection from plasma and neutrals, may be interpreted.

V. DISCUSSION

Deflection of He-Ne and CO$_2$ laser beams by a relativistic electron beam diode allows measurement of plasma and neutral density gradients. The He-Ne laser deflection is primarily a result of neutral density gradients of $(10^{19} - 10^{19})$ cm$^{-4}$. Prior to shorting, neutral density gradients are not observable ($<10^{18}$ cm$^{-4}$). The neutral gradients build up during the first microsecond after the diode shorts, and decay over many microseconds. Near the cathode (anode), the neutral density increases in the direction of the cathode (anode).

The CO$_2$ laser deflection is largely a result of plasma density gradients of $(10^{14} - 10^{15})$ cm$^{-4}$ during the final microsecond preceding diode shorting, and during the subsequent arc. Near the cathode (anode), the plasma density prior to shorting increases in the direction of the cathode (anode). Near the middle of the diode, plasma density increases in the direction of the cathode prior to shorting.

With CO$_2$ laser deflection, plasma density gradients as small as $\sim 1 \times 10^{14}$ cm$^{-4}$ can be observed throughout the diode. Thus, CO$_2$ laser deflection is a promising plasma diagnostic for long-pulse relativistic electron beam diodes. The He-Ne laser deflection provides a diagnostic of neutral density gradients. When CO$_2$ laser deflection is used in conjunction with He-Ne laser deflection, plasma and neutral density gradients may be determined prior to shorting and during the subsequent arc.
