tential of Mg(3s3p P 1), the analogous 1 P 2 MgH 2 surface is likely to be highly ionic and attractive, and will be the entrance channel for the insertive rotational component, but end-on attack could also proceed with some efficiency. Experimental results 13,14 and theoretical calculations 13-15 for the Li(CP)-H 2 and Na(CP)-H 2 systems have also indicated the importance of similarly attractive surfaces with substantial ionic character.

The rotational distributions of MgH(v=0) resulting from the reaction of Mg(1P 1 ) with a whole range of hydrocarbons 16 are virtually identical and are similar to the abstractive branching component of the Mg(1P 1 )-H 2 reaction. Steric hindrance and the absence of strong charge-transfer interactions appear to favor a direct end-on attack of alkyl C-H bonds by Mg(1P 1 ).

Coverage-dependent surface enhanced Raman spectra of halide ions on colloidal silver

Robin L. Garrell, Keith D. Shaw, and Samuel Krimm

Department of Physics and Macromolecular Research Center, The University of Michigan, Ann Arbor, Michigan 48109
(Received 28 July 1981; accepted 13 August 1981)

Surface enhanced Raman spectroscopy (SERS) provides a sensitive method for observing vibrational excitations of molecules that interact with metal surfaces. Theoretical studies of this effect suggest that the observed frequencies and scattered intensities are a function of the extent, density, and homogeneity of surface coverage.1-4 Some experimental studies support these predictions, such as frequency shifts of halide ion bands observed as a function of applied voltage in electrochemical cells3 and coverage-dependent intensity variations seen for pyridine adsorbed on Ag surfaces prepared in ultrahigh vacuum.3 In the case of halide ions, numerous observations5-8 of a band near 240 cm-1 have been interpreted by Nichols and Hexter4 as arising from an Ag-Cl stretching vibration, and they have predicted that this frequency should vary continuously as the surface coverage changes from complete to single atom. Similar predictions were made for the other halide ions.4 We have obtained SERS spectra of Cl-, Br-, and I- as a function of coverage on Ag sols, and find agreement with some of the predictions of Nicholls and Hexter. However, we also find that the observed bands show a definite fine structure, which we believe can be attributed in part to the discrete nature of surface coverage structures.

Our samples were prepared by adding 1-50 μl amounts of 0.1-15.0 mM halogenides to 0.5 ml portions of Ag sols prepared following the procedure of Creighton et al.10 Electron micrographs of this preparation show faceted Ag particles about 300 Å in diameter. Raman spectra were obtained at a bandwidth of ∼1 cm-1 on a spectrometer11 to which data acquisition capabilities (Cromemco Z-6 microcomputer system) had been added. Further experimental details will be given in a subsequent publication.12

The spectra of $\Gamma$ sols [Figs. 1(G) and 1(H)] show analogous but less pronounced effects. The highest frequency maximum occurs at 113 cm$^{-1}$, the same as the calculated (100) full coverage frequency. Fine structure components are seen at lower and higher frequencies: (G) 100, 107, 113, 121; (H) 99, 108, 115, 117, 121, 123.

The theory of Nichols and Hexter$^4$ is based on coupling within a monolayer of vibrating dipoles consisting of real-plus-image charges, and predicts a continuously decreasing frequency with decreasing surface coverage, from the full coverage value to the static field frequency of a single ion (159, 100, and 82 cm$^{-1}$ for $\text{Cl}^-$, $\text{Br}^-$, and $\Gamma^-$, respectively). Our results indeed show a downward frequency shift in the overall band center as coverage decreases, although we are not able to quantitate this dependence. What is even more interesting, however, is that our bands show a fine structure: each observed band appears to be a sum of components whose frequencies are (or nearly are) constant, but whose relative intensities vary, with surface coverage. This result is not unexpected.

In the above theory$^4$ lattice dipole sums at intermediate coverage are obtained by multiplying the full coverage lattice sum by the coverage fraction. In reality the lattice sums vary discretely and are affected primarily by the near-neighbor dipole arrangements: changes in nearest neighbor site occupancy cause large discrete changes in the frequency of a given dipole, while smaller changes about these values result from occupancy variations at more distant sites. Of course, the actual frequencies depend on the value of the full coverage frequency, which is a function of the packing of ions on the particular Ag plane [e.g., (100) or (111)].

Using this model, we have been able$^2$ to calculate the approximate frequency distribution to be expected as a function of coverage fraction. There is good enough general agreement between peaks in these distributions and those in our spectra to suggest that the observed fine structure arises from specific local arrangements of halide ions on the Ag surfaces.

We are indebted to G. W. Ford and W. H. Weber for helpful discussions. This research was supported by National Science Foundation grants DMR 78-00753 and PCM 79-21652, and by the Macromolecular Research Center (R.L.G.).

Spin–orbit coupling and $\Lambda$ doubling in NaAr

David L. Cooper a)

Physical Chemistry Laboratory, South Parks Road, Oxford, England OX1 3QZ

(Received 12 September 1980; accepted 12 November 1980)

The van der Waals molecule NaAr has been extensively studied and a considerable amount of spectroscopic information is available. Smalley et al. have observed $\Lambda$ doubling in the $A^3\Pi$ state of this molecule and have attempted, using a rather crude model, to use calculated potentials to account for the observed splittings. This was rather unsuccessful. In this work, we shall reproduce the magnitude and variation with vibrational quantum number of the $\Lambda$-doublet splittings using a more quantitative model. We shall also calculate $\Lambda$-orbit coupling constants—these are known experimentally but with rather large error limits. Close to its equilibrium geometry, NaAr ($A^3\Pi$) behaves as a good Hund’s case (a) molecule and good ab initio values might be expected. However, the system is more complex (in terms of the number of electrons) than systems previously studied. NaAr thus presents an interesting challenge.

The fluorescence excitation spectrum of the $X^2\Sigma^+$–$A^3\Pi$ optical transition has been measured in a supersonic expansion of sodium in a helium carrier gas containing a few percent argon. The $X^2\Sigma^+$ ground state Na(2Pd) + Ar(4S0) is only weakly attractive and only the $v'' = 0$ to $v'' = 4$ levels are known. The $A^3\Pi$ state is much more strongly bound and transitions to vibrational levels $v'' = 7$ to $v'' = 11$ have been observed. A mainly repulsive $B^2\Sigma^+$ state has been studied indirectly by the $\Lambda$ doubling in the $A^3\Pi_{1/2}$ state. These states both dissociate to Na(2Pd) + Ar(4S0) and are close in energy. (The $A^3\Pi$–$B^2\Sigma^+$ interaction should dominate the contributions due to other $\Sigma^+$ states.)

In the conventional theory of $\Lambda$-doubling in $\Sigma^+$ states, the splitting in the $v$th vibrational level may be expressed to second order in terms of two parameters ($\frac{1}{2}p_0 + q_0$) and $q_v$ where:

\[
p_0 = 4 \sum_{\sigma v} \frac{\langle \frac{1}{2} \Pi v | H_{\text{SO}} | n' v' \rangle \langle n' v' | B(L' S' + L' S') | \frac{1}{2} \Pi v \rangle}{E_{n' v'} - E_{n v}} ,
\]

\[
q_v = 2 \sum_{\sigma v} \frac{\langle \frac{1}{2} \Pi v | B(L' S' + L' S') | n' v' \rangle^2}{E_{n' v'} - E_{n v}} .
\]

The summations are over all vibrational levels of all $\Sigma^+$ states—$k$ is even for $\Sigma^+$ states and odd for $\Sigma^-$ states. The denominator in both expressions is the energy separation between the interacting vibronic levels; $B$ is an operator proportional to $1/\mu R^2$, where $\mu$ is the reduced mass and $R$ is the internuclear distance; $L'$ and $S'$ are the raising operators for orbital and spin angular momenta, respectively; $H_{\text{SO}}$ is the spin–orbit coupling operator.

A method due to Hutson et al. has been previously used for the direct evaluation of the vibrational summations in the expressions for $p$ and $q$. A quantity $|n' \omega')$ may be obtained such that the expressions reduce to:

\[
p_0 = 4 \sum_{\sigma v} (-1)^k \langle \frac{1}{2} \Pi v | H_{\text{SO}} | n' \omega' \rangle ,
\]

\[
q_v = 2 \sum_{\sigma v} (-1)^k \langle \Pi v | B(L' S' + L' S') | n' \omega' \rangle ,
\]
