Contribution of nonhydrodynamic interactions to the concentration dependence of the friction factor of the mutual diffusion coefficient

George D. J. Phillips

Department of Chemistry, The University of Michigan, Ann Arbor, Michigan 48109

(Received 19 September 1980; accepted 31 October 1980)

The mutual diffusion coefficient \( D_m \) of a Brownian particle may be expressed as the ratio of a thermodynamic factor \( K \) and a friction factor \( f_m \). In contrast to our earlier calculation [J. Chem. Phys. 67, 4690 (1977)] in which the direct interaction contribution \( \Delta f_m \) to the Stokes' Law drag coefficient was obtained from a fluctuation-dissipation equation, \( \Delta f_m \) is here obtained directly from a mechanical argument based on the equations of motion of the macromolecules in solution. \( \Delta f_m \) is explicitly evaluated for the case of particles which interact through a weak Gaussian potential.

I. INTRODUCTION

The frictional force \(-f\nu\) on a moving macroparticle has usually been interpreted in terms of hydrodynamic effects, the concentration dependence of the drag coefficient \( f \) being taken to arise entirely from perturbations of the solvent flow around a probe macroparticle due to the other macroparticles in the solution. Direct interparticle interactions then affect \( f \) in a secondary way; by altering the relative likelihood of different configurations of neighboring macroparticles, the direct interactions influence the probability of perturbations of the solvent flow around a probe macroparticle. Some years ago, Mazo\(^1\) showed that direct interactions between diffusing particles also can make an intrinsic contribution to \( f \), as reflected by measured values\(^2\) for the tracer diffusion coefficient of sodiumlauryl sulphate micelles. More recently, this author argued\(^3\) that, in the absence of hydrodynamic interactions, direct interactions should increase the Stokes' law drag coefficient \( f_S \) of a macromolecule in concentrated solution.

The calculations of Refs. 1 and 3 are both based on fluctuation-dissipation type relations which equate a drag coefficient to a time integral over a force-force correlation function. While a relation such as

\[
f = \frac{1}{3K_BT} \int_0^t \langle \mathbf{F}(0) \cdot \mathbf{F}(t) \rangle \, dt \tag{1}
\]

is a convenient starting point for a calculation, Eq. (1) and its usual derivations mask the casual chain leading from the movements of a probe macromolecule through the series of events which reposition the other macromolecules in the system into configurations in which \(-f\nu\) is enhanced. Furthermore, Eq. (1) and the arguments based on it apply directly to the Stokes' law drag coefficient \( f_T \) which is relevant to the tracer diffusion coefficient \( D_T = K_BT/f_T \). For the mutual diffusion coefficient \( D_m \) and its associated drag coefficient \( f_m \), matters are more complex. Indeed, Weissman\(^4\) argues that while the fluctuation-dissipation argument does apply to \( f_T \), a more comprehensive analysis shows that there is not a direct interaction contribution to \( f_m \).

In this paper a novel direct mechanical procedure is used to estimate the effect of direct intermacromolecular interactions on \( f_m \). In Sec. II, we re-examine the case of a macromolecule moving with constant velocity \( \mathbf{v}_0 \), using the new procedure to rederive the central result of Ref. 3. Having demonstrated the procedure in a simple case, we proceed in Sec. III to estimate the (frequency dependent) contribution of direct interactions to \( f_m \). Section IV discusses our results.

II. DIRECT INTERACTIONS AND STOKES' LAW DRAG

Reference 3 obtains a fluctuation-dissipation form for the direct contribution to \( f_m \). Using the prescription (see Appendix)

\[
\int_{-\infty}^{\infty} \mathcal{D}[N] \exp[-(W - A)] - \int_{-\infty}^{\infty} \mathcal{D}[N] \exp[-(W - A)]
\]

\[
\times \exp\left(\sum_{k=1}^{N} \gamma_{k} \exp(-i\mathbf{k} \cdot \mathbf{r}_k)\right),
\]

(2)

(where \( \mathbf{r}_k \) is the location of one of the \( N \) macroparticles in the system, \( W \) is their total potential energy, \( A \) is the Helmholtz free energy, \( \mathcal{D}[N] \) denotes an integral over all particle configurations, \( \langle |\mathbf{a}_k|^2 \rangle \) is the ensemble average of the squared magnitude of the \( k \)th spatial Fourier component of the macroparticle density, and \( \int_{-\infty}^{\infty} \mathcal{D}[N] \) denotes a constrained integral limited to configurations for which

\[
\sum_{k=1}^{N} \exp(i\mathbf{k} \cdot \mathbf{r}_k) = \gamma_0,
\]

(3)

to replace the constrained integral with an unconstrained integral [Eq. (2.9) of Ref. 3] becomes

\[
f(r) = -\frac{K_BTc_0\gamma_0}{(2\pi)^3} \int dq \frac{\langle h(q) \rangle^2}{\langle |\mathbf{a}(0)|^2 \rangle} \langle \mathbf{q} \cdot \mathbf{v}_0 \rangle^2
\]

\[
\times \left\{ \exp\left(-i\mathbf{q} \cdot \mathbf{v}_0 - \Gamma_\mathbf{q} \right) - 1 \right\}/(\langle i\mathbf{q} \cdot \mathbf{v}_0 - \Gamma_\mathbf{q} \rangle)
\]

(4)

where \( g(r) \) is the macroparticle radial distribution function, \( \Gamma_\mathbf{q} \) is the relaxation time for macroparticle density fluctuations of wave vector \( q \), and

\[
\hat{h}^{(3)}(q) = \int \mathcal{D}[r] \exp(i\mathbf{q} \cdot \mathbf{r}) g(r) - 1.
\]

(5)
Using the numerical approximations of Ref. 3, except assuming \( \Gamma_e = K_q g d^2 / \langle a_0 (t) \rangle \), one finds

\[
f = -v_0 a_0 \int \frac{d k}{(2\pi)^3} \left( \hat{b}_0 \cdot k \right)^2 \langle h(k) \rangle^2,
\]

which result was previously obtained in Ref. 3.

Our new argument considers a probe molecule in a suspension of similar particles. Initially \((t = 0)\) the radial distribution of particles around the probe is spherically symmetric. The probe is then brought instantaneously to some (small) velocity \(v_0\). The distribution of particles around the probe attempts to track the motion of the probe. However, because the relaxation time of the suspension is not zero, the particles in the radial distribution function tend to lag behind the probe, their positions being characterized by a distribution function \(g(r; \Delta x, t)\) which expresses the probability of finding a particle at \(r\) relative to the probe given that the probe moved through \(\Delta x\) during the interval \((0, t)\). \(g(r; \Delta x, t)\) is not spherically symmetric; the asymmetry in \(g\) produces a net retarding force on the probe. An argument related to this appears in the classic paper of Onsager and Fuoss; these authors, however, explicitly state that the effect which they treat does not modify the mutual diffusion coefficient. We now estimate \(g\) and compute the drag force which it produces.

Because of its symmetry, the initial \(g_e(x_0)\) for a particle at the origin can be expanded entirely in terms of cosine waves, namely,

\[
g_e(x_0) = 1 + \frac{1}{(2\pi)^3} \int dq h(q) \cos(q \cdot x_0).
\]

In describing the distribution of particles around a probe located at \(\Delta x\), one commonly discusses the symmetric \(g_e(r)\) as the space-fixed coordinate and \(r\) as the particle-fixed coordinate, \(R = r + \Delta x\)

\[
g_e(R) = 1 + \frac{1}{(2\pi)^3} \int dq h(q) \left[ \cos(q \cdot R) \cos(q \cdot \Delta x) + \sin(q \cdot R) \sin(q \cdot \Delta x) \right].
\]

Equation (8) would always be exact if the solution adjusted instantaneously to the changing position of the probe. The behavior of a real system may be described by the expansion

\[
g'(r; \Delta x, t) = 1 + \frac{1}{(2\pi)^3} \int dq \left[ a_q(t) \cos(q \cdot R) + b_q(t) \sin(q \cdot R) \right],
\]

where \(a_q(t)\) and \(b_q(t)\) being implicit functions of \(\Delta x\). For \(g(R)\) around a moving probe, the \(a_q(t)\) and \(b_q(t)\) do not achieve their limiting values \(\langle h(q) \rangle \cos(q \cdot \Delta x)\) and \(\langle h(q) \rangle \sin(q \cdot \Delta x)\).

Their relaxation rates are determined by diffusion; assuming that their regression is adequately described by a linear process, one finds

\[
\frac{da_q(t)}{dt} = -\Gamma_e \langle a_q(t) \rangle - h(q) \cos(q \cdot \Delta x(t))
\]

\[
\frac{db_q(t)}{dt} = -\Gamma_e \langle b_q(t) \rangle - h(q) \sin(q \cdot \Delta x(t)).
\]

If we initially have an equilibrium ensemble of probes, at \(t = 0\), \(a_0(h(q)) = 0\) and \(b_0(h(q)) = 0\);

\[
a_q(t) = h(q) e^{-\Gamma_q t} + \Gamma_e \int_0^t ds e^{-\Gamma_e (t-s)} h(q) \cos(q \cdot \Delta x(s))
\]

\[
b_q(t) = \Gamma_e \int_0^t ds e^{-\Gamma_e (t-s)} h(q) \sin(q \cdot \Delta x(s))
\]

where, when \(\Delta x = 0\), direct probe-particle interactions do not affect the temporal behavior of the \(b_q(t)\). In this case, the probe-solution forces are spherically symmetric, tending equally to increase (or decrease) the concentration at points \(+R\) and \(-R\). However, the \(b_q(t)\) are antisymmetric around the probe; forces having equal effects at \(+R\) change the \(a_q(t)\) but have the wrong symmetry to couple to the \(b_q(t)\). Hydrodynamic interactions between the probe and its neighbors will affect \(\Gamma_e\) in that an Oseen-type interaction will uniformly slow the motion of near neighbors of the probe, regardless of whether the motion is out of a region where \(b_q \sin(q \cdot R)\) is positive or into a region where \(b_q \sin(q \cdot R)\) is negative. If hydrodynamic interactions are ignored and clusters containing more than two particles are unimportant, the relaxation rates of the \(a_q\) and \(b_q\) are the same. If these conditions are not satisfied, \(\Gamma_e\) describes an aspect of the decay of the three-point density correlation function.

Given that the density of particles around the probe is not spherically symmetric, the nonvanishing force on the probe is

\[
(F) = c_0 \int dr g(r; \Delta x, t) \frac{\partial W}{\partial x}.
\]

Using Eqs. (9) and (11) for \(g\), one has

\[
(F) = c_0 \int dr \left[ 1 + \frac{1}{(2\pi)^3} \int dq \left[ \cos(q \cdot R) \right] \right]
\]

\[
\times \left[ \exp(-\Gamma_q t) + \Gamma_e \int_0^t ds \exp(-\Gamma_e (t-s)) h(q) \cos(q \cdot \Delta x(s)) \right]
\]

\[
+ \sin(q \cdot R) \Gamma_e \int_0^t ds e^{-\Gamma_e (t-s)} h(q) \sin(q \cdot \Delta x(s)) \frac{\partial W}{\partial y}.
\]

For a particle moving with constant velocity, \(\Delta x = v_0 s\); for this case the time integrals give

\[
(F) = c_0 \int \left[ 1 + \frac{1}{(2\pi)^3} \int dq \left[ \cos(q \cdot R) \right] \right]
\]

\[
\times \left[ \exp(-\Gamma_q t) + \Gamma_e \left( \Gamma_e \cos(q \cdot v_0 t) + \frac{q \cdot v_0 \sin(q \cdot v_0 t)}{\Gamma_e + (q \cdot v_0)^2} \right) \right]
\]

\[
+ \sin(q \cdot R) \Gamma_e \frac{\Gamma_e \sin(q \cdot v_0 t) + q \cdot v_0 \cos(q \cdot v_0 t) - \Gamma_e \exp(-\Gamma_q t)}{\Gamma_e + (q \cdot v_0)^2} \frac{\partial W}{\partial y}.
\]
Expanding \( q \cdot R \) in terms of \( r \) and \( v_{ij} \), integrating by parts on \( r_j \), applying the approximation

\[
W = -K_B T \langle e^{-\beta W} - 1 \rangle, 
\]

which is obviously valid for \( |\beta W| \ll 1 \), and using spherical symmetry to eliminate terms in \( \sin(q \cdot r) \),

\[
\langle F \rangle = -v_0 \frac{c_d k_B T}{(2\pi)^3} \int dq (\hat{\nu}_0)^2 \frac{[h^{(1)}(q)]^2}{H^2 + (q \cdot \nu_0)^2 + A},
\]

where \( A \) represents terms vanishing exponentially as \( t \to -\infty \). If \( \Gamma^2 \gg (q \cdot \nu_0)^2 \) and \( \Gamma = K_B T q^2/\sigma_0 \), which approximations were also used in Ref. 4,

\[
\frac{1}{N} \lim_{t \to 0} \left( \sum_{i,t} \exp[i(k \cdot r_i(t))] \right) [i \cdot v_{II}(t)]
- \int_0^t ds k \cdot v_{II}(s) k \cdot v_{II}(t),
- 2 \int_0^t ds k \cdot v_{II}(s) k \cdot v_{II}(t) \right). 
\]

This form is the same as Eq. (6), which was, however, obtained by indirect means. The approximations used to obtain Eqs. (6) and (17), such as Eq. (15), do not appear to be identical in all respects.

III. DIRECT INTERACTION AND \( f_m \)

The procedure of Eqs. (7)-(17) is now applied to estimate the effects of direct interactions on the friction factor of the mutual diffusion coefficient. We consider explicitly the behavior of the dynamic structure factor

\[
S(k, t) = \sum_{i=1}^N N! \exp[i(k \cdot r_i(t) - r_i(t))]
\]

at small times, defining

\[
D_m = \frac{1}{k} \lim_{t \to 0} \frac{dS(k, t)}{dt} |S(k, t)|^{-1},
\]

The limit \( t \to 0 \) is interpreted so that \( t \) is always much greater than the Brownian velocity relaxation time \( \tau_B \). The relation of \( D_m \) to the quantity measured in the classical boundary-spreading measurement will not be considered here.

By dividing the velocity of each particle into an interactive part \( v_{II}(t) \) and a Brownian part \( v_{II}(t) \), one obtains to lowest order in time (see Appendix)

\[
\lim_{t \to 0} \frac{dS(k, t)}{dt} = \frac{1}{N} \lim_{t \to 0} \left( \sum_{i=1}^N \exp[i(k \cdot r_i(0))] \right) [i \cdot v_{II}(t)]
- \int_0^t ds k \cdot v_{II}(s) k \cdot v_{II}(t),
- 2 \int_0^t ds k \cdot v_{II}(s) k \cdot v_{II}(t) \right). 
\]

The first line of Eq. (20) will be treated elsewhere; it is found that in the absence of hydrodynamic interactions

\[
\frac{1}{N} \lim_{t \to 0} \left( \sum_{i=1}^N \exp[i(k \cdot r_i(0))] \right) [i \cdot v_{II}(t)]
- \int_0^t ds k \cdot v_{II}(s) k \cdot v_{II}(t) \right) S(k, 0). 
\]

In this section the final term of Eq. (20), viz.,

\[
I = \lim_{t \to 0} \frac{2}{N} \left( \sum_{i=1}^N \exp[i(k \cdot r_i(0))] \right)
\times \left( \int_0^t ds [k \cdot v_{II}(s)][k \cdot v_{II}(t)] \right)
\]

is considered. [A term proportional to \( k \cdot v_{II}(s) k \cdot v_{II}(t) \) is of second order in \( t \) and will be neglected here.]

The force on a probe is again obtained from Eq. (13); however, in this section \( \Delta x(t) \) is assumed to arise from the random motions of the probe. The average \( \langle \cdot \rangle \) then includes an average over all possible paths \( \Delta x(t) \). Replacing \( R = \Delta x(t) + r \) and integrating by parts on \( r \), Eq. (13) becomes

\[
F(t) = \int dr \, dq \, k_B T h(q) \cos(q \cdot r) \left[ \sin(q \cdot \Delta x) \right] \left( \exp(\Lambda \Lambda \cdot \Delta x) + \sum_{i=1}^N \exp[i(k \cdot r_i(t))] \right)
\times \left( \int_0^t ds \exp[-\Lambda \Lambda \cdot \Delta x] \sin(q \cdot \Delta x) \right). 
\]

\( r \), being measured from the moving probe, is implicitly time dependent; terms in \( \sin(q \cdot r) \) are eliminated by spherical symmetry in \( r \). To proceed further, the approximation (15) is applied. Substitution of Eqs. (15) and (23) into Eq. (22) gives

\[
I = \lim_{t \to 0} \frac{2}{N} \left( \sum_{i=1}^N \exp[i(k \cdot r_i(0))] \right)
\times \left( \sum_{i=1}^N \exp[i(k \cdot r_i(0))] \right)
\times \left( \int_0^t ds \exp[-\Lambda \Lambda \cdot \Delta x] \sin(q \cdot \Delta x) \right),
\]

Equation (24) appears to be the simplest general form for \( f \) for weak potentials. To effect a significant further reduction in Eq. (24), an explicit expression for \( h(q) \) is needed. For particles with purely weak interactions, we use the Gaussian form

\[
h(q) = B_0 q_0^3 \exp(-q^2 q_0^2), 
\]

\[
g(r) = 1 + \frac{B_0 \exp(-r^2/4r_0^2)}{8r_0^3 r^2},
\]
where $r_0$ and $B_0$ determine the range and strength of the potential, respectively. From Eqs. (24) and (26b), $W(0) = -K_BT B_0/(8\pi r_0^2)$. Combining (26a) and (24), performing the angular part of $\int dq$, making an integration by parts on $|q|$ and replacing $r_0 \rightarrow 2r_0$, where $\Delta x = \Delta x(s) - \Delta x(t)$ and $\cdot$ indicates a unit vector. The integral on $q$ gives a confluent hypergeometric function. From Luke [Eq. 4.2(2)]

$$F_1(\alpha, \nu+1, -\lambda^2/4z^2) = \frac{(\nu+1)!e^{-(\lambda^2/4z^2)}}{\Gamma(\nu+1)\lambda^{2\nu}} - \int_0^\infty du \exp(-\lambda^2 u)u^{\nu-1}J_\nu(\lambda u).$$

(28)

Noting $\sin x = (\pi x/2)^{1/2} J_{1/2}(x)$, and

$$F_1(\alpha; \beta; x) = \sum_{n=0}^\infty \frac{(\alpha)^n}{n!} \frac{x^n}{\beta^n},$$

(29)

where

$$\int_0^\infty \exp(-z u^2)u sin(\lambda u)du = \frac{\sqrt{\pi/2}}{2z^{3/2}} \exp(-\lambda^2/4z^2),$$

(30a)

$$\int_0^\infty \exp(-z u^2)u^3 \sin(\lambda u)du = \frac{\sqrt{\pi}}{16z^3} (6z^2 - \lambda^2) \exp(-\lambda^2/4z^2),$$

(30b)

$$\int_0^\infty \exp(-z u^2)u^3 \sin(\lambda u)du = \frac{15\sqrt{\pi}}{16z^4} \left\{ \exp(-\lambda^2/4z^2) \left[ 1 - \frac{4\lambda^2}{3z^2} + \frac{4}{15} \left( \frac{\lambda^2}{4z^2} \right)^3 \right] \right\},$$

(30c)

If the potential $W$ is weak, the Brownian displacement during the period $(0, t)$ will be given in first approximation by its unperturbed form

$$P(\Delta x(s) - \Delta x(t)) = [4\pi D_0(t-s)]^{3/2} \exp\left[ \frac{(\Delta x(s) - \Delta x(t))^2}{4D_0(t-s)} \right].$$

(31)

Equation (31) allows evaluation of the average over displacements, the reduction

$$\langle (\Delta x(t)^2 - (\Delta x(s) - \Delta x(t))^2) \rangle = -4(\Delta x(s) - \Delta x(t))^2$$

being used as needed. At this point the integration over $s$ is elementary.

$$I = \frac{D_0^2 C_0 R_0^2}{24\sqrt{2\pi}^3} \left\{ -4y^{-1/2} + \frac{1}{3} y^{-3/2} + \left( x + \frac{8}{9} b \right) y^{-5/2} \right\},$$

(32)

where $x = D_0/y_0^2$ and $y = 1 + x$.

In the limit $t \rightarrow \infty$,

$$I = \frac{0.3917}{24\sqrt{2}} D_0^2 \psi(\beta - 1) \frac{\phi_\pi \rho_0 V(\beta(0) - 1)}{24\sqrt{2}}.$$

(33)

where $\psi = C_0 V$ is the thermodynamic volume fraction of particles in the system, the "volume" $V$ of a Gaussian particle being defined:

$$V = \int dr (g(r) - 1) = 4|B_0| r_0^2.$$

(34)

From Eqs. (19)-(21) and (33) the cross correlation between $V_B(t)$ and $\psi_\beta(s)$ serves to retard the decay of $S(k, t)$.

Combining these equations, for weak Gaussian particles,

$$D_n = \frac{K_BT}{S(k, 0)} \left[ 1 - \phi_n - \frac{0.3917}{24\sqrt{2}} \phi_\pi \rho_0 V(\beta(0) - 1) \right],$$

(35)

$\phi_n$ being the hydrodynamic volume fraction of the solute.

If $D_m$ is expressed formally as a ratio of thermodynamic, hydrodynamic, and kinematic factors as

$$D_m = \frac{K_BT}{S(k, 0)} \int f(1 - \phi_n),$$

(36)

to first order in concentration one may write

$$\int_0^1 f \left[ 1 - \frac{0.3917}{24\sqrt{2}} \phi_\pi \rho_0 V(\beta(0) - 1) \right].$$

(37)

Direct interactions therefore do serve to increase the effective drag coefficient in the mutual diffusion coefficient.

For weakly interacting particles, this effect is not large. Equations (17) and (26a) give the change in the Stokes’ law drag coefficient $f_s$ for our model potential as

$$f_s = \frac{[1 + \phi_\pi \rho_0 V(\beta(0) - 1)]}{24\sqrt{2}}$$

(38)

or

$$\frac{f_s - f}{f} = 0.39 + 0(\phi^2).$$

(39)

Direct interactions between diffusing particles are moderately less effective at hindering diffusion than at hindering very slow steady motion, at least in this system.

There is a classical argument, due originally to Einstein, that in the solvent-fixed reference frame $f_m$ should be identically the same as $f_s$. This argument is now understood to apply only as a low-temperature, low-frequency (i.e., $t \rightarrow \infty$) limit, in which the fluctuating forces relax in a time $\tau$ much shorter than the time $t$ of interest for diffusion. In the present case, the motion of the probe particle and the relaxation of the force fluctuations are governed by the same diffusion coeffi-

cient \( D_k \); requiring \( t \gg \tau \) is effectively the same as requiring \( D_k \ll D_{sk} \), which is an absurdity. In other words, if encounters between diffusing macroparticles are taken into account, the low-frequency limit, needed if \( f_m = f_s \) is to obtain, does not exist.

Weissman \(^4\) has suggested that direct interactions do not contribute to \( f_m \). This argument is based on the assertion that the molecular mean potential (expressed as the chemical potential \( \mu \)) "depends on no variables which do not equilibrate rapidly with \( c \)." However, it means at a rate faster than \( D_k b^3 \ldots \) Our result, however, is that the intermolecular forces contain terms (variables) which relax at rates which are not faster than \( D_k b^3 \), namely, there are terms which relax as \( D_k b^3 \) for \( q \leq k \). Weissman's ingenious argument would therefore appear to fail because its underlying assumptions do not apply to the systems of interest here.

Schurr \(^5\) has previously obtained a result related to that of this paper. Using the Kirkwood form \(^6\) for the drag coefficient, he demonstrated that fluctuating electrolyte-small ion interactions substantially enhance the friction factors of isolated, diffusing polyelectrolytes.

APPENDIX: DEMONSTRATION OF Eqs. (2) AND (20)

This Appendix summarizes the justifications for the use of Eqs. (2) and (20), as will eventually be presented in full detail in Ref. 6.

The purpose of the prescription (2) is to replace a constrained integral, in which the integration is held to the \((3N-1)\)-dimensional hypersurface determined by Eq. (3), to an unconstrained integral over a \(3N\)-dimensional space. In the unconstrained integral, the effect of the constraint is to be supplied by an additional factor in the kernel of the integral [the exponential on the right-hand side of Eq. (2)]. The justification for (2) is that it is the simplest substitution which gives the correct answer when applied to the constrained integrals:

\[
\int_{m_0} d[N] \exp[-\beta(W-A)] \left[ \sum_{i=1}^N \exp[ik \cdot r_i] \right]^n = a_s^n, \quad (A1)
\]

\[
\int_{m_0} d[N] \sum_{i=1}^N \exp[iq \cdot r_i] \exp[-\beta(W-A)] = 0 \quad \text{for} \quad k \neq q, \quad (A2)
\]

\[
\int_{m_0} d[N] \exp[-\beta(W-A)] \sum_{i,t} \exp[iq \cdot (r_i - r_t)] = Ns(q) \quad \text{for} \quad k \neq q. \quad (A3)
\]

(A1) follows from the definition of \( m_0 \), while (A2) and (A3) are required by the statistical independence of \( a_s \) and \( a_q \) for \( k \neq q \). Equation (2) loses many mode-mode coupling effects, which are neglected consistently throughout this paper.

A previous paper of this author \(^3\) replaces the exponential with the product form

\[
\int d[N] \exp[-\beta(W-A)] \prod_{i=1}^N \left[ 1 + a_{mk} \exp[-i(k \cdot r_i)] \right], \quad (A4)
\]

which lacks the self-terms \( \exp[i(k \cdot (r_i + r_t))] \) needed to satisfy Eq. (A1) for \( n > 1 \). The normalizing factor \( \langle a_s^2 \rangle \) in (2) has a physical interpretation, beyond the need for its presence in order to satisfy (A1). \( a_q(0) \) may be increased either by changing the relative positions of the particles within clusters of nearby particles. The smaller \( \langle |a_q|^2 \rangle \), the harder it is to distort a cluster; as \( \langle |a_q|^2 \rangle \) becomes smaller, a given value of \( a_q(0) \) corresponds more and more to the re-location of noninteracting particles.

Equation (20) is obtained from Eqs. (18) and (19) by first expanding (18) in terms of the displacements

\[
r_i(t) - r_i(0) = \int_0^t f_i(s) ds, \quad (A5)
\]

and then decomposing \( f_i(s) \) into its Brownian and interactive parts \( f_{Bi}(s) \) and \( f_{Ii}(s) \) obtaining

\[
S(k, t) = N^{-1} \sum_{t, s, i} \exp[i(k \cdot r_i(0) - r_i(0))] \int \frac{[i(k \cdot r_i(s) + r_i(s))] ds^2}{n}. \quad (A6)
\]

One notes that

\[
\langle k \cdot v_{Bi}(s) \rangle = 0,
\]

\[
\left\langle \int_0^t ds_1 \int_0^t ds_2 r_i(s_1) r_i(s_2) \right\rangle = 2Dk^2 t,
\]

and

\[
v_{Ii}(t) = f_i(t)/f_i,
\]

where \( f_i \) and \( f_i(t) \) are the force on \( i \) and the drag coefficient of \( i \), respectively. Taking \( \lim_{t \to 0} \int d(k, t)/dt \) and observing that all terms containing two or more factors \( f_i^{(0)} ds \) vanish at \( t = 0 \), a term-by-term expansion of the nonzero part of Eq. (A6) yields Eq. (20).
