| 16. Abstract<br><br>A review of the literature on the role of vehicle handling in accident causation shows that there has been much conjecture regarding the link between vehicle handling and accidents. Little of a defensible nature is apparent other than vehicle size seems to correlate with accident experience. An examination of available mass accident data also shows this apparent size effect as well as some correlations between (1) vehicle track width and rollover accidents, (2) driver age and size of car, (3) size of car and accidents on curves, and (4) driver age and accidents on curves.<br><br>For purposes of the present study, hypotheses were developed linking vehicle handling characteristics to accident descriptors. Careful consideration is then given towards developing a statistical analysis method that would serve to support or negate such hypotheses and which would further define the amount of data required to support a given hypothesis. Implementation of the methodology to investigate the role of vehicle handling, as proposed, requires that four kinds of data be collected: exposure-to-risk data, accident data, vehicle handling descriptors, and "image risk" data. The requirement for each of these data categories is discussed at length. In addition to defining an accident data collection and analysis methodology, efforts were also devoted towards advancing the present state of the art in reconstructing the pre-crash phase of accidents and towards outlining a deterministic analysis procedure for relating vehicle handling performance directly to accident avoidance performance. The conclusions emphasize the formidable and costly nature of implementing the proposed methodology, but point up that by dovetailing efforts with other areas (of concern to accident causation analysis) agencies could substantially increase the benefit/cost ratio of follow-on research and implementation. |  |  |   |   |           |

## APPENDIX B

### ANALYSIS OF MASS ACCIDENT DATA FOR VEHICLE HANDLING CAUSATIVE FACTORS

This appendix consists of the detailed tables and figures from whence the broad conclusions in Section 5 were derived. The discussions are of mass accident data from King County (Seattle), Washington and from the State of Texas. Each set of accidents is from 1973 with the data from Texas representing a 5% sample of all the accidents from Texas during that year. Further, each data set was filtered to include only passenger cars, unimpaired drivers, and wet or dry surfaces. The data from King County were further restricted to contain only vehicles involved in single-vehicle accidents, or the striking vehicle in multi-vehicle accidents. The data from Texas consisted only of vehicles involved in single-vehicle accidents.

The specific findings from each of these investigations are discussed next.

#### B.1 King County (Seattle), Washington Accident Data

Bivariate tables of vehicle types versus several conjectured accident variables were constructed for the King County filtered data set. Two vehicle type variables were used. The vehicle make/model categories are shown in Table B.1, and the vehicle body type categories in Table B.2. Classifications of make/models into body types are given in Table B.3. These two variables were then separately coupled with several other variables to determine their joint influences on the accident record. A listing of the tables that were constructed and an assessment of the utility of the derived information is given in Table B.4.

In addition to the vehicle type variables, some other combinations of variables were also examined, independent of vehicle type. A listing of the tables constructed for these ancillary variables is given in Table B.5. In the subsections that follow, each of the variables which were coupled with the vehicle type variables are discussed separately. The ancillary variables are discussed next. The bulk of the raw tables constructed in the study are not included but can be made available to those interested.

B.1.1 Vehicle Type Variables. The two vehicle type variables are Vehicle Make/Model and Vehicle Body Type. The joint influence of these variables on the accident record is discussed as follows:

#### Character of Road

The vehicle body type categories ranked in terms of highest and lowest involvements on curved sections of road are shown in Table B.6. (Make/Model involvements on curves are given in Table 5.2 of Section 5.) It is evident that those vehicles having the highest incidence of accidents on curves are the sporty and sub-compact body types. The least involved vehicles are generally in the luxury model class. These findings suggest that either smaller and sporty vehicles and/or people who drive smaller and sporty vehicles are more apt to be involved in accidents on curved sections of road.

#### Road Surface

The body type categories ranked in terms of highest and lowest involvements on wet surfaces are shown on Table B.7. Similar data for specific Make/Model categories are given on Table 5.6 of Section 5. The data do not show any consistent trends in either Body Type or Make/Model. Specific vehicle make/models vary by as much as 1/3 more or less than the mean of 36% involvement in wet accidents. None, however, with more than 100 accident cases varies by more than 1/4 from the mean. While the most involved

$$\% = \frac{(100) \text{ Accidents on Wet Surfaces for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

vehicle types are the European sport cars and specialty/pony types, the least involved are the super sport class. These findings do not presently suggest any clear trends toward vehicles which are more heavily involved in wet-surface accidents.

#### Type of Accident

Forty-four types of accidents are classified in the King County data file. Of these, four types seem to have some relevance to vehicle handling properties: overturning, rear-end, sideswipe, and turning collision accidents.

Overturning accidents are the most recognizable accident type that are associated with vehicle size, or more specifically, track width. The overturning potential of a vehicle is directly related to the ratio of its center-of-gravity height to track width. Since the center of gravity cannot be made any lower than ground clearance and passenger packaging dictates, the major factor which practically determines overturning potential is the track width. In the data shown on Table B.8, the body type categories are ranked in terms of highest and lowest involvements in overturning accidents. Data for specific Make/Model categories are given in Table 5.9 of Section 5. It is immediately evident from Table B.8 that the vehicles showing the highest frequency of rollover accidents are the smaller types, i.e., the ones with the narrowest track width. The implications with respect to specific values of track width and specific makes and models are discussed in Section 5.

Rear-end accidents should provide some idea of the braking performance of specific vehicles. The data for rear-end collisions in the filtered sample for the Seattle data are for vehicles which are the striking vehicle in two- or more-vehicle collisions. Thus, braking performance differences should appear.

Make/model and body type vehicle categories are ranked in terms of highest and lowest involvements in rear-end accidents on Tables B.9 and B.10, respectively. The two most heavily

| Super Sport         | 16.0 (50)                |
| Total % Involvement | 32.6 (9,523)             |

$$\% = \frac{(100) \text{ Rear-End Accidents for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

involved models are the AMC Gremlin and the AMC Ambassador—albeit each has a low number of total accident involvements. Except for these two, the accident frequencies for the "Most Involved" vehicles are not greatly higher than the rear-end involvement frequency of 32.6% for the total sample. Some of the "Least Involved" vehicles have frequencies substantially less than the total sample; however, the Maverick has a rear-end involvement percentage of almost one-third less than that of the total sample.

Sideswipe and turning collision accident frequencies could indicate the presence (or lack thereof) of side visibility problems in driving a vehicle. Make/model and body type vehicle categories are ranked in terms of highest and lowest involvement frequencies on Tables B.11 and B.12, respectively, for sideswipe accidents and on Tables B.13 and B.14, respectively, for turning collision accidents. In the "Most Involved" class, the Oldsmobile 88; Ford Capri; and Cadillac Calais, DeVille, Brougham show higher than total sample frequencies in both turning collision and sideswipe accidents. There are no common make/models in the "Least Involved" category.

In the body type categories, the least involved vehicles are super sport and European sports car types. In general, however, the findings are mixed. No definite conclusions are apparent.

#### Vehicle Mix

The "Vehicle Mix" variable refers to the mix of vehicles, objects, pedestrians, etc., that were involved in the collision accident. At this writing, there seems to be little that can be determined from this variable relative to vehicle handling.

#### Vehicle Body Type - Vehicle Style

The "Vehicle Body Type" classifications are given on Table B.2. The relationship between these and Vehicle Make/Model classifications is shown on Table B.3. It should be kept in mind that these classifications were determined by General Motors Corporation as part of their original work in developing the

| Total % Involvement | 6.2 (9,523)               |

$$\% = \frac{(100) \text{ Turning Collision Accidents for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

Collision Performance and Injury Report (CPIR) form. The classifications may not be the best for vehicle handling studies. In future work, it seems evident that more refined classes of vehicles will have to be developed.

The distribution of accident frequencies of make/model classes as a function of body style is not shown here due to the bulkiness of the table. An indication of the variability of body types within a given make/model classification can be obtained from Table B.15. This table shows the highest and lowest percentages of accidents involving station wagons among the listed make/models. It is evident that some make/model classes are more homogeneous than others. Again, the need for more refined classes of vehicles is apparent.

#### Contributing Actions

Actions contributing to an accident are divided into Miscellaneous Actions and Major Contributing Actions in the Seattle data file. Among the miscellaneous actions, skidding accidents provide the most information with respect to vehicle handling considerations. The highest and lowest percentages of skidding accidents for the make/model and body type variables are shown on Tables B.16 and B.17, respectively. It is evident that the super sport and sub-compact/mini type vehicles are the most involved in skidding accidents, while the least involved are the intermediate and luxury models. An exception in the least involved category is the Vega.

Major contributing actions include speeding, following too close, failure to yield, and inattention. The highest and lowest percentages of accidents involving speeding for make/model and body type categories are shown on Tables B.18 and B.19, respectively. Not unexpectedly, the highest involvement in speeding accidents are among the super sport, European sports car, and specialty/pony classes. Somewhat of a surprise, however, is that the leading make/model in speeding accidents is the VW Beetle. Further, it

$$\% = \frac{(100) \text{ Speeding Accidents for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

is interesting to note that four of the make/models most involved in skidding accidents are also most involved in speeding accidents—VW Beetle, Firebird, Camaro, and Opel. The least involved vehicles in speeding accidents are the luxury models.

The trends in following-too-close accidents are not clear. Tables for the most and least involved make/models and body types are given on Tables B.20 and B.21, respectively. It is evident that the over-involved body types are not much more involved than the mean involvement, and that the specific over-involved make/model types represent a mixture of vehicle classes.

Failure-to-yield and inattention accidents are the most common accidents with luxury vehicles. The most and least involved make/models and body types for failure-to-yield accidents are given on Tables B.22 and B.23, respectively. Similar data for inattention accidents are given on Tables B.24 and B.25. One might speculate that a soft ride quality could be a factor in both inattention and failure-to-yield accidents. On the other hand, since luxury vehicles are least involved in speeding and following-too-close accidents, it is necessary that the kind of accidents such vehicles are involved in show up more heavily in other areas. (Again, the percentages shown are based on the total number of accidents of a particular vehicle or class. Thus, if 10% of a vehicle's accidents involve speeding, the other 90% must be allocated to other kinds of accidents. The percentages given, therefore, do not give an absolute picture as to how the accident experience of a particular vehicle compares with other vehicles. Rather, the picture is that of the distribution of the accidents within a particular vehicle class. All manner of exposure data would be required to arrive at specific conclusions regarding the absolute accident experience of a particular vehicle. Specific conclusions about the lulling qualities of a soft ride toward precipitating inattention and failure-to-yield accidents should, therefore, be held in abeyance.)

Table B.20. Percent Following-Too-Close Accidents

Vehicle Make/Model

| <u>Make/Model</u>                  | <u>% Involvement (N)</u> |
|------------------------------------|--------------------------|

### Number of Occupants

The number of occupants in a vehicle can affect both the handling qualities of the vehicle and the attention level of the driver. The highest and lowest percentages of accidents with just one occupant in the vehicle (the driver) are shown on Tables B.26 and B.27, respectively, for make/model and body type classifications. Vehicles having the most accidents with just one occupant are comprised of a mixture of luxury and sub-compact vehicles. Vehicles having the least accident frequencies with just one occupant (i.e., vehicles most frequently involved in accidents with more than one occupant) are the convertible and super sport classes. Significantly, the one vehicle having the lowest frequency of accidents with just one occupant, or the highest frequency with more than one occupant, is the VW Beetle. This finding might suggest a load-related handling problem with the VW. Later findings will show, however, that the VW is primarily driven by younger students and skilled workers in the Seattle area, so that the load-related factors seemingly apparent here must be tempered with exposure considerations (e.g., as a matter of course, is the VW Beetle more frequently driven with more than one occupant in the vehicle than are other vehicles in the Seattle area?). Somewhat surprising (although perhaps not completely unexpected) is the finding that luxury models and station wagons—relatively larger vehicles—are some of the most involved vehicles in accidents with just one occupant.

### Residence Proximity

Conceivably, residence proximity has a bearing on accident causation through the familiarity of the driver with the local roads. Make/model and body type classes for the most and least involved vehicles in accidents within 15 miles of the driver's residence are given on Tables B.28 and B.29, respectively. The findings in terms of specific make/model classes show a maximum

Table B.26. Percent Accidents With Just One Occupant.

| Vehicle Make/Model                    |                          |

$$\% = \frac{(100) \text{ Accidents Within 15 Miles of Residence for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

of 98% involvement in accidents within 15 miles of the residence for the AMC Classic, Rebel, Matador class and a minimum of 80% for the Buick Riviera. When looking at body type classes, however, the maximum involvement is 90.9% for both sub-compacts and intermediates; the minimum involvement is 86.4% for personal luxury vehicles; while the involvement frequency for the total sample is 89.1%. Obviously, the differences from the mean are not great. It is, therefore, difficult to establish any correlation between residence proximity and vehicle classes in accident causation. With exposure data, these conclusions may change.

### Driver Occupation

In sorting out the role of vehicle handling in accident causation, a major question that must be answered concerns whether it is the vehicle that causes the accident or the driver who chooses and drives the vehicle. Driver sex, age, and occupation are three of the factors that have been traditionally examined in attempting to answer this question. Driver occupation is discussed here, with sex and age being discussed in the following sections.

Make/model and body type classes for the most and least involved vehicles in accidents with professional people as drivers are given on Tables B.30 and B.31, respectively. Such drivers are most involved in accidents with luxury sedans and super sport classes and least involved with specialty/pony and sub-compacts. The least involved types are not greatly less than the involvement of the total sample, while the most involved types approach almost twice the involvement frequency of the total sample.

Similar rankings for clerical and sales people are shown on Tables B.32 and B.33. These people are more apt to be involved in accidents with sub-compact, sub-compact/mini, and super sport classes of vehicles. The least involvements are with standard and luxury models. Note, however, that the involvement of sub-compact vehicles for this class of drivers is over 50% higher than that of the total sample, while the least involved vehicle types are not

$$\% = \frac{(100)\text{Accidents With Clerical and Sales People as Drivers for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

appreciably below the total sample frequency. Thus, the preponderance of accidents with sub-compact vehicles is substantially above the other classes of vehicles. (Note also that the number of cases is high, which lends further credence to this finding.)

Least and most involved vehicle rankings for skilled and semi-skilled workers are shown on Tables B.34 and B.35. These people experience almost twice the frequency of the total sample of accidents in super sport type vehicles. Experience in other classes of vehicles is not substantially different from the total sample. It is noteworthy that the highest involvement in accidents for a specific make/model (nearly twice the total sample involvement) is with the VW Beetle.

Rankings for accidents involving housewives and domestics as drivers are shown on Tables B.36 and B.37. It is clearly evident that such drivers are primarily involved in accidents with luxury model vehicles and least involved with the sporty vehicles. There is a suspicion that in two-car families, one car is often a larger luxury model or station wagon which is used for family transportation, while the other is a smaller vehicle used for single-occupant commuting. With children in school and the husband away at work, the larger vehicle is used by the housewives in mid-day transportation. This scenario could account for the indicated accident experience. Exposure data is necessary to confirm such speculations, however.

Vehicles involved least and most in accidents with students and children as drivers are ranked on Tables B.38 and B.39. There is also clear evidence here that the most involved vehicles are the European sports car and sub-compact/mini types. Luxury and muscle car classes are the least involved. As with skilled and semi-skilled workers, the accident involvement frequency for the VW Beetle is almost twice the total sample frequency for student and child drivers.

Table B.34. Percent Accidents with Skilled or Semi-Skilled Workers as Drivers.

$$\% = \frac{(100)\text{Accidents With Students and Children as Drivers for a Given Make/Model}}{\text{Total Accidents for a Given Make/Model}}$$

Table B.39. Percent Accidents With Students and Children as Drivers

Vehicle Body Type

| <u>Type</u>         | <u>% Involvement (N)</u> |
|---------------------|--------------------------|
| European Sports Car | 27.3 (132)               |
| Sub-Compact/Mini    | 22.6 (265)               |
| Specialty/Pony      | 18.8 (718)               |
| Compact             | 18.3 (1,158)             |
| Intermediate        | 17.0 (1,416)             |
| Sub-Compact         | 15.3 (386)               |
| Standard/Full Size  | 15.0 (2,337)             |
| Luxury Sedan        | 10.2 (177)               |
| Super Sport         | 8.0 (50)                 |
| Personal Luxury     | 6.2 (192)                |
| Total % Involvement | 15.7 (9,523)             |

$$\% = \frac{(100)\text{Accidents With Students and Children as Drivers for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

In summary, the highest involved vehicle types by occupation are listed as follows:

|                              |   |
|------------------------------|---|
| Professional                 | Luxury Sedan<br>Super Sport             |
| Clerical/Sales               | Sub-Compact<br>Super Sport              |
| Skilled/Semi-Skilled Workers | Super Sport<br>Luxury Sedan             |
| Housewives/Domestics         | Luxury Sedan<br>Personal Luxury         |
| Students/Children            | European Sports Car<br>Sub-Compact/Mini |

Some caution should be used in interpreting these results in that the accident involvement frequencies may also correlate highly with vehicle selection and usage patterns. Specific conclusions about vehicle handling factors in accident causation can be most readily obtained when accident and usage experience do not correlate.

#### Driver Sex

There has been much written over the years concerning the different accident patterns among males and females in the driving population. Until a few years ago, the female had definitely been considered to be the safer driver; this conclusion was based on recorded accident frequencies. With the recent acquisition of driver exposure data—albeit limited—a pattern seems to be emerging that suggests fewer differences between the sexes than had been originally thought [127]. Among younger drivers, the female seems to be slightly superior. In middle and older ages, however, the male seems to be slightly superior. Further, it appears that the differences are minor if comparisons are made between male and female drivers who have similar mileage exposure.

Rankings of most involved and least involved vehicle classes with males as drivers are shown on Tables B.40 and B.41. Although it is obvious that certain vehicles experience a high frequency of accidents with male drivers, few clear patterns are apparent, the main exception being the over-involvement of male drivers in the super sport class of vehicles. At the other extreme, male drivers are least involved (or conversely, female drivers are most involved) with sub-compact vehicles. The difference between accident frequencies with the sub-compact (60.7%) and the involvement frequency for the total sample (64.7%) is not great, however.

### Driver Age

It is well known that the frequency of accidents for young drivers is the highest for any age segment of the driving population. The lowest accident frequencies occur for drivers in middle age brackets. Accident frequencies are also high for older drivers, but not as high as for younger drivers.

With the expanding population, it is generally true that the number of drivers in a given age bracket decreases with increasing age. That is, there are more drivers between ages 20-24 than there are between ages 50-54. Further, drivers who are killed at a younger age are not part of the driving population in older brackets, and hence there is a trend toward safe drivers in the older age brackets through natural selection. All these factors, and more, must be weighed in determining the influence of driver age on accident experience. For example, if there are more drivers in the younger age brackets, then the accident frequencies of drivers in these brackets must be weighted accordingly so as not to distort the results.

A most important consideration in determining the role of vehicle handling in accident causation relates to the make-up of the driving population which chooses to use particular vehicles. If European sports cars have the highest accident experience and younger drivers most frequently drive European sports cars, it is not immediately clear whether the sports car or the younger driver is at fault, or perhaps some combination.

Table B.40. Percent Accidents With Male Drivers

Table B.44. Mean Driver Age Rankings of Accident Involved  
Vehicle Body Types

| <u>Type</u>         | <u>Mean Driver Age</u> |
|---------------------|------------------------|
| European Sports Car | 24.6                   |
| Specialty/Pony      | 26.3                   |
| Sub-Compact         | 26.5                   |
| Sub-Compact/Mini    | 27.4                   |
| Super Sport         | 29.0                   |
| Intermediate        | 32.1                   |
| Compact             | 32.2                   |
| Standard/Full Size  | 34.8                   |
| Personal Luxury     | 37.3                   |
| Luxury Sedan        | 41.2                   |
| Mean Age            | 32.2                   |

In summary, then, there is a general pattern of higher frequencies of accidents at younger ages which tapers off to a relatively stable level after age 30. For some classes of vehicles, namely, specialty/pony, super sport, sub-compact, sub-compact/mini, and European sports cars, there is a relative over-involvement of accidents with younger drivers. For others, such as the personal luxury and luxury sedan classes, there is a relative under-involvement. The question which remains to be answered is whether the drivers or the vehicles are the most culpable factor. Answering this question will require a knowledge of the distribution of ages in the driving population in general and for specific vehicle classes in particular.

#### Seat Belt Usage—Driver

Seat belt usage in the context of vehicle handling was examined because of the speculation that belt usage is an indicator of driver attitudes toward safety, and because it has been conjectured that the stabilizing influence of a seat belt may cause a driver to execute more severe maneuvers (e.g., tighter cornering) than would ordinarily be the case.

The percent usage of seat belts for make/model and body type classes most and least involved in accidents are given on Tables B.45 and B.46, respectively. Indications from the body type classifications are that drivers of smaller vehicles are more likely to be wearing seat belts when involved in accidents than are drivers of larger vehicles. An outstanding exception is the VW Beetle where the usage of seat belts by drivers involved in accidents is less than one-half the average. The question of whether a seat belt stabilizes a driver during a maneuver is treated more specifically in the next section where seat belt usage and accident frequency on curves is examined.

Table B.45 . Percent Seat Belt Usage

Vehicle Make/Model

| Total % Involvement | 26.3                     | (9,523) |

$$\% = \frac{(100)\text{Accidents Where Driver Used Seat Belts for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

B.1.2 Ancillary Variables. In addition to the vehicle type variables, the filtered data sample for handling-related accidents was also analyzed for several other variables, independent of vehicle type. A typical example would be the frequency of accidents on curved sections of road as a function of driver occupation. In addition, some tri-variate cases were examined. One of these was concerned with the incidence of accidents on curves for specific combinations of driver occupation and vehicle body type. The combinations of variables which are described next were listed earlier on Table B-5.

#### Character of Road

The variation of accident frequencies on straight or curved sections of road (Character of Road) were examined in relation to number of vehicle occupants, driver occupation, driver sex, driver age, and seat belt usage.

Table B-47 shows that the frequency of accidents on curved sections of road increases with the number of vehicle occupants. The frequency of accidents with three or four occupants in the vehicle is almost twice that with just one occupant in the vehicle. This finding could either suggest that (1) the driver is less efficient (e.g., distracted) when other passengers are in the vehicle or (2) vehicles with more than one occupant handle less effectively on curves. The latter hypothesis was investigated more thoroughly by examining the prevalence of accidents on curves for specific vehicle make/models and vehicle body types. The results, ranked in terms of most and least involved are given on Tables B.48 and B.49, respectively. It is immediately obvious from these tables that the sub-compact and sporty-type vehicles are the most heavily involved in these kinds of accidents. There seems a good likelihood, then, that accidents occur more frequently on curves when certain types of cars are heavily loaded. As indicated here, the smaller vehicles may be more susceptible to overloading since the occupants in a smaller vehicle represent a greater percentage of the total vehicle weight.

Table B.47. Accidents on Curved and Straight Sections of Road Versus Number of Vehicle Occupants.

| No. Occupants | Character of Road |     |        |    | Total (Including Unknown) |
|---------------|-------------------|-----|--------|----|---------------------------|
|               | Straight          |     | Curved |    |                           |
|               | #                 | %   | #      | %  |                           |
| 1             | 6,765             | 88  | 915    | 12 | 7,680                     |

$$\% = \frac{(100)\text{Accidents on Curves With More Than One Occupant for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

Accidents on curved and straight sections of road as a function of driver occupation are shown on Table B.50. Individuals most involved in accidents on curves are students and military personnel; the least involved are commercial drivers and housewives. These findings suggest some interesting speculations. On the one hand, the low incidence of accidents with commercial drivers suggests that driving skill is a factor in accident experience on curves. On the other hand, the lower accident experience of housewives (a group not particularly remarkable for driving skill) suggests that caution and prudence may also be important factors in reducing accidents on curves. It may be, however, that housewives are not as exposed to driving on curves in the Seattle area to the extent that the other groups are.

This subject was examined a bit closer by looking at the frequency of accidents on curves as a function of driver occupation and vehicle body type. The most and least involved occupation/body type combinations in accidents on curves are shown on Table B.51. Although military personnel in aggregate have the highest frequency of accidents on curves, none of the individual combinations of military personnel and body type have enough accident cases to draw any specific conclusions. Of the combinations that do have enough cases, it is evident that student/children drivers have the worst record of accidents on curves. These drivers show high accident frequencies with four different vehicle body types. Specialty/pony vehicles show up as the most heavily involved body type for the six "Most Involved" combinations. The least involved vehicles are the standard/full size and intermediate body types, with housewives/domestics and clerical/sales occupations the least involved driver occupations.

These data show that there are certain combinations of driver occupation and vehicle body type that show up more heavily in accidents on curves. A careful analysis of this and other types of accident data (e.g., skidding, speeding, overturning, etc.) could lead to recommendations for matching vehicles to drivers.

Table B.50. Accidents on Curved and Straight Sections of Road Versus Driver Occupation.

$$\% = \frac{(100)\text{Accidents on Curves for Specific Occupation and Body Type}}{\text{Total Accidents for Specific Occupation and Body Type}}$$

Accident frequencies on curves and straight sections of road as a function of driver sex are given on Table B.52. It is apparent that there is a significant difference (less than 0.0000032% chance that the differences represent a random occurrence) between males and females with respect to accidents on curves.

A comparison of the percent accidents on curves, treating combinations of males and females along with particular vehicle body types as groups, is given on Table B.53. In all combinations the percent accidents on curves for females is less than for males. These findings, as indicated earlier for housewives, suggest that females are either less frequently exposed to driving on curves or that they drive with more caution and prudence. In general, vehicle body type appears to be a large factor in accident experience on curves regardless of sex. The smaller, sporty vehicles are obviously more heavily involved than the larger, more conventional types.

Table B.54 shows a frequency of accidents on curved and straight sections of road as a function of driver age. There are clear indications from these data that the frequency of accidents on curves decreases with increasing age. Driver experience, skill, prudence, etc., are apparently important factors.

Seat belt usage as a function of accidents on curves is shown on Table B.55. When seat belts are used, the accident experience is significantly lower (less than 1.4% chance that the differences represent a random occurrence) on curved sections of road. This finding suggests that seat belt usage either (1) improves a driver's ability to negotiate curved sections of road or (2) is consistent with a population of drivers who generally drive more prudently.

An attempt was made to investigate the latter contention by determining the most and least frequently involved combinations of driver age groups and vehicle body types in accidents when seat belts are used. The results are shown on Table B.56. If seat belts do indeed reduce the chance of having an accident, then it

$$\% = \frac{(100)\text{Accidents When Seat Belts are Used for Specific Age Group \& Body Type}}{\text{Total Accidents for Specific Age Group \& Body Type}}$$

can be expected that the combinations of driver age and vehicle type having the lowest accident experience when seat belts are used would be the most safely operated vehicles. That is, the absence of accidents with seat belts in a particular combination implies that drivers wearing seat belts are not getting into accidents and these, therefore, are safer drivers. The data on Table B.56 are somewhat surprising in that there is apparently a stronger dependence on vehicle type than on driver age. A dependence on vehicle type would then suggest handling implications. Intermediate and sub-compact/mini's make up all of the most involved combinations, while standard/full size vehicles make up four of the six least involved classes. This finding must be considered tentative, however, since in most age/body type combinations involving the luxury and sporty vehicles there were too few cases to be considered valid for comparison.

The influence of seat belt usage on accidents on curves was also examined by looking at how specific vehicle make/models and body types ranked in such accidents. These rankings were determined by taking the seat belt accidents for each make/model and body type and determining what proportion of these accidents occurred on curves. If seat belt usage has no connection with accidents on curves, then it would be expected that these rankings would be somewhat unordered. Instead, the rankings closely match those for accidents on curves irrespective of the use of seat belts. Table B.57 shows accidents on curves when seat belts are used when compared to accidents with seat belts as a group. The table shows rankings of specific make/models. Table 5.2, repeated from Section 5, is shown next for comparison. Four of the most involved vehicles on Table 5.2 are also most involved with seat belt usage on Table B.57. Similarly, five out of the six least involved vehicles on Table 5.2 are in the least usage category on Table B.57. The same comparisons by body type are shown on Tables B.58 and B.6 (again repeated here). As can be noted, here, the relative rankings are remarkably similar. Both the make/model and body type rankings indicate that seat belt usage is an indicator of driver prudence. Accidents when seat belts

$$\% = \frac{(100)\text{Accidents on Curves for a Given Body Type}}{\text{Total Accidents for a Given Body Type}}$$

are used are much less prevalent for vehicles which have a low involvement of accidents on curves, and vice versa. (Keep in mind that the normalizing data base for the percentages on Tables B.57 and B.58 is that of accidents where seat belts are used and not accidents on curves.) Two possible conclusions can be drawn from these findings:

1. Driver/vehicle combinations that are underinvolved in accidents on curves are also underinvolved in accidents on curves when seat belts are used; i.e., fewer accidents occur when seat belts are used. Hence, seat belt usage is an indicator of driver prudence.
2. Driver/vehicle combinations that are overinvolved in accidents on curves are also overinvolved in accidents on curves when seat belts are used, i.e., more accidents occur when seat belts are used. Hence, seat belt usage is an indicator of more risk-taking in curve travel (the driver is more stable in the driver's seat).

These findings might appear to be conflicting but they are not.

#### Model Year of Vehicle

Vehicle age has been conjectured on many occasions as being a factor in the accident record—primarily as the result of vehicle defects. Vehicle age may be correlated with other factors in the accident record, however, e.g., number of vehicle occupants, driver occupation, driver sex, driver age, and perhaps others. These four are discussed here. Vehicle defects are not discussed, since the reported accident cases where a vehicle defect is listed as a contributing factor are far too small to produce any significant conclusions.

The relationship between the number of vehicle occupants and vehicle model year is shown on Table B.59. There is an indication, although not strong, that the number of vehicles involved in accidents with just one occupant increases as the age of the vehicle decreases. With model year 1967 and earlier, between 76% and 80% of the vehicles involved in accidents had just one occupant; after 1967, the percentage ranged between 81 and 83%.

The relationship between driver occupation and age of vehicle is shown on Table B.60. There are some interesting trends indicated. Those engaged in professional and clerical/sales occupations show an increasing share of the accidents as the model year becomes newer. The trend is the reverse for skilled/semi-skilled workers, other workers, and student/children categories. The trend is relatively constant across model years for military personnel and housewives/domestics. These findings more than likely indicate vehicle usage characteristics among the drivers.

The distribution of accidents for male and female drivers across vehicle model year is shown on Table B.61. Although there are fewer female accidents in the earlier model years, no clear-cut trends are evident.

The relationship between driver age and vehicle model year in accident experience is shown on Table B.62. For drivers between ages 15-19 there is a clear trend of higher accident frequencies with older vehicles. For ages 20-24, accident experience is relatively uniform with vehicle model year. For ages 25-29 and 30-34 there is a clear trend toward more accidents with newer vehicles. The findings are inconclusive for the older age groups. It is evident, then, that the 15-19-year driver age group is unique in experiencing more accidents with older vehicles.

## B.2 Texas Accident Data

In contrast to data obtained through a broader filter on the Seattle data set, the Texas data discussed here are somewhat limited in the number of specific vehicle variables for which good data are available. After the initial filter described earlier (see the introduction to this appendix) was applied to the Texas State 5% sample file, the case vehicles remaining were found to be coded poorly for many of the variables which appeared to have a bearing on vehicle handling. For example, no information was readily useful from bivariate tables for vehicle make/model or vehicle body type versus degree of road curvature, driver violations in general, major contributive actions, etc. In other cases, the type of information available in the Seattle data set was not coded by the Texas Department of Public Safety, such as Seat Belt Usage, Driver Occupation, Residence Proximity, and reliable information regarding vehicle dynamics (such as skidding). In addition, a number of tables which were originally generated for these analyses are not realistically useful for inclusion at present, given the size of the study data set.

Two types of tables were generated to examine vehicle involvement in various types of accidents—vehicle make/model tables and vehicle body type tables. The method used to rework these tables deserves some attention here.

A recoding of all specific make/model codes selected in the original file was employed to obtain a workable set of codes which represent make/model combinations of the original codes. Several additional make/model codes were added in this process for purposes of comparison with the Seattle data. Using the same body type scheme as the Seattle file contains, another categorization of make/models was generated. Table B.63 lists the full Texas recode format while Table B.64 lists each make/model under its respective body type category.

A list of the tables constructed is given in Table B.65. A discussion of each of the accident variables which was coupled with a vehicle type variable follows next.

#### Road Surface/Road Alignment

Tables B.66 through B.68 present data for vehicle body type involvements in certain road surface and road alignment situations. (Note that vehicle make/model rankings for alignment and surface situations are given in Tables 5.3 and 5.7, respectively, of Section 5.)

Looking at the data for road alignment in Table B.66, vehicle size may play a role in accident involvement on curved roads. This is not strongly supported by the body type data in Table B.66, but there is somewhat of a trend. These data look very much like their make/model counterparts (see Table 5.3 of Section 5), with the subcompact/minis and the specialty/pony types at the higher end of the involvement rankings and the luxury sedans and personal luxury vehicles at the low involvement end. Vehicle size appears to have an inverse relationship to accident involvement on curved roads, although the subcompact is an exception to the trend.

Table B.67 shows vehicle body types ranked from highest to lowest in accidents on wet roads. The rankings here are somewhat suggestive of those for curved roads in that smaller classes of vehicles are again overinvolved. The ordering of classes is different, however, and in this case the subcompact/mini class is an exception to the rule.

Involvement in accidents on curved wet roads is presented in Table B.68. The body types involved in accidents on wet roads and in accidents on curved roads, as shown in Tables B.66 and B.67 are fairly similar, although there are problems with small data populations for some of the categories. Controlling for the effects of wetness on road alignment, as shown in Table B.68, there is a trend in the data toward poorer performance of smaller cars on curved roads. Body types in the smaller ranges are at the top of the involvement

$$\% = \frac{(100)\text{Accidents on Curved, Wet Roads for a Given Body Type}}{\text{Total Accidents on Curved Roads for a Given Body Type}}$$

rankings. This fact lends further credence to the speculation that there is a relationship between vehicle size and accident involvement on curved or wet roads. Again, the data are not large enough to draw conclusive inferences, but the scraps of evidence available are suggestive of a trend. Specific data for vehicle make/models are not presented along with Table B.68, because there are not sufficient numbers of data in the curved, wet category of accidents.

### Accident Type

In order to further explore the specific involvements of certain make/model and body type categories, it was necessary to take a closer look at the type of accidents in which the case study vehicles were involved. Tables B.69 through B.74 present data for out-of-control, overturned-in-road, and parked-car collisions. The Opel Kadette, usually found as most involved in previous tables, appears as the least involved vehicle make/model, despite a small total number of cases, in out-of-control accidents (Table B.69). In Table B.69, the Toyota Corona is a fairly solid leader for out-of-control accidents. Looking at body type for these same accidents (Table B.70), and removing European sports cars because of population size, there is again some movement in the direction of larger vehicles being less involved in out-of-control accidents.

Table B.71 shows rankings of vehicle body types in out-of-control accidents on wet roads. Although there are some problems with sample size in some of the categories, there is, nevertheless, virtually no trend in vehicle size in these rankings.

Overturned-in-road accidents are ranked for the several body types on Table B.72. If the European sports car and super sport classes are eliminated for the moment because of a small number of cases, there is a near-perfect small-to-large ordering from high to low involvement in overturned-in-road accidents. It may be noted that the subcompact and subcompact/mini classes have approximately

three and six times the involvement rate of the total vehicle population, respectively. As noted in Section 5, involvements in overturning accidents are highly correlated with vehicle track width.

Parked-car involvements are presented in Tables B.73 and B.74. Full-sized vehicles are represented in the most involved make/model category, but it is the body type variable (Table B.74) that shows that the larger vehicles are more involved in parked-car collisions. Perhaps the sheer bulk of the larger vehicles plays a role in the tendency of these vehicles to collide with parked cars.

#### Driver Sex

Several tables were generated for these analyses, which were also controlled for driver sex, and nearly all of these—driver violation variables, pre-crash maneuver variables, etc.—were useless because of the small size of the resulting data set. A general distribution for driver sex, however, is presented in Tables B.75 and B.76, again by make/model and by body type, respectively.

The Ford Pinto and the Oldsmobile Delta 88, Delmont 88 make/models are the most involved and least involved, respectively, in accidents with male drivers. The super sport and luxury sedan classes are the most- and least-involved body types, respectively, but in general, no trends can be observed here, just as a quick look at the driver sex tables, not included in this report, seemed to indicate. It is interesting, though, that three out of the four most involved types are in the "sporty" category. Keeping in mind that there are not enough data on the car population of each body type to determine its relative exposure to such factors as sex, road type, etc., and thus lay a sound foundation for the following conclusion, it can be seen from Table B.77 that the proportion of

Table B.73. Percent Collisions with Parked Cars

$$\% = \frac{(100) \text{ Accidents for a Given Sex and Body Type}}{\text{Total Accidents for a Given Sex}}$$

male drivers of each body type to the rest of the male driving population involved in accidents is roughly equal to its female counterpart. On the basis of this tenuous observation, apparently sex is not a significant factor in accident causation among the various body types.

### Driver Age

Several different presentations of driver age data are given in this section. Table B.78 shows vehicle body types ranked in terms of the lowest mean driver age to the highest. There is a clear indication that younger drivers tend to have accidents in vehicles which are concentrated in the smaller sporty classes, while older drivers have accidents in the larger vehicles.

Table B.79 shows some interesting driver age data for selected data subsets of road surface and driver sex. It will be recalled from the discussions of the King County data that male drivers had a significantly larger proportion of accidents on curves than did female drivers (Table B.53). As noted here in Table B.79, the mean age of male drivers is over three years younger than that for female drivers. This age difference, although the comparison is across two different accident sets, may account for the higher accident experience of males on curves.

In another study of age influences, Table B.80 gives the distribution of mean driver age by body type for dry road surfaces and wet road surfaces. The total means for dry and wet roads indicate that wet-road accidents involve drivers with an average age of almost two years lower than that of drivers in dry-road accidents. Six out of the ten body type classes show this relationship. The exceptions are the intermediate, super sport, and specialty/pony, for which no appreciable age differences exist. European sports cars again are too few to allow any generalization.

Table B.78. Mean Driver Age by Body Type for Accident-Involved Vehicles.

| Body Type           | N     | Mean Driver Age |
|---------------------|-------|-----------------|
| European Sports Car | 9     | 19.1            |
| Specialty/Pony      | 245   | 21.8            |
| Subcompact/Mini     | 118   | 22.4            |
| Subcompact          | 80    | 24.1            |
| Super Sport         | 15    | 24.5            |
| Compact             | 280   | 27.0            |
| Intermediate        | 541   | 27.5            |
| Standard/Full Size  | 1010  | 31.8            |
| Personal Luxury     | 52    | 34.7            |
| Luxury Sedan        | 100   | 39.8            |
| Total               | 2,527 | 28.8            |

Table B.79. Mean Driver Age by Road Surface and by Driver Sex  
 (Based on Vehicle Make/Model Data)

| <u>Road Surface</u> | <u>N</u> | <u>Mean Driver Age</u> |
|---------------------|----------|------------------------|
| Dry                 | 2441     | 29.3                   |
| Wet                 | 697      | 27.4                   |
| <br>                |          |                        |
| <u>Driver Sex</u>   |          |                        |
| Male                | 2234     | 28.0                   |
| Female              | 890      | 31.2                   |

Table B.80. Mean Driver Age by Body Type  
Controlling for Road Surface

| Body Type           | Dry Roads |       |                 | Wet Roads |       |                 |
|---------------------|-----------|-------|-----------------|-----------|-------|-----------------|
|                     | N         | %     | Mean Driver Age | N         | %     | Mean Driver Age |
| Subcompact/Mini     | 91        | 4.7   | 22.8            | 27        | 4.7   | 20.7            |

| Luxury Sedan        | 82        | 4.2   | 40.6            | 18        | 3.1   | 36.0            |
| Total               | 1,950     | 100.0 | 29.2            | 577       | 100.0 | 27.3            |

The same mean driver age data are presented in Table B.81, but controlling here for road alignment. In three out of the ten body type classes, primarily large vehicles—personal luxury, standard/full size, and subcompact/mini (mostly Volkswagens)—drivers are younger on curved roads as compared to those involved in accidents on straight roads. Another four showed no appreciable differences in mean driver age, the smaller vehicles—subcompact, compact, specialty/pony, and intermediate. Luxury sedans offer the only major example (there really wasn't enough data for comparison in the super sport class) where drivers were older in curved-road accidents than on straight-road accidents.

Table B.82 documents mean driver age by body type, controlling for driver sex. The mean ages for males and females are 27.8 and 31.5, respectively. Only in the super sport category are male drivers substantially older than their female counterparts. (The reader is again cautioned to consider the small size of the super sport population.) For personal luxury, luxury sedan, and subcompact/mini classes, there is no appreciable age difference between male and female drivers.

In Table B.83, the individual body type classes are given with ten bracketed age groups for each. By and large, most accident involvement occurs between the ages of 15 and 24, where nearly 55% of all accidents happen. Nearly 75% of all involvements occur with drivers under 35. The only major exceptions are personal luxury and luxury sedan classes. Luxury sedans tend to have a fairly uniform distribution. Personal luxury types peak at the ages of 25-29 and 45-49. Specialty/pony vehicles and European sports cars tend to be overwhelmingly more involved in accidents with drivers under 25, as are, to a lesser extent, compacts, subcompacts, and subcompact/minis. The super sport class has a single peak at ages 25-29.

Table B.81. Mean Driver Age by Body Type Controlling for Road Alignment.

| Body Type           | Straight Roads |       |                 | Curved Roads |       |                 |
|---------------------|----------------|-------|-----------------|--------------|-------|-----------------|
|                     | N              | %     | Mean Driver Age | N            | %     | Mean Driver Age |

### B.3 Conclusion

Generally, small cars are overinvolved in accidents in which the surrounding conditions deviate from the normal, e.g., curved and wet roads. Small cars are also more involved in accidents involving loss of control, overturning, speeding violations, and with male drivers and younger drivers. To some extent, the sporty cars form an exception to the small car group. Sports cars go out of control less than the remainder of the small cars but more than the large cars; they rank about the same as large cars in cases of overturning; and they take the lead in accidents involving both speeding violations and/or male drivers.

The effect of driver sex in a vehicle handling context is not clear. Female drivers as a group experience significantly fewer accidents on curves than do males. Male drivers involved in accidents average over three years younger in age than do females, however. Further, males tend to be involved in accidents with older, and sporty vehicles, but also larger luxury models. The confounding effects are obviously quite complicated. As a result, no conclusions can be drawn as to why a specific body type is more involved in certain types of accidents while another is less involved. For example, from Table B.66, small cars were found to be overinvolved in accidents on curved roads. But is this because small cars are not built to handle curves as well as large cars, or is it because small cars are driven by younger and possibly more inexperienced drivers who are more likely to commit some error that an older and more experienced driver would not? Further study on a sufficiently large data set is clearly necessary in order to isolate accidents by specific age groups, sex, body types, and other factors.

As in any age-related problem, the question involves not only the actual driver age but also the amount of driving experience that those drivers have. In addition, such effects as driver's

education programs, make/model preferences, family size, and transportation needs often become hidden by simplistic age/accident involvement analyses. Obviously, more detailed data on drivers involved in accidents could yield more precise findings than those obtainable from data currently available.

The data for accident experience across driver age are presented in the form of curves rather than tables, since there is presumably some continuous connection between accident experience and vehicle usage across age brackets (i.e., an ordinal relationship). Figures B.1 and B.2 show the driver age distribution for vehicles in the specialty/pony classes. A high concentration of young drivers is clearly evident. By contrast, Figures B.3 and B.4 show driver age distributions for vehicles in the personal luxury and luxury sedan classes, respectively. Personal luxury car accidents peak between ages 25 and 35, while luxury sedan accidents tend to be relatively uniform with age. (Note that the apparent peak at ages 55-64 for luxury sedans is somewhat distorted, in that the 55-64-year age bracket covers ten years, while the younger age brackets cover five years.)

The sub-compact and sub-compact/mini classes of vehicles (Figures B.5 and B.6, respectively) also show high concentrations of accidents involving young drivers. The percentage of accidents with drivers between 20-24 years for sub-compact/mini vehicles is nearly as high as that for European sports cars.

Moving next to compact and intermediate vehicles (Figures B.7, B.8, and B.9 to B.11, respectively), there is a similar trend from a high frequency of accidents among young drivers to lower frequencies after age 35. (It should be remarked that the data for the intermediate class of vehicles are grouped with the three vehicles with the highest number of accidents plotted on the same figure—Figure B.9. The next three vehicle models in order of numbers of accidents were plotted on Figure B.10, and the three with the lowest numbers of accidents on Figure B.11. Differences in the smoothness of the data across age groups are clearly apparent in looking progressively from Figure B.9 through Figure B.10 and then at Figure B.11.)

Figure B.1. Percent accidents by age bracket (specialty/pony).

Figure B.2. Percent accidents by age brackets (specialty/pony)

Figure B.3. Percent accidents by age bracket (personal luxury).

Figure B.4. Percent accidents by age bracket (Luxury sedan).

Figure B.5. Percent accidents by age bracket (sub-compact).

Figure B.6. Percent accidents by age bracket (sub-compact/mini).

Figure B.7. Percent accidents by age bracket (compact).

Figure B.8. Percent accidents by age bracket (compact).

Figure B.9. Percent accidents by age bracket (intermediate).

Figure B.10. Percent accidents by age bracket (intermediate).

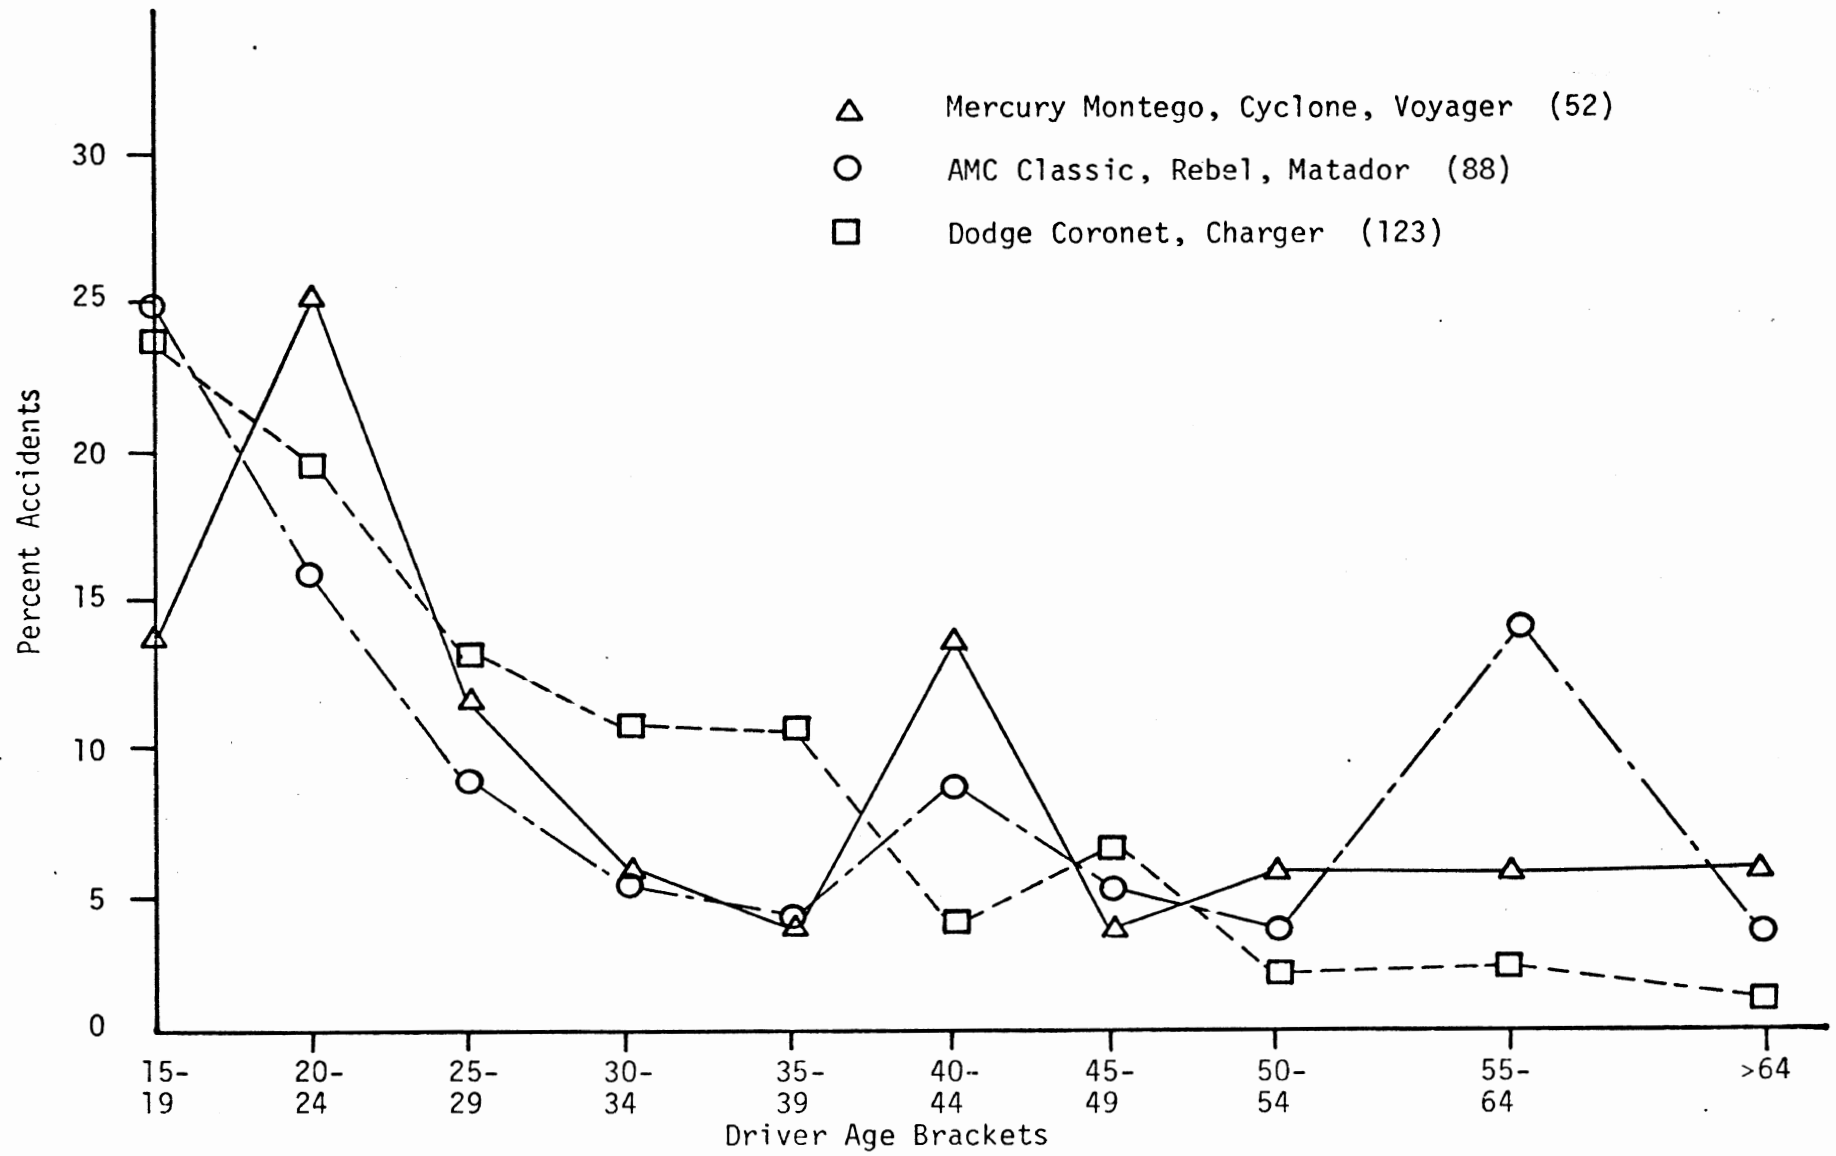

Figure B.11. Percent accidents by age bracket (intermediate).

With the standard/full-size vehicles (Figures B.12 to B.14), the trend of higher accidents at younger ages is not as pronounced. Beyond age 24, accident experience is relatively uniform across the higher age brackets. Again, the data are grouped according to numbers of accidents for specific models. The data are noticeably more erratic on Figure B.14 than on Figure B.12.

The mean age for each make/model is given on Table B.42. The make/models having the youngest and oldest mean age values are given in Table B.43. Body types ranked in terms of increasing mean driver age are given in Table B.44. It is quite evident that vehicles having accidents with the youngest drivers are the European sports cars, specialty/pony, sub-compact, and sub-compact/mini classes. Older drivers have the most accidents in the luxury sedan and personal luxury classes.

The most involved and least involved body types for each of the age groups is listed as follows.

| <u>Age Group</u> | <u>Most Involved</u> | <u>Least Involved</u> |
|------------------|----------------------|-----------------------|
| 15-19            | Specialty/Pony       | Personal Luxury       |
| 20-24            | European Sports Car  | Luxury Sedan          |
| 25-29            | Sub-Compact          | Standard/Full Size    |
| 30-34            | Personal Luxury      | Sub-Compact           |
| 35-39            | Standard/Full Size   | Super Sport           |
| 40-44            | Luxury Sedan         | Specialty/Pony        |
| 45-49            | Luxury Sedan         | European Sports Car   |
| 50-54            | Personal Luxury      | Sub-Compact/Mini      |
| 55-64            | Luxury Sedan         | European Sports Car   |
| >64              | Luxury Sedan         | European Sports Car   |

---

There is clearly a trend through the age groups from accidents with the sporty vehicles at younger ages, to the smaller domestic vehicles during the young family years, to the luxury models in middle and old age.

## APPENDIX C

### INDIRECT STANDARDIZATION - AN EXAMPLE

As a test of the analytical methodology developed in Section 7.1, analyses were carried out on existing data from corresponding accident and exposure files currently maintained at the Highway Safety Research Institute. Accident rates were established for three geographic areas: (1) the State of Texas, (2) King County (Seattle) Washington, and (3) Washtenaw County (Ann Arbor) Michigan. For each, an appropriate accident and exposure file exists, although none is adequate with respect to the requirements established in Section 7.3. The methods of indirect standardization were applied only to the King County accident rates.

The Texas accident file was derived from a larger file of all vehicles involved in police-reported accidents in the State of Texas in 1970. The smaller file used here consisted of a randomly chosen sample of 5% of the vehicles involved in accidents in the larger file. Of the accident variables recommended for use in Section 7.3.2, driver age and sex, weather and light conditions, and vehicle make, model and model year, among others, are included in this data file. After filtering out those cases which appeared to be most probably related to vehicle handling factors (see Section 5.1.2), approximately 19,000 cases remained. Missing data was handled by assigning the missing elements to cells in proportion to cell size.

The Texas exposure data was derived from a Driver Exposure File, also maintained at the Highway Safety Research Institute. This file contains 8,000 records of interviews conducted at driver license renewal offices throughout the country during 1970. Four of these offices were in Texas: El Paso, Corpus Christi, McCulloch-Coleman County, and Houston, and over 400 interviews were conducted at these offices. Variables of interest that were

recorded during the interviews included mileage by driver age and sex, light and weather conditions, and vehicle make, model, and model year. Mileage figures are for 30 days. One drawback is that the make, model, and model year information was self-reported and the model, especially, is subject to error. This latter variable was therefore not used in the subsequent analysis.

One problem connected with using this particular exposure file was that the sampling rates were not known. Since this example is a test of the technique, accuracy is not necessarily a prime consideration. The estimated cell mileages for the entire State of Texas were therefore determined by multiplying by:

$$\frac{\text{TOTAL ESTIMATED TRAVEL MILES FOR TEXAS IN 1970}}{\text{TOTAL SAMPLE INTERVIEW MILES}}$$

The numerator estimate was obtained from Reference 128.

Another difficulty with this exposure file is that combinations of factors are not reported. To overcome this difficulty, independence of factors was assumed and the marginals of each separate confounding variable were multiplied to obtain combined factors. For example, if an individual did 10% of his driving in the rain, and 20% at night, then  $(.10)(.20) = 2\%$  (.2) was assumed to be driven on rainy nights.

Given the simplifications and approximations stated above, the estimated number of accidents in Texas in 1970 by age, sex, light and weather conditions is presented in Table C.1. The associated mileage estimates are given in Table C.2, and the ratios (accident rates) are given in Table C.3.

It is apparent that some of the accident rates are very much larger than the others. There may be a number of reasons why these statistics could be in error. Given all the simplifying assumptions and the possible biases in the data, it would be best to compare these figures with others from different populations before any conclusions are drawn.

TABLE C.1

ESTIMATED NUMBER OF VEHICLE HANDLING RELATED ACCIDENTS IN TEXAS IN 1970  
BY  
AGE, SEX, LIGHT, AND WEATHER\*

## ALL FACTORS ACCIDENTS

| AGE/SEX | ≤ 25    | 26-40  | > 40    | TOTAL   |
|---------|---------|--------|---------|---------|
| M       | 102,331 | 59,285 | 74,503  | 236,119 |
| F       | 50,346  | 39,682 | 49,513  | 139,541 |
| TOTAL   | 152,677 | 98,967 | 124,016 | 375,660 |

## DAY ACCIDENTS, ONLY

| AGE/SEX | ≤ 25    | 26-40  | > 40    | TOTAL   |
|---------|---------|--------|---------|---------|
| M       | 69,119  | 41,312 | 59,827  | 170,258 |
| F       | 40,675  | 33,055 | 43,192  | 116,922 |
| TOTAL   | 109,794 | 74,367 | 103,019 | 287,180 |

## NIGHT ACCIDENTS, ONLY

| AGE/SEX | ≤ 25   | 26-40  | > 40   | TOTAL  |
|---------|--------|--------|--------|--------|
| M       | 33,687 | 18,179 | 14,489 | 66,355 |
| F       | 9,570  | 6,494  | 6,061  | 22,125 |
| TOTAL   | 43,257 | 24,673 | 20,550 | 88,480 |

## DRY WEATHER ACCIDENTS, ONLY

| AGE/SEX | < 25    | 26-40  | > 40    | TOTAL   |
|---------|---------|--------|---------|---------|
| M       | 81,892  | 48,146 | 61,131  | 191,169 |
| F       | 41,667  | 31,754 | 41,830  | 115,251 |
| TOTAL   | 123,559 | 79,900 | 102,961 | 306,420 |

## WET WEATHER ACCIDENTS, ONLY

| AGE/SEX | ≤ 25   | 26-40  | > 40   | TOTAL  |
|---------|--------|--------|--------|--------|
| M       | 20,398 | 11,133 | 13,380 | 44,911 |
| F       | 8,695  | 7,915  | 7,719  | 24,329 |
| TOTAL   | 29,093 | 19,048 | 21,099 | 69,240 |

\* Note: All accident and mileage numbers in this and all other tables have been adjusted to account for missing data. Because of this, the sum of the accident figures in each set of comparable cells from the levels of a variable may not equal the total accidents for that cell.

| TOTAL   | 7.36  | 1.89  | 2.74 | 3.19  |

\*All numbers are in units of accidents/10<sup>6</sup> miles.

Accident mileage exposure, and accident rate statistics for King County (Seattle), Washington are given in Tables C.4, C.5, and C.6. The accident file consisted of all accidents in King County in the year 1970 and the exposure information came from the same driver exposure files as the Texas data, but was filtered for King County drivers only. In addition to the variables used in the Texas analysis, the accident file also contains the road class and vehicle make variables. There are 220 interviews in the exposure file and 19,000 accidents in the accident file. The accident rates for King County are more consistent than for Texas, yet there are still wide differences, particularly with respect to driver sex.

The final set of statistics are from Washtenaw County (Ann Arbor), Michigan. The exposure data is from an exposure survey conducted in 1973. There were 1,100 interviews conducted, with most of the same variables recorded as the national exposure survey. Unfortunately, vehicle make was not recorded and it is not included in the analysis of this population. The corresponding accident data is from a file of all Michigan accidents in 1973 filtered on those which occurred in Washtenaw County. (The county of residence of the driver was not listed in this file. Therefore, the analysis was centered on accidents occurring in Washtenaw County independent of the driver's residence.) This accident data file was also filtered to remove all non-handling-related accidents with the result that 2,600 cases remained for analysis. Tables C.7, C.8, and C.9 present the accident, mileage, and accident rate statistics for Washtenaw County. The accident rates for Washtenaw County are of the same order of magnitude as those for the King County data. This finding tends to reinforce the impression that the accident rate estimates for Texas are in error.

\*All numbers are in units of accidents/10<sup>6</sup> miles.

The technique of indirect standardization was applied to the Seattle data. Table C.6 showed the raw accident rates for the vehicle make, and the standard accident rates for each combination of factor levels. Table C.10 presents the standardized accident rates for the various vehicle classes, where weather and light conditions are accounted for. These rates were computed by using Equations (7.1) and (7.2) of Section 7, viz.:

$$R'_k = \frac{\sum_j r_{Sj} M_{kj}}{\sum_j M_{kj}} \quad (7.1)$$

$$R_k^{ind} = R_S \frac{R_k}{R'_k} \quad (7.2)$$

where the various  $r_{Sj}$  and  $M_{kj}$  data values were obtained from the appropriate data files. Mileage figures for the various combinations of light and weather conditions were estimated by assuming that light and weather are independent.

The standardized accident rates for each of the vehicle makes shown on Table C.10 represent the best estimate of accident proneness for a particular vehicle that can be obtained from available data. These rates should be considered as a demonstration of the use of the indirect standardization method, however, rather than as a true measure of accident susceptibility. There are too many limitations and inaccuracies in the existing exposure data to consider these rates as truly representative. Only when the procedures recommended in Section 7 are followed, and substantially more data are collected, can the results be considered meaningful. In the end, these more accurate standardized accident rates would be used as independent variables in a regression analysis.

## APPENDIX D

### SUPPLEMENTAL ACCIDENT REPORT FORM FOR VEHICLE HANDLING

The accident report form given in this appendix is entitled as a Vehicle Handling Supplement. It is intended for use in conjunction with the Collision Performance and Injury Report (CPIR) Long Form. The Supplement was developed for gathering information which could be used to identify vehicle handling factors in an accident. In separating vehicle handling factors from an accident, it is necessary to identify confounding influences which may also be accident causation factors. Thus, the Supplement is divided into sections which encompass:

- (1) Environment
- (2) Roadway
- (3) Vehicle
- (4) Operator
- (5) Accident Kinematics

The Supplement is assembled in a modular fashion such that parts (or pages) can be added or deleted depending upon the case. For example, while it is clear that the Environmental conditions surrounding two vehicles involved in an accident will almost always be the same, the Roadway conditions could be entirely different—e.g., two vehicles approaching on separate roads. Therefore, if there is interest in the two separate vehicles, a roadway section for each would be prepared. Further, the roadway section is streamlined in other ways. The shoulder and sign sections are set up so as to be applicable to either the right or left shoulder by designating which in the appropriate blank. Two shoulder sections would be necessary if both right and left shoulders are of interest.

The major emphasis in the Vehicle section is on maintenance condition and modifications from original equipment. The identification of the vehicle (except for tires) will be given in the CPIR form. Emphasizing maintenance and modifications is not for

the purpose of assigning accident causation to these factors. (Keep in mind that causation factors relating to original design are the main concern here.) Rather, the purpose is to identify the variations in maintenance and owner modification so that their effect on the "as-new" handling qualities of the vehicle can be assessed. It is anticipated that the accident data acquired by way of the Vehicle Handling Supplement will be used in correlation studies with measured handling data from a set of new vehicles. The variation of the accident-involved vehicle from its measured status will therefore be of prime interest.

Most of the material on the Vehicle is self-explanatory, except perhaps for the following points. A separate page is provided for recording the tread profile of each individual tire. These profiles are to be obtained with a contour gauge like that pictured in Figure 8.11 of Section 8.

It is rather widely believed that the vehicle Operator is a large factor in accident causation. Further, it has been shown that age and sex are two driver characteristics that seem to correlate with accident experience. The specific driver qualities that make age and sex important, however, have never been identified. For example, is it physical strength, stature, mental attitude, experience, combinations thereof, or are there other driver qualities which make age and sex correlate with accident experience. To take another tack, is driver-vehicle matching a factor? Are young people more involved in accidents because they drive more Volkswagens, or are Volkswagens more involved in accidents because they are driven more by young people? Whatever the case (if indeed there is a connection), pinpointing the answer will require as much specific information as possible about driver characteristics. The operator information required in the Supplement is again self-explanatory and is designed to add to information already collected in the CPIR form.

The final three pages in the Supplement deal with Accident Kinematics. The emphasis in this part is a careful analysis of skid marks. On the final page (which can be expanded to several pages for any number of skid marks) each skid mark (numbered serially according to the Accident Schematic) and causative tire are identified. Space is allotted for recording the coordinates of the skid mark curve, and for denoting the angle of striation marks at these coordinates. Space is also allotted for denoting the vehicle motions and driver actions that seemingly correlate with the skid mark information. The information is again supplemental to the CPIR form with the intent that the information would be used in carefully reconstructing the accident by means of computer simulation.

## DEFINITIONS

- Primary Road - A highway of first importance (in most states they form a designated system of main highways known as the State System)
- Secondary Road - Not of primary importance (and usually not considered a part of the state primary system)
- Farm-to-Market - A road outside the primary state highway system which connects farms with towns or primary highways
- Land Service Road - A road which is used primarily to give access to land
- Major Arterial Street - A class of street which brings traffic to and from the expressway (if any) and serves those major movements of traffic within or through the metropolitan area not served by expressways. Major arterials interconnect principal traffic sources with the city and important rural routes
- Collector Street - Serves internal traffic movement within an area of the city and connects with the major arterial system. A collector does not handle long through trips and is not continuous for any great distance.
- Local Street - Primary for access to residence, business or other abutting property.
- Expressway/Freeway - A divided highway for through traffic with full, or occasionally partial control of access and generally with grade separations at intersections.

## APPENDIX E

### SUPPLEMENTAL DATA ON RELATIONSHIPS BETWEEN VEHICLE HANDLING PARAMETERS (AND INDICES) AND ACCIDENT DESCRIPTORS

The information contained in this appendix consists of plots of vehicle handling parameter and index values as a function of accident frequencies. The plots are supplemental to those given in Section 7.3. Unlike those in Section 7.3, however, the plots presented here show no consistent trends between increasing values of vehicle handling parameters (and indices) and accident experience. The purpose of including the plots here is for completeness in showing both positive and negative results.

The statistics shown represent that percentage of accidents of a particular type as compared to the total number of accidents occurring for vehicles with a particular parameter or index value. Again it should be cautioned that with existing data, and hence the analysis limitations that arise therefrom, neither the existence nor lack of an apparent relationship can be considered as a definitive finding.

For the various vehicle handling parameters and indices, one set of plots is grouped according to accidents occurring on curves, under wet conditions, on curves under wet conditions, and those involving skidding. These are termed set No. 1 descriptors. Another set of plots is grouped according to accidents involving rollover, avoidance maneuvers, female drivers, and vehicles with more than one occupant. These are termed set No. 2 descriptors. A complete list of the plots is given in Table E.1.

Table E.1

| <u>Figure</u> | <u>Title</u>   |
|---------------|--|
| E.1           | Overall Height vs. Set No. 1 Descriptors                               |
| E.2           | Overall Height vs. Set No. 2 Descriptors                               |
