A statistical investigation of the effects of random mistiming on the forced response of nearly cyclic assemblies made of mono-coupled single-mode component systems (blades) is presented. Various probabilistic methods of analysis are applied to generate the statistics of the forced response of this basic N-degree of freedom cyclic system: an analytical first-order statistical perturbation method, a purely numerical Monte Carlo simulation, and a hybrid approach that combines the two. Means and variances of the component systems’ amplitudes are obtained. The limitation, accuracy, and computer costs of the various techniques are discussed. Also, the effects of the system parameters on the expected value of the largest amplitude experienced by the assemblies at any excitation frequency are investigated. It is found that weakly coupled systems are more sensitive to mistuning than strongly coupled ones through a greater increase in largest amplitude and that the accuracy of the various approaches depends strongly on the relative magnitudes of coupling, mistuning, and damping.

Nomenclature

\( b \) = viscous damping coefficient
\( F \) = external force vector
\( j \) = pure imaginary unit complex number
\( k_b \) = nominal component system’s stiffness
\( k_{bi} \) = equivalent stiffness of /th component system
\( k_c \) = coupling stiffness
\( m_i = m \) = equivalent mass of /th component system
\( n \) = engine order excitation
\( N \) = number of component systems
\( q_{0i} \) = displacement of /th component system for unperturbed assembly
\( q_i \) = displacement of /th component system
\( \delta q_i \) = first-order perturbation of /th component system’s displacement
\( \bar{q}_0 \) = displacement amplitude of /th component system for unperturbed assembly, \( = |Q_0| \)
\( \bar{q}_i \) = displacement amplitude of /th component system, \( = |Q_i| \)
\( q_m \) = maximum displacement amplitude throughout the assembly at a given excitation frequency
\( q_i \) = largest displacement amplitude throughout the assembly at any excitation frequency, i.e., the largest value of \( q_m \) as \( \omega \) varies
\( q \) = displacement vector
\( Q_0 \) = complex amplitude of /th component system for unperturbed assembly
\( Q_i \) = complex amplitude of /th component system
\( \delta Q_i \) = first-order perturbation of /th component system’s complex amplitude
\( \delta |Q_i| \) = first-order perturbation of the modulus of the /th component system’s complex amplitude
\( R^2 \) = dimensionless coupling, \( = k_c/k_b \)

\( \omega \) = excitation frequency
\( \omega_b \) = nominal blade natural frequency, \( = \sqrt{k_b/m} \)
\( \omega_{bi} \) = natural frequency of /th component system, \( = \sqrt{k_{bi}/m} \)
\( \omega_c \) = coupling frequency, \( = \sqrt{k_c/m} \)
\( \delta_i \) = Kronecker symbol, \( = 1 \) for \( i = j \) and \( = 0 \) for \( i \neq j \)
\( \Delta_{ij} \) = mistuning of /th component system, \( = (\Omega_{0j} - \Omega_{0i})/\omega_c^{2} \)
\( \phi_i \) = phase angle of force for /th component system
\( \sigma \) = standard deviation of mistuning
\( \sigma_{Q_i} \) = standard deviation of /th component system’s amplitude
\( \bar{f} \) = viscous damping ratio, \( = b/(2\sqrt{k_b m}) \)
\( T \) = superscript, denotes a transpose
\( \text{Re}[\cdot] \) = real part of complex number
\( \text{Im}[\cdot] \) = imaginary part of complex number
\( \mathcal{O}[\cdot] \) = order of the argument
\( E[\cdot] \) = mathematical expectation
\( |\cdot| \) = modulus
\( \langle \cdot \rangle \) = \( |d(\cdot)/dt| \)

Introduction

Because of manufacturing and material tolerances, some degree of blade mistuning is inevitable in bladed-disk assemblies. Such small mistuning may increase the vibrational amplitudes of some blades significantly and result in the unexpected damage (or failure) of these blades. The extent to which blade mistuning affects the vibrational amplitudes is a major concern in the design of blade assemblies.

A number of studies to predict the increase in the maximum amplitudes experienced by blades have been conducted through the analysis of deterministic mistuning arrangements (see the survey paper by Srinivasan and the references contained therein). However, the mistuning distribution in a given assembly is randomly selected from a large population of blades. Therefore, the increase in maximum amplitude due to mistuning is expected to vary among the individual ensembles of a population of bladed-disk assemblies. In order to account for the influence of mistuning in the design of bladed-disk assemblies, a statistical analysis of the forced response must be performed by considering the modal properties of the blades as random variables.
Sogliero and Srinivasan\textsuperscript{2} applied Monte Carlo simulation techniques to estimate the fatigue life of mistuned blades. Griffin and Hoosac\textsuperscript{3} also generated the statistics of the forced response by a Monte Carlo simulation of a large number of bladed-disk assemblies. The advantages of Monte Carlo methods lie in the accuracy of the results and the simplicity of the algorithm. However, because of the high computer costs, only limited results can be generated through Monte Carlo simulation, especially for parametric studies of systems with large numbers of degrees of freedom (DOF). Therefore, alternative approaches must be considered to calculate the statistics of the forced response.

Several alternative approaches were developed to generate the statistics of each component system's amplitude. Huang\textsuperscript{4} considered blade mistunings as statistical variables, and developed a perturbation method to generate the expectation and variance of the blades' vibrational amplitudes. However, his approach could only be applied to blade assemblies with very closely spaced blades. Sinha\textsuperscript{5} combined first-order perturbation methods with statistical theory to yield the probability density functions of the blades' amplitudes for mistuned systems with an arbitrary number of blades. Although the mistuning distribution was assumed to be Gaussian in this study, Sinha and Chen\textsuperscript{6} extended the approach to non-Gaussian distributions. Nevertheless, the accuracy of these techniques was found to depend strongly upon the amount of damping and blade mistuning. For instance, significant errors were observed for systems with low-damping ratios or relatively large mistuning strengths. Also, as will be seen later, some important statistical properties of the forced response, such as the mean and variance of the largest amplitude experienced by an assembly, cannot be generated through these analytical techniques. Therefore, although such analytical approaches can reduce the computer costs, there are always some significant limitations associated with them. It is very important to identify such limitations before applying those techniques, as otherwise erroneous conclusions could result.

Two issues are addressed in this paper. One is to develop and review various probabilistic approaches to obtain the statistics of the forced response of mistuned systems. In particular, approaches alternate to Monte Carlo simulations are applied to a basic 7V-DOF cyclic system. The limitations, accuracy, and computer costs of these methods are discussed. The other is to study the effects of the system parameters on the statistics of the forced response of a simple bladed-disk assembly model. Two key parameters governing the sensitivity of the forced response have been shown to be the mistuning strength and the interblade coupling strength.\textsuperscript{7,8} Here, the effects of these parameters on the expected value of the largest amplitude are studied systematically. This is achieved through the application of Monte Carlo simulation techniques, as well as as statistical perturbation methods, described in the third section.

Equations of Motion

The nearly cyclic assembly of $N$ coupled component systems (blades) shown in Fig. 1 is studied. Each component system, consisting of a single-DOF oscillator with viscous damping, is coupled to the adjacent component systems through linear springs. This system has been used by Wei and Pierre\textsuperscript{4,8} as a simple model of continuously shrouded bladed-disk assemblies to study localized free and forced vibrations in mistuned assemblies. Since one of the primary goals of this paper is to understand the influence of coupling, this much simplified representation of interblade coupling is adopted toward that end. For simplicity, mistuning is assumed to originate from discrepancies among the component systems' stiffnesses. The equations of motion are given by

\begin{equation}
\ddot{q} + 2\zeta \omega_0 \dot{q} + \omega_0^2 [A] q = (1/m) F
\end{equation}

where

\begin{equation}
[A] = \begin{bmatrix}
1 + 2R^2 + \Delta f_1 & -R^2 & 0 & \cdots & 0 & -R^2 \\
-R^2 & 1 + 2R^2 + \Delta f_2 & -R^2 & 0 & \cdots & 0 \\
0 & \cdots & \cdots & \cdots & \cdots & \cdots \\
0 & \cdots & \cdots & \cdots & \cdots & \cdots \\
-R^2 & 0 & \cdots & \cdots & \cdots & -R^2 \\
0 & \cdots & \cdots & \cdots & \cdots & 1 + 2R^2 + \Delta f_N
\end{bmatrix}
\end{equation}

is a "nearly cyclic" matrix, and

\begin{equation}
F = F e^{i\phi} \{1, e^{i\phi_1}, \ldots, e^{i\phi_N}\}^T
\end{equation}

\begin{equation}
\phi_i = \frac{2\pi n(i-1)}{N}
\end{equation}

The external force adopted here is a traveling wave excitation that has been widely used for bladed-disk assemblies in the literature.\textsuperscript{9} Two key dimensionless parameters in Eq. (2) are $R^2$ and $\Delta f$: $R^2$ is the dimensionless coupling between component systems and $\Delta f$ is considered a random variable whose statistical properties can be obtained from the survey of a large population of manufactured blades.

Solution Techniques

The statistics of each blade's vibrational amplitude can be obtained by the following methods.

Monte Carlo Simulation

The Monte Carlo technique is a purely numerical simulation of the probabilistic behavior of the system. It can be outlined...
by four steps:
1) An ensemble of mistuning values $(\Delta f_i)_{i=1,...,N}$ is generated from a random variable generator with given statistical distribution.
2) The modal properties of the free undamped mistuned system are obtained by solving the $N$-DOF eigenvalue problem numerically.
3) Modal analysis is applied to obtain the force response amplitude of each component system.
4) Steps 1-3 are repeated many (say several hundred) times, thereby generating the statistics of the response amplitudes by averaging over an ensemble of realizations of the mistuned system.

Even though the results are accurate when the sample size is large, Monte Carlo simulations are highly expensive.

**Hybrid Statistical Perturbation Method Via Free Response**

This method, which combines perturbation theory with Monte Carlo simulation techniques, basically consists of a Monte Carlo simulation of the perturbation results. It is different from the Monte Carlo simulation described in the previous paragraph in that the modal properties of the free undamped mistuned system are obtained as perturbations of those of the tuned system (see Ryland II and Meirovitch, Courant and Hilbert, or Wei and Pierre). An advantage of this method is that instead of solving an $N$-DOF eigenvalue problem for each mistuning pattern, only $[(M/2) - 1]$ if $M$ is even, or $[(M - 1)/2]$ if $M$ is odd, 2-DOF eigenvalue problems need to be solved by this perturbation method (due to the double eigenvalues of the tuned system). Therefore, the computer costs in the second step are significantly reduced. Also, the method retains the accuracy of the Monte Carlo simulations, as second- or even higher-order perturbation schemes can be used.

**Hybrid Statistical Perturbation Method Via Forced Response**

This method is similar to the one described in the previous paragraph, but here the forced response amplitude of each component system is obtained directly as a perturbation of the forced response of the tuned system. Therefore, the computer costs in the second and third steps are reduced.

**Analytical Statistical Perturbation Method**

Here, perturbation methods are combined with multivariate statistical analysis (see Soong and Bogdanoff, Collins and Thomson, and the review paper by Ibrahim). From the first-order perturbation method (see Appendix), the steady-state displacement of each component system can be expressed as

$$q_i = q_{0i} + \delta q_i \quad i = 1, ..., N$$

where $q_{0i}$ is the displacement of the $i$th component system for the tuned assembly and $\delta q_i$ accounts for the displacement change due to mistuning.

For convenience, the steady-state displacements are written as

$$q_i = Q_0 e^{i \omega_t t}$$

$$q_{0i} = Q_{00} e^{i \omega_t t}$$

$$\delta q_i = \delta Q e^{i \omega_t t}$$

where $Q_0$, $Q_{00}$, and $\delta Q$ are time-independent complex amplitudes which depend on the system parameters and the excitation frequency. Note that $Q_{00}$ and $\delta Q$ are obtained in the Appendix. Note also that the vibrational amplitude of the $i$th component system, $q_i$, is the modulus of $Q_i$. Thus, the first-order approximation of the $i$th component system's amplitude becomes

$$|Q_i| = |Q_{0i} + \delta Q_i|$$

$$= \sqrt{|\text{Re}(Q_{0i}) + \text{Re}(\delta Q_i)|^2 + |\text{Im}(Q_{0i}) + \text{Im}(\delta Q_i)|^2}$$

$$= |Q_{0i}| + \frac{\text{Re}(Q_{0i})}{|Q_{0i}|} \text{Re}(\delta Q_i) + \frac{\text{Im}(Q_{0i})}{|Q_{0i}|} \text{Im}(\delta Q_i) + H.O.T.$$  

Therefore, the first-order variation of the amplitude due to mistuning is

$$\delta |Q_i| = \frac{\text{Re}(Q_{0i})}{|Q_{0i}|} \text{Re}(\delta Q_i) + \frac{\text{Im}(Q_{0i})}{|Q_{0i}|} \text{Im}(\delta Q_i)$$

and the mathematical expectation of the change of the $i$th component system's amplitude is

$$E(\delta |Q_i|) = \frac{\text{Re}(Q_{0i})}{|Q_{0i}|} E(\text{Re}(\delta Q_i)) + \frac{\text{Im}(Q_{0i})}{|Q_{0i}|} E(\text{Im}(\delta Q_i))$$

where the expectation of $\delta Q_i$ is, from Eq. (A14)

$$E(\delta Q_i) = E\left(\sum_{k=1}^{N} \sum_{l=1}^{N} a_{kl} \Delta f_i\right)$$

$$= \sum_{k=1}^{N} \sum_{l=1}^{N} a_{kl} E(\Delta f_i)$$

where $a_{kl}$ is derived in the Appendix. If the mean value of mistuning is zero, then $E(\delta Q_i) = 0$. Therefore, the expectation of each component system's amplitude is

$$E(|Q_i|) = |Q_{0i}| \quad i = 1, ..., N$$

Hence, to the first order, the mean amplitude of a given component system is the unperturbed one, that is, the tuned system's amplitude. Note, however, that this would not be true for the maximum amplitude throughout the assembly at a given excitation frequency, or for the largest amplitude experienced by the assembly at any excitation frequency, for which the mean is not equal to the tuned, or unperturbed, value.

The variance of the $i$th component system's amplitude is (for mistuning with zero mean)

$$\sigma^2_{Q_i} = E[(\delta |Q_i|)^2]$$

$$= \frac{1}{|Q_{0i}|^2} \sum_{k,l,m,n=1}^{N} [\text{Re}(Q_{0k}) \text{Re}(a_{lm}) + \text{Im}(Q_{0k}) \text{Im}(a_{lm})]$$

$$\times [\text{Re}(Q_{0l}) \text{Re}(a_{mn}) + \text{Im}(Q_{0l}) \text{Im}(a_{mn})] E(\Delta f_i \Delta f_m)$$

where $E(\Delta f_i \Delta f_m)$ defines the covariance matrix for the random variables $(\Delta f_i)_{i=1,...,N}$ of mean zero. The $\Delta f_i$'s can be considered to be independent (and therefore uncorrelated) and identically distributed variables, because the blades of a given assembly are selected individually from a large population. Therefore, under this assumption,

$$E(\Delta f_i \Delta f_m) = \sigma^2_{\Delta f} \delta_{im}$$

where $\sigma^2_{\Delta f}$ is the variance of mistuning. Hence, the variance of each component system's amplitude can be simplified as

$$\sigma^2_{Q_i} = \frac{\sigma^2_{\Delta f}}{|Q_{0i}|^2} \sum_{k=1}^{N} \sum_{l=1}^{N} [\text{Re}(Q_{0k}) \text{Re}(a_{kl}) + \text{Im}(Q_{0k}) \text{Im}(a_{kl})]^2$$

(13)
Equations (10) and (13) give the expectation and variance of each component system's response amplitude for independent (uncorrelated) blade mistuning variables with zero mean. In general, the variances of the blades' response amplitudes can be obtained easily from Eq. (11) for correlated mistuning variables of given covariance matrix $E(\Delta f/\Delta A)$. Also, it is worth noting that the probability density functions of the amplitudes can be derived from Eqs. (7) and (A14) directly. The advantage of this analytical approach is that it can be applied to systems with any number of blades and to non-Gaussian distributions of the component systems' modal properties.

Results and Discussion

Here the results obtained by the hybrid and analytical statistical perturbation methods are compared with those of Monte Carlo simulations; the limitations, accuracy, and computer costs of the various techniques are discussed. In the Monte Carlo simulations, samples of five hundred assemblies were generated to calculate the statistics of the forced response. Also, the effects of system parameters on the statistics of the forced response are investigated. For simplicity, the statistical distributions of the mistuning, $\Delta A$, are assumed to be identical and Gaussian with standard deviation $\sigma_A$ and zero mean.

Figure 2 displays the mean value and standard deviation (three-sigma bound) of the first component system's amplitude, in terms of excitation frequency, obtained by analytical statistical perturbation method (SPM) and by Monte Carlo simulation. The analytical SPM yields very accurate results for this set of parameters, and the computer cost was found to be only two-hundredths of that of the Monte Carlo simulation. Therefore, the analytical SPM is preferred here to generate the statistics of the individual component system's amplitudes. Unfortunately, not all the statistical properties of the forced response of the assembly can be calculated by the analytical SPM. For instance, the maximum amplitude throughout the assembly at a given excitation frequency can only be obtained by considering the forced response amplitude pattern for each mistuning configuration. Hence, the expected value of the maximum amplitude cannot be derived analytically. In this case, the hybrid SPM must be applied instead.

Figure 3 shows the expected value of the maximum amplitude in the frequency domain, by both Monte Carlo simulation and hybrid SPM via forced response. The hybrid SPM provides accurate results for this set of parameters without solving the eigenvalue problem and applying modal analysis. However, as mentioned by Sinha and Wei and Pierre, the accuracy of a perturbation method based on the forced response deteriorates as the ratio of mistuning strength to damping ratio increases. For instance, Fig. 4 is for the same parameters as Fig. 3, except that the damping ratio is decreased to 0.01. It is observed that the hybrid SPM via forced response significantly overpredicts the Monte Carlo result at excitation frequencies close to the resonant frequency. Therefore, other methods should be considered for such systems with low damping ratios. Here, the hybrid SPM via free response is adopted.

Figure 5 displays the expected value of the maximum amplitude in the frequency domain by Monte Carlo simulation and hybrid SPM via free response. It is shown that for the same set of parameters as in Fig. 4, the hybrid SPM via free response provides accurate results.
generates much more accurate results than the hybrid SPM via forced response for this low damping ratio. In fact, the accuracy of the hybrid SPM via free response is insensitive to the value of the damping ratio, which is a clear advantage of the method over a forced response formulation, especially for systems with low damping. Nevertheless, as discussed by Wei and Pierre, the accuracy of this method depends on the ratio of mistuning strength to coupling strength. For weak coupling, very significant errors may be generated by considering mistuning as a perturbation.

In this case, the modified perturbation method described by Wei and Pierre that treats the small coupling as the perturbation parameter should be used. However, if the ratio of mistuning to coupling is of the order of one (that is, in the intermediate cases), in the authors' opinion only Monte Carlo simulations can be applied effectively, as none of the perturbation schemes yields satisfactory results.

An objective of this paper is to carry out a parametric study of mistuning effects. Therefore, in the rest of this section, Monte Carlo simulations are performed to study the effects of the system parameters on the statistics of the forced response. However, results obtained by other approaches are also presented for comparison in some cases.

Figure 7 shows the expected value of the largest amplitude throughout the assembly at any excitation frequency vs the interblade coupling for various standard deviations of mistuning. It is observed that for the tuned system ($\xi = 0$) the largest amplitude decreases monotonically as the coupling increases. Nonetheless, for the mistuned systems, the largest amplitude increases to a maximum value as coupling increases from zero, then decreases as coupling further increases. Also,
the increase in largest amplitude due to mistuning is more significant for small values of the interblade coupling. Therefore, weakly coupled systems are more sensitive to mistuning than strongly coupled ones through a greater increase in largest amplitude.

The effect of the number of component systems (blades) on the mean largest amplitude ratio, which is defined as the ratio of the mistuned system's mean largest amplitude to the tuned system's largest amplitude, is shown in Fig. 8. It is observed that, globally, increasing the number of component systems increases the largest amplitude ratio; that is, the effect of mistuning increases as the number of blades increases. Also, it is found that the largest amplitude ratio is larger for weakly coupled systems than for strongly coupled ones; hence, weakly coupled systems are more sensitive to mistuning.

Figure 9 displays the mean largest amplitude vs the number of component systems for a strongly coupled mistuned system by various statistical methods. Again, one observes that the hybrid SPM via forced response significantly overpredicts the largest amplitudes at this low damping ratio, whereas the hybrid SPM via free response generates very accurate results.

Figure 10 displays the mean largest amplitude vs the mistuning standard deviation for various coupling values. It is shown that, for any nonzero coupling, the largest amplitude increases linearly as the mistuning standard deviation increases from 0 to approximately 0.1%, reaches a maximum value at a certain mistuning standard deviation, then decreases as the mistuning standard deviation further increases. This behavior can be

---

Fig. 9 Comparison of the mean largest amplitude by hybrid SPM via forced response, hybrid SPM via free response, and Monte Carlo simulation, for $f = 0.001$, $R = 1.0$, and various numbers of component systems.

Fig. 10 Mean largest amplitude throughout the assembly at any excitation frequency vs mistuning standard deviation, for $f = 0.001$ and various couplings.

Fig. 11 Mean largest amplitude throughout the assembly at any excitation frequency vs mistuning standard deviation, for $f = 0.01$ and $R = 1.0$.

Fig. 12 Mean largest amplitude throughout the assembly at any excitation frequency vs mistuning standard deviation, for $f = 0.1$ and $R = 1.0$. 

---
explained by the analytical SPM. It is known from the first-order result of Eq. (13) that the standard deviation of each component system's amplitude increases linearly as the standard deviation of mistuning increases. Therefore, we may expect as well the mean largest amplitude to increase linearly with the mistuning standard deviation. However, the accuracy of the analytical SPM depends on coupling, mistuning, and damping, the method being valid only for \( \sigma_{\eta}/R \leq O(1) \) and \( \sigma_{A}\Delta f/\xi \leq O(1) \). Hence, for \( \xi = 0.001 \), the analytical SPM is only valid for mistuning standard deviations approximately smaller than 0.1%, which explains why the linear increase of the mean largest amplitude only occurs in the mistuning range from 0 to 0.1%. Also note that the slopes of linear increase are different for various interblade couplings and that the slope appears larger for weak coupling, indicating again that weakly coupled systems are more sensitive than strongly coupled ones. From this figure, one can also see that the largest amplitude of a mistuned system does not necessarily decrease as the mistuning standard deviation decreases—an interesting result.

Figure 11 shows the mean largest amplitude vs the mistuning standard deviation for a larger damping ratio \( \xi = 0.01 \). It is observed that the range of linear increase of the largest amplitude is much greater than that in the previous figure, as it extends to mistuning values of up to 1%. Therefore, as the damping ratio increases, one can expect the range of mistuning strength that leads to a linear increase of the largest amplitude to increase. Figure 12 is for \( \xi = 0.1 \) and confirms this finding. Finally, it is observed in Figs. 11 and 12 that the hybrid SPM via free response provides very accurate results for the strongly coupled mistuned system; hence, this method can be applied to study the effects of mistuning standard deviation on the forced response of strongly coupled systems efficiently.

Conclusions

The following conclusions can be drawn from this study:

1) Various approaches were presented to calculate the statistics of the forced response of mistuned assemblies. Their accuracy depends on the relative magnitudes of coupling, mistuning, and damping. The analytical SPM and hybrid SPM via forced response are only valid for \( \sigma_{\eta}/R \leq O(1) \) and \( \sigma_{A}\Delta f/\xi \leq O(1) \). The hybrid SPM via free response can be applied to systems with \( \sigma_{\eta}/R \leq O(1) \) and any damping ratio. For systems with \( \sigma_{\eta}/R > O(1) \), that is, weakly coupled systems, only Monte Carlo simulation can be used.

2) In the design and manufacturing of bladed-disk assemblies, a decrease in mistuning strength (that is, a decrease of the manufacturing tolerances) does not necessarily lead to a decrease in the largest amplitude throughout the assembly. Only in the range \( \sigma_{\eta}/\xi \leq O(1) \) is it certain that reductions in manufacturing tolerances decrease the largest amplitude.

3) Weakly coupled systems are more sensitive to mistuning than strongly coupled ones through a greater increase in largest amplitude.

Appendix: Perturbation Method Via Forced Response of Tuned System

The forced response of the strongly coupled mistuned system is obtained as a perturbation of that of the corresponding tuned system. From the equation of motion

\[ \dot{q} + 2i\omega q + \omega_0^2 \mathbf{A} q = (1/m)F \]  \hspace{1cm} (A1)

let

\[ q = q_0 + \delta q \]  \hspace{1cm} (A2)

\[ \mathbf{A} = [\mathbf{A}_0] + [\delta \mathbf{A}^t] \]  \hspace{1cm} (A3)

where

\[ [\mathbf{A}_0] = \begin{bmatrix} 1 + 2R^2 & -R^2 & 0 & \cdots & 0 & -R^2 \\ -R^2 & 1 + 2R^2 & -R^2 & 0 & \cdots & 0 \\ 0 & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & \cdots & \cdots & \cdots & \cdots & \cdots \\ -R^2 & 0 & \cdots & 0 & \cdots & 1 + 2R^2 \end{bmatrix} \]  \hspace{1cm} (A4)

\[ [\delta \mathbf{A}^t] = \begin{bmatrix} \Delta f_1 & 0 & \cdots & 0 \\ 0 & \Delta f_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & \cdots & \Delta f_N \\ 0 & \cdots & 0 & 0 \end{bmatrix} \]  \hspace{1cm} (A5)

\( q_0 \) is the forced response of the tuned system, and \( \delta q \) accounts for the effect of mistuning.

Introducing Eqs. (A2) and (A3) into Eq. (A1) and equating the zeroth- and first-order terms, one obtains

\[ \delta q_0 + 2i\omega_0 \delta q_0 + \omega_0^2 \mathbf{A}_0 \delta q_0 = (1/m)F \]  \hspace{1cm} (A6)

\[ \delta q_0 + 2i\omega_0 \delta q_0 + \omega_0^2 \mathbf{A}_0 \delta q_0 = -\omega_0^2 [\delta \mathbf{A}^t] q_0 \]  \hspace{1cm} (A7)

The solution of Eq. (A6) is the forced response of the tuned system and can be obtained by modal analysis. The displacement of each component system is

\[ q_0 = Q_0 e^{i\omega t} \]  \hspace{1cm} (A8)

where

\[ Q_0 = \left( \frac{F e^{i\omega t}}{m \omega_0^2} \right) \frac{1}{\lambda_{n+1} - (\omega^2/\omega_0^2)} + j[2(\omega/\omega_0)] \]  \hspace{1cm} (A9)

and

\[ \lambda_{n+1} = 1 + 2R^2 \left( 1 - \cos \frac{2\pi n}{N} \right) \]  \hspace{1cm} (A10)

Equation (A7) can be decoupled by using the same modal matrix \( [P] \), whose columns are the eigenvectors of the tuned system \( U_0 \). Introducing \( \delta q = [P] \delta q \) into Eq. (A7), \( \delta q \) is obtained as

\[ \delta q_i = -\frac{T_i}{M_i} U_0^t \delta \mathbf{A}^t q_0 \]  \hspace{1cm} (A11)

where

\[ T_i = \frac{1}{[\lambda_{0i} - (\omega^2/\omega_0^2)] + j[2(\omega/\omega_0)]} \]  \hspace{1cm} (A12)

and \( M_i \) is the generalized mass (the square of the norm of \( U_0 \)). The first-order perturbation of each component system's displacement is obtained as

\[ \delta q_i = \sum_{k=1}^{N} P_{ik} \delta \eta_k \]  \hspace{1cm} (A13)

\[ = \delta Q_i e^{i\omega t} \]  \hspace{1cm} (A13)

where

\[ \delta Q_i = \sum_{k=1}^{N} \sum_{l=1}^{N} a_{kl} \Delta f_l \]  \hspace{1cm} (A14)
and

\[ a_{ik} = -\frac{T_k}{M_k} P_{ik} P_{kl} Q_{li} \]  \hspace{1cm} (A15)

where \( P_k \) and \( P_{ik} \) are elements of the modal matrix \([P]\).
