Received 12 March 2007; revised 23 March 2007; accepted 1 May 2007; published 6 June 2007.

The question of how much interplanetary shock (IP) events contribute to the geoeffectiveness of solar wind drivers is assessed through numerical experiments using the WINDMI model, a physics-based model of the solar wind-driven magnetosphere-ionosphere system. Analytic fits to solar wind input parameters \((B_{\text{IMF}}^2, u_{\text{sw}}, n_{\text{sw}})\) allowed shocks and associated shock-sheath plasma to be removed while leaving other features of the solar wind driver undisturbed. Percent changes in WINDMI-derived AL and Dst indices between runs with and without the observed shock and sheath signatures were taken as a measure of its relative contribution to the geoeffectiveness. The major magnetic storms during 15–24 April 2002 and 3–6 October 2000 were selected for this experiment. In both cases, the IP shock and sheath features contributed significantly to the geoeffectiveness of the solar wind driver. The magnetic field compressional jump is important to producing the changes in the AL during these two storm intervals.

1. Introduction

Interplanetary coronal mass ejections (ICMEs) are the interplanetary counterparts of coronal mass ejections (CMEs) at the Sun and are observed as enhanced magnetic structures in the solar wind lasting on the order of a day [Zurbuchen and Richardson, 2006]. Magnetic clouds (MCs) are a subclass of ICMEs with above-average strength magnetic fields which rotate smoothly through a large angle in a low beta plasma. Earth-directed Halo ICMEs often trigger geomagnetic storms such as the storms of 3–6 October 2000 and 15–24 April 2002. Interplanetary (IP) shocks and their resulting geomagnetic activity are usually caused by Halo ICMEs and their associated dynamic interaction regions, also known as “sheath regions” [Gosling et al., 1990]. These sheath regions are accelerated due to the momentum exchange from the fast CME, and they have enhanced densities and temperatures, since they have interacted with the shock. Solar wind velocity and magnetic field strength variation are correlated with the Dst index [Echer et al., 2004]. Shock effects on the aurora as measured by the FAST and DMSP satellites have been studied by Zhou et al. [2003]. It was found that there was a significant increase in electron precipitation the dawnside and duskside auroral oval zone after the shock/pressure pulse arrivals.

In order to understand the effect of IP shock/sheath events on geomagnetic activity, we use the WINDMI model which uses the solar wind driving dynamo voltage \(V_{\text{sw}}(t)\) derived from Advanced Composition Explorer (ACE) satellite data [Stone et al., 1998] as input and outputs a predicted westward auroral electrojet index (AL) and disturbance storm time index (Dst). We construct analytic solar wind plasma fields from ACE data for the 3–6 October 2000 event and derive an analytic input driving voltage. There are three basic phenomena that can lead to perturbations in the AL and Dst: 1) the CME, as defined by its composition or magnetic field configuration 2) the sheath compressed solar wind and 3) the shock itself. The role of the shock events are examined by removing both the shock and sheath features individually from each analytic plasma field: solar wind density, velocity, and interplanetary magnetic field (IMF) magnitude, then examining the change in the WINDMI output of AL and Dst.

2. WINDMI Model and ACE Data Methodology

We use the low dimensional WINDMI physics model of eight coupled ODE’s which conserves energy and charge in the solar-wind driven magnetosphere-ionosphere system [Horton and Doxas, 1998]. WINDMI outputs a predicted AL and Dst index and with the solar wind driving and ionospheric damping, even at constant solar wind dynamo voltage there is a rich spectrum of possible magnetosphere-ionosphere states.

Measurements of solar wind proton density, solar wind velocity and the IMF in GSM coordinates for the two geomagnetic storm periods are available from the ACE satellite. We use these quantities to derive the input dynamo driving voltage for the WINDMI model. The dynamo driving voltage \(V_{\text{sw}}(t)\) was calculated from the analytic data using a formula given by Siscoe et al. [2002] and Ober et al. [2003] for the coupling of the solar wind to the magnetopause using the solar wind dynamic pressure \(P_{\text{sw}}\) to determine the standoff distance. The formula for \(V_{\text{sw}}\) is given by:

\[
V_{\text{sw}}(kV) = 30.0(kV) + 57.6E_{\text{sw}}(mV/m)P_{\text{sw}}^{-1/6}(nPa)
\]

where \(E_{\text{sw}} = u_{\text{sw}}(B_x^2 + B_z^2)^{1/2}\sin(\theta/2)\) is the solar wind electric field with respect to the magnetosphere and the dynamic solar wind pressure \(P_{\text{sw}} = n_{\text{sw}}m_{p}\sqrt{kT_{\text{sw}}}/2\). Here \(m_p\) is the mass of a proton and only the proton density contribution has been included in \(n_{\text{sw}}\), even though the He can provide important contributions to the dynamic pressure of the plasma. The IMF clock angle \(\theta\) is given by \(\tan^{-1}(B_y/B_z)\) and \(u_{\text{sw}}\) is the solar wind flow velocity.
3. WINDMI Analysis

3.1. Period 15–24 April 2002

The AL index is derived from measurements of the horizontal component of the Earth’s magnetic field at stations located along the auroral oval in the Northern hemisphere [Rostoker, 1972]. The minimum values are taken to be the strongest activity of the westward auroral electrojet which is given by the region 1 field aligned current in the model, that closes in the nightside magnetosphere through the nightside auroral ionosphere. The Dst index is obtained from the measurement of the Earth’s magnetic field from observatories that are sufficiently distant from the auroral and equatorial electrojets [Sugiura, 1964]. The Dst index is compared to the output from the WINDMI model through the ring current energy $W_r$ using the Dessler-Parker-Schopke relation [Dessler and Parker, 1959].

[6] The $AL$ index is derived from measurements of the horizontal component of the Earth’s magnetic field at stations located along the auroral oval in the Northern hemisphere [Rostoker, 1972]. The minimum values are taken to be the strongest activity of the westward auroral electrojet which is given by the region 1 field aligned current in the model, that closes in the nightside magnetosphere through the nightside auroral ionosphere. The $DST$ index is obtained from the measurement of the Earth’s magnetic field from observatories that are sufficiently distant from the auroral and equatorial electrojets [Sugiura, 1964]. The $DST$ index is compared to the output from the WINDMI model through the ring current energy $W_r$, using the Dessler-Parker-Schopke relation [Dessler and Parker, 1959].

MAYS ET AL.: EFFECT OF IP SHOCKS ON AL AND DST

the ACE data were constructed using hyperbolic tangent functions. To study the role of the shock, the shock and sheath features are removed from the solar wind parameters \((u_{sw}, \eta_{sw}, B_z)\) individually while the ICME signature is kept. The shock and sheath features were removed from the data for the duration of the shock time up until before the associated ICME signatures. The methodology is to test the effect of each shock/sheath feature on the geospace response by removing the feature from the analytic fields while the other fields downstream remain unchanged.

Figure 2 shows how the model fields without the compressional jumps in the solar wind \(B_\perp = (B_z^2 + B_\parallel^2)^{1/2}\) are expressed for the April 2002 storm. The three curves in the top panel give the analytic model \(B_\perp\) profile with the first S1 (dashed line), second S2 (dotted line), and third S3 (solid line) shock/sheath features individually removed. The bottom panel shows the ACE magnetometer data for the \(B_\perp\) signal.

The solar wind driving voltage was calculated using the equation given in Section 2 with our analytic solar wind fields with and without the shock/sheath feature. Using this input solar wind driving voltage the model outputs were compared with and without the shock/sheath. In Figure 3 we compare WINDMI results from runs using both data and analytic input fields from which the shock/sheath feature has been removed from \(B_\perp\). The analytic shock field \(B_\perp\) without all three \(\delta B_\perp\) shock/sheath features (top panel of Figure 2), and ACE data for the \(u_{sw}\) and \(\eta_{sw}\) parameters were used to derive the input solar wind dynamo voltage shown in the top panel of Figure 3 (solid black line). WINDMI – AL and Dst results for this input are shown in the middle and bottom panels (dashed lines), respectively. When the \(\delta B_\perp\) shock/sheath feature is removed there is a significant decrease of 50% in the AL peaks – 1600 nT (17 April 1100 UT), –1824 nT and –1851 nT (19 April 1648 UT and 20 April 0451 UT), and –1297 nT (23 April 0741 UT) associated with these shocks. Model results for the Dst (bottom panel of Figure 3) show a –Dst decrease of 10–20% for roughly 12 hours after the first shock (17 April 1120 UT to 18 April 0700 UT) and a decrease of 20%–30% after the second shock (19 April 0900 UT to 20 April 0400 UT).

The jump \(\delta B_\perp\) has the most significant impact on the AL and Dst compared to the other parameters. Removing the shock/sheath features from \(u_{sw}\) produces a slight decrease of 15%, 25% and 10% in the first, second, and third AL peaks respectively. There is only a slight increase of 10% and 5% of the first and third AL peaks when the shock/sheath features are removed from \(n_{sw}\). The compressional jump \(\delta n_{sw}\) is only \(\sim 2 \text{ cm}^{-3}\) for the second shock event. When the shock/sheath features are removed from all of the plasma fields \((B_{IMF}^z, u_{sw}, n_{sw})\) the –AL peaks decrease by a similar amount as when the \(\delta B_\perp\) features are removed only. The jump \(\delta B_\perp\) has the most impact on producing the three –AL peaks during this storm. The second shock/sheath feature is removed there is a significant decrease of 50% in the AL peaks when the shock/sheath feature is removed there is a

3.2. Period 3–6 October 2000

An unusual feature of the 3–6 October 2000 solar wind driver was the appearance of a fast forward shock advancing into a preceding magnetic cloud [Wang et al., 2003]. ACE data shows a magnetic cloud from 3 October at 1018 UT through 5 October at 0534 UT lasting about 42 hours. The signature of the magnetic cloud can be seen from the sinusoid-like waveforms of \(B_{IMF}^z\) and \(B_{IMF}^\perp\) as the IMF clock angle changes linearly through an angle of 180° during this period. The fast forward shock occurs at 0240 UT on 5 October with a calculated shock speed of 534 km/s and compression ratio of 2.3. There are jumps in the velocity from 364 km/s to 460 km/s, in the proton...
density from 7 cm$^{-3}$ to 16 cm$^{-3}$, and in perpendicular magnetic field from 7 nT to 16 nT across the shock front. [14] The AL data shows a first large spike with a peak of $-1938$ nT occurring at 0651 UT on 5 October 2000. A second, larger spike of approximately $-2790$ nT in the AL index occurs at 1210 UT on 5 October 2000 initiated by a strong southward IMF excursion detected at ACE about an hour earlier. Periodic substorms occur in the interval of 0600–1200 UT 4 October and have been identified as sawtooth oscillations by Huang et al. [2003] and Reeves et al. [2003]. The Dst minimum of $-180$ nT is reached on 5 October slightly after the strong southward IMF surge. Consistent with April 2002 analysis, when the shock/sheath feature is removed from $B_z$, the first AL peak of $-1938$ nT occurring at 0720 UT 5 October 2000 decreased by $\sim50\%$. There is also a decrease of $-Dst$ by $\sim25\%$ after the shock arrival time. The AL peak only decreases by 10\% when the shock/sheath is removed from $u_{sw}$ and the removal of the feature from $n_{sw}$ produces an increase of 10\% in the AL peak. Again, when the shock is dropped from all three plasma fields the result is similar to removing the $\delta B_{\perp}$ shock only. These results demonstrate that the first large AL peak was triggered by the shock/sheath front, and most strongly by the $\delta B_{\perp}$ jump.

4. Summary

[15] The question of how much IP shock/sheath events contribute to the geoeffectiveness of solar wind drivers was examined based on a series of numerical experiments with WINDMI using observed solar wind drivers for the 15–24 April 2002 and 3–6 October 2000 events, each of which had interesting shock features. In these experiments, analytic fits to solar wind input parameters ($B_{\perp}^{\text{IMF}}, u_{sw}$, and $n_{sw}$) allowed shock/sheath features to be easily removed while leaving other features of the solar wind driver undisturbed. Percent changes in WINDMI-derived AL and Dst indices between runs with and without the observed shock/sheath feature were taken as a measure of its relative contribution to the geoeffectiveness. The main results of this study are the following:

1. The interplanetary shock/sheath events during these storm periods are strongly related to storm and substorm geomagnetic activity predicted by the WINDMI model.

2. The $\delta B_{\perp}$ jumps at the shocks/sheath have a strong impact on the three AL peaks during the April 2002 storm. During the October 2000 storm the first large AL spike was triggered by the shock/sheath feature in $B_z$. The Siscoe et al. [2002] solar wind dynamo variance includes contributions from the number density, clock angle, and $B_{\perp}^{\text{IMF}}$ ($B_{\perp}^{\text{IMF}} = (B_z^2 + B_y^2)^{1/2}$) which are not included in the rectified $u_{sw}$ $B_z$ $L_y$ dynamo voltage more typically used. This is particularly important for the April 2002 shocks in which, for example, the second shock had a $\delta B_{\perp}^{\text{IMF}} < 1$ nT while $\delta B_{\perp}^{\text{IMF}} \sim 10$ nT therefore producing dynamo voltage $V_{sw} = 600$ kV while the rectified voltage is only 200 kV.

3. The solar wind-magnetosphere coupling dynamics is most sensitive to variations in the solar wind velocity and interplanetary magnetic field. This can be seen from the equation for the input Siscoe solar wind dynamo voltage where the input $V_{sw} \propto u_{sw}^{2/3} n_{sw}^{-1/6} B_{\perp}^{1/2}$ so it is expected that the removal of the shock compressional feature in the velocity and magnetic field parameters to decrease the driving voltage $V_{sw}$ and in the number density to increase $V_{sw}$. During these storms the magnetic field component $B_z$ has a $1.5–3$ times increase across the shock front while the velocity does not increase by more than 1.5 times. The jump in the number density can be as high as 4 times the upstream value, however, the $n_{sw}$ dependence in the calculated $V_{sw}$ hides this effect. Also shock features in the velocity and number density increase the solar wind dynamic pressure which causes the magnetopause to move close to the Earth and produces stronger coupling.
