Abstract. It is demonstrated that large-amplitude low-frequency waves (LFW) can generate lower hybrid waves (LHW) in the auroral zone and ring current region. The LHW could then heat the ions. The ion energization due to the LHW may be comparable with that produced by the ponderomotive force of the LFW.

Introduction

Wave-particle interactions are of crucial importance to magnetospheric and ionospheric plasma behavior. Space plasmas support a wide variety of large-amplitude waves. For example, in the region of overlap between the ring current and the outer plasmasphere numerous observations have shown large-amplitude waves with frequencies below the local proton cyclotron frequency [McPherron et al., 1972; Taylor et al., 1975; Kintner and Burnett, 1977; Young et al., 1981; Perraut, 1982; Roux et al., 1982; Fraser, 1985; Labelle et al., 1988]. These observations indicate the presence of waves with both left-hand polarization (Alfvén waves), and right-hand polarization (fast magnetosonic waves). It is known that the generation of ion cyclotron waves may occur as a result of an instability in the high energy anisotropic component of the ring current during interaction with the plasmasphere [Cornwall, 1965, 1966; Kennel and Petschek, 1966; Liemohn, 1967; McKeen et al., 1994]. In the auroral region, simultaneous occurrences of upward-flowing ions and field-aligned electrons have been observed by the Viking satellite. The occurrence is strongly correlated with large amplitude low-frequency fluctuations of the electric field [Hultqvist et al., 1988; Lundin et al., 1990]. Large-amplitude shear Alfvén waves were also observed by sounding rockets [Boehm et al., 1990] in the auroral ionosphere.

When such low-frequency waves (LFW) propagate in a plasma, a ponderomotive force is produced which may lead to significant effects at the plasma. Boehm et al. [1990] suggested that this ponderomotive force can be the cause of significant density perturbations. Allan [1993] has investigated mass transport caused by the ponderomotive force of hydrodynamic waves in the middle magnetosphere. It was also suggested that significant plasma energization could occur in these regions. Li and Temerin [1993] have studied the ion energization by the ponderomotive force of large-amplitude Alfvén waves (E > 100 mV/m; ω < ωc) in the auroral zone.

It is well known [eg., Akhiezer et al., 1975] that in the field of a LFW, electrons and ions move with different velocities. A significant ion-electron relative velocity may lead to a current instability which may produce, for example, lower hybrid waves (LHW). The purpose of this paper is to consider the possibility of such LHW generation by large-amplitude LFW in a space plasma and to compare the effects of LHW and the ponderomotive force in the processes of heating and acceleration in the plasma.

Below we discuss the possibility of LHW generation in the ring current region and in the auroral zone and mechanisms for LH instability saturation. The LHW power level and the resulting plasma energization due to the LH turbulence are estimated. The plasma energization due to LH turbulence is compared with that due to the ponderomotive force.

Analysis

Lower Hybrid Current Instability Due to Low-Frequency Waves

If a plasma is subjected to a variable electric field \( \vec{E} \) (for instance, the electric field of an Alfvén or fast magnetosonic wave, which has a component at a right angle to the external magnetic field \( \vec{B}_0 \)), the electrons and ions will acquire different velocities \( \vec{u}_e \) and \( \vec{u}_i \) under the action of that field. If the frequency \( \omega_o \) of the field is considerably lower than the electron cyclotron frequency, the electron and ion velocities will be given by [eg., Akhiezer et al., 1975]:

\[
\vec{u}_e = \frac{e}{m_e} \frac{\vec{E} \times \hat{b}}{B_0} \left[ 1 - \frac{e(\vec{E} \cdot \hat{b}) \hat{b}}{m_e \omega_o} \right]
\]

\[
\vec{u}_i = \frac{e}{m_i} \left( \frac{1}{\omega_B^2 - \omega_o^2} \right) \left( \omega_B (\vec{E} \times \hat{b}) + i \omega_o (\vec{E} \times (\vec{E} \times \hat{b})) \right)
\]

where \( \hat{b} \) is a unit vector in the direction of the external mag-
netic field and $\omega_{Bi}$ is the ion cyclotron frequency. In a low-frequency field the component of the parallel electric field is small, and the perpendicular drift velocities of the electrons and ions may be comparable to, or even larger than, the parallel electron velocity. We will restrict ourselves to the case when the parallel electric field and parallel electron velocity may be neglected.

In a coordinate system where the magnetic field $\vec{B}_0$ is parallel to the $z$ axis and a low-frequency ($\omega_0 << \omega_{Bi}$) electric field $\vec{E} = E_0 e^{-i\omega_0 t}$ is parallel to the $x$ axis, the real part of the relative velocity of the ions with respect to the electrons, $\vec{u} = \vec{u}_i - \vec{u}_e$, is:

$$Re u_x = -\frac{e\omega_0}{m_i\omega_{Bi}} E_0 \sin \omega_0 t. \quad (2)$$

Here we took into account the inequality $\omega_0 << \omega_{Bi}$ and neglected terms proportional to $m_0/m_i$.

For some cases, the relative velocity (2) can be larger than the ion thermal velocity $v_{Ti} = \sqrt{T_i/m_i}$. It may lead to the occurrence of the current instability even for the relatively small electric field of low-frequency oscillations. The inequality $u > v_{Ti}$ leads to:

$$\frac{E^2}{8\pi nT} \geq \frac{\omega_{Bi}^4}{\omega_0^2 \omega_{pe}^2}, \quad (3)$$

where $n$ and $T$ are density and temperature of the plasma, respectively; $\omega_{pe}$ is the ion plasma frequency.

For plasmas in the auroral region and near the plasmapause, condition (3) requires a LFW electric field greater than that observed on average, but one that is not uncommon. Inequality (3) appears to be satisfied in observations reported by Taylor et al. [1975] and Young et al. [1981] for the ring current region ($L=4-5$). It was found that $B^2/B_0^2 = 5 \times 10^{-4}$ ($B$ is the magnetic field of the Alfvén wave, $B_0$ is the ambient field), $\omega_0=1-3 \, s^{-1}$, $n_{cold}=30 \, cm^{-3}$, $n_{hot}=1 \, cm^{-3}$, $T_{cold}=0.5 \, eV$, $T_{hot}=(5-50) \, keV$. If the plasma is isothermal, $T_e = T_i$, and $u = 1.3v_{Ti}$, then the flux instability for LH oscillations occurs [Akhiizer et al., 1975]. So, inequality (3) is satisfied if $B^2/B_0^2 \geq 10^{-4}$, and therefore for this plasma. For the auroral acceleration region, the example considered by Li and Temerin [1993], in which $E=200 \, mV/m; \omega_0=6 \, s^{-1}; n_{cold}=4 \, cm^{-3}; n_{hot}=6 \, cm^{-3}; T_i=0.5 \, eV$, satisfies inequality (3) above 4500 km. The ion-sound instability occurs if $u > 2v_{Ti}$ and the existence of the ion-sound oscillation is possible ($T_e \geq T_i$). In a plasma with hot ions and cold electrons, $T_e \ll T_i$, and $u \leq v_{Ti}$, the relative motion of ions with respect to electrons across the magnetic field can lead to the excitation of electron sound waves [eg. Akhiizer et al., 1975]. Also, depending on $u, \omega_0$, and the plasma parameters, the excitation of other types of plasma oscillations is possible, even for $u < v_{Ti}$ [Gamayunov et al., 1993].

Consider an isothermal plasma $T_e = T_i$, for which low-frequency oscillations lead to the inequality $v_{Ti} \ll u < v_{Ti}$. In this case, there occurs an aperiodic flux instability of LH oscillations [eg. Akhiizer et al., 1975]:

$$Re \omega - Im \omega = \frac{\omega_{pe} \omega_{Be}}{\sqrt{\omega_{pe}^2 + \omega_{Be}^2}} = \omega_{LH}. \quad (4)$$

Estimation of Lower Hybrid Energy Density

Let us estimate the energy density of the LH oscillations. Generation of these waves takes place in the region of angles where $\cos^2 \theta - m_e/m_i$ ( $\theta$ is the angle between the wave vector of LH oscillations $k$ and the magnetic field $\vec{B}_0$). The main nonlinear process which leads to saturation of the LH instability for such angles is induced scattering of LH oscillations from electrons. The characteristic damping rate for the induced scattering is [Musher et al., 1978]:

$$\gamma_e = \frac{\omega_{pe} \omega_{Be}}{\omega_{pe}^2 + \omega_{Be}^2} \frac{W}{\omega_{LH} nT} \quad (5)$$

where $W$ is the energy density of the LH oscillations and $\omega_{Be}$ is the electron cyclotron frequency.

From the balance of the generation rate (4) and the damping rate (5) (i.e., the stationary condition) we can estimate the energy density of quasi-stable LHW as:

$$W = \frac{nT m_i}{nT} \left[1 + \frac{\omega_{Be}^2}{\omega_{pe}^2} \right] \left( R^2 - \frac{\omega_{Be}^2}{\omega_{pe}^2} \right) \left( \omega_{Be} > \omega_{pe} \right) \quad (6)$$

At these energy densities the plasma should not be considered as weakly turbulent, since the condition

$$\frac{W}{nT} > \frac{m_i}{nT} \frac{v_{Ti}^2}{m_i} \left( \frac{\omega_{Be}}{\omega_{pe}} \right) \quad (7)$$

exists, and at this level, there occurs a modulation instability of LH which leads to the formation of cavities [Musher and Surman, 1975]. Here, $k$ is the characteristic value of the wave number from the spectrum of these waves. Using (4) and $k = \omega_{LH} / u$, we can present condition (7) in the form:

$$\frac{W}{nT} > \frac{m_i}{nT} \frac{v_{Ti}^2}{m_i} \left( \frac{\omega_{Be}}{\omega_{pe}} \right) \quad (8)$$

Taking into account the inequality $u > v_{Ti}$, it is clear from (6) and (8) that condition (7) is fulfilled. Let us evaluate the velocity of the energy deposition $Q$ into the plasma due to the LH turbulence. In this case, according to Musher et al. [1986], we have:

$$Q = \frac{nT m_i}{nT} \left[1 + \frac{\omega_{Be}^2}{\omega_{pe}^2} \right] \left( R^2 - \frac{\omega_{Be}^2}{\omega_{pe}^2} \right) \left( \omega_{Be} > \omega_{pe} \right) \quad (9)$$

This means that excitation of LHW by a LFW can lead to the appearance of an additional channel of energy transfer from, for example, Alfvén or fast magnetosonic waves, to the particles. This process can influence the formation of the plasma distribution function through particle acceleration in its "tail" during the collapse. This influences the transport processes, since additional collisions of particles with cavities will occur [Musher et al., 1986]. As is well known, the strong LH turbulence contributes to transverse ion heating [Chang and Coppi, 1981].

The process described above can develop in the following way. The plasma temperature will increase until the thermal ion speed reaches the threshold of excitation for LHW. When $u = v_{Ti}$, relation (3) will not be satisfied anymore and the gen-
eration of the current instability will be destroyed. At that
time the ion energy is approximately
\[ E_{\text{LH}} = \frac{m_i \varepsilon^2}{2} = \frac{\omega_{pe}^2}{\omega_{th}^2} \frac{E_0^2}{16 \pi n} \]  
(10)

Expression (9) allows us to estimate the effective frequency of
collisions, \( \nu_{\text{eff}} \), of plasma particles with LH cavities. If
we introduce \( \nu_{\text{eff}} \) with the expression \( Q = \nu_{\text{eff}} n \tau \) and compare
it with (9), we obtain:
\[ \nu_{\text{eff}} = \nu_{\text{LH}} \frac{m_e}{m_i} \left(1 + \frac{\omega_{pe}^2}{\omega_{th}^2}\right) \]  
(11)

This frequency may be greater than the collisional frequency
for ions in the magnetosphere. For example, for the ring cur-
current region (\( L=4 \)) \( \nu = 3 \times 10^{-4} \text{s}^{-1} \); \( \omega_{\text{LH}} = 250 \text{ s}^{-1} \); and \( \nu_{\text{eff}} = 0.1 \text{ s}^{-1} \).

In a multicomponent plasma where species have different
Drift velocities, the ion LH caviton collisions may lead to an
effective frictional force. Thus, the LH turbulence, which
occurs in a field of low-frequency oscillations, will influence
the plasma energy density and momentum.

Comparison of Lower Hybrid Turbulence and
Ponderomotive Force Energization

Let us compare the effects of LH turbulence and the pon-
deromotive force on the processes of acceleration and heating
in the plasma. The expression for the ponderomotive force
\( \tilde{F}_p \), which affects particles in a cold, magnetized plasma can be
written [Li and Temerin, 1993]:
\[ \tilde{F}_p = \frac{e^2}{4m} \nu \left( \frac{E_0^2}{\omega_{th}^2} - \frac{E_0^2}{\omega_{pe}^2} \right) \]  
(12)

For the ions, in the case \( \omega_{th}^2 >> \omega_{pe}^2 \), we have:
\[ \tilde{F}_p = \frac{e^2}{4m_i} \nu \left( \frac{E_0^2}{\omega_{th}^2} \right) \]  
(13)

Let us now compare the effects of the energization of the
plasma due to the ponderomotive force and LH turbulence. The
ponderomotive force is a potential force. In this case, the
energy gain over length \( \ell \) is simply determined by the poten-
tial drop \( \Psi_p = - \left( e^2 E_0^2 / (4m_i \omega_{th}^2) \right) \) on this scale. If the char-
acteristic length of the potential drop is \( L \), and we neglect the
initial energy of the particle, the obtained ion energy can be
written as:
\[ \varepsilon_p = \frac{e^2 E_0^2 \ell}{4m_i \omega_{th}^2 L} = \frac{\omega_{th}^2}{\omega_{pe}^2} \frac{E_0^2 \ell}{16 \pi n L} \]  
(14)

Therefore, the ion energization depends on the magnetic field,
the scale length of the energy density of the low-frequency
oscillation, and the length of the region of acceleration.

The heating due to the LH turbulence (10) is determined by
the relation between the frequency of the LH oscillation and
the cyclotron frequency of the ions and will take place in all
regions where LHW exist and where the condition of the gen-
eration of LH oscillations, \( \omega_{\text{LH}} >> \nu_{\text{T}} \), is satisfied.

The comparison of \( \varepsilon_p \) and \( E_{\text{LH}} \) shows that the effective-
ness of these processes depends on the relation between the
parameters \( \Omega/L \) and \( \omega_{pe}^2 / \omega_{th}^2 \). The contribution of the LH tur-
bulence to the ion heating will be the predominant process
during the first stages of the plasma acceleration until \( \ell << L \)
and \( \Omega / \omega_{pe} \omega_{th} \).

Discussion and Conclusions

Let us examine some of the above-mentioned relations for
the region of the ring current and estimate the time scale for
energy deposition from Alfvén oscillations, \( (\gamma_p^A)^{-1} \), due to
the generation of the LH oscillation current. In this region,
large-amplitude Alfvén waves generated by anisotropic pro-
tons were observed by Taylor et al. [1975] and Young et al.
[1981]. Due to exponentially weak Alfvén wave damping and
regularity of the magnetic field in the equator region along
magnetic lines, the ponderomotive potential drop
\( \Psi_p - E_0^2 / B_0^2 \) and the ion energy change under the influence
of the ponderomotive force (17) are negligible. However, as
discussed by Gamayunov et al. [1992], the excitation of LH
turbulence by Alfvén waves can play an important role in the
saturation of the Alfvén oscillations, limiting their energy
density level. For steady-state conditions, the following
relation can be used:
\[ \gamma_p^A W_A = \gamma_p W \]
where \( \gamma_p^A \) is the linear growth rate of Alfvén wave; and \( W_A \)
and \( W \) are the energy densities for Alfvén and LHW, respec-
tively. The linear growth rate of Alfvén wave generation by
anisotropic protons of the ring current during the cyclotron
interaction has the form [Kennel and Petschek, 1965]:
\[ \gamma_p^A = \frac{A \sqrt{\pi}}{2} \mu \frac{\omega_{th}^2}{k_i V_{T_i} \omega_A} \]

where \( A \) is the temperature anisotropy of the ring current pro-
tons and \( \mu \) is the relative concentration of anisotropic par-
ticles. For \( \mu \sim 10^{-2} \) and \( V_A / V_{T_i} \sim 10^{-1} \) (\( V_{T_i} \) is the thermal
speed of hot protons), we have \( \gamma_p^A \sim 10^{-1} \omega_A \). Using (4)
and (6) for \( L=5 \), \( \rho_{hot} = 1 \text{ cm}^3 \), \( \rho_{cold} = 10^2 \text{ cm}^3 \), \( T_{hot} = 2.5 \times 10^4 \text{ eV} \)
and \( T_{cold} = 0.5 \text{ eV} \) we can estimate \( W_A = 2 \pi B_0^2 \).
The obtained result is in good agreement with experimental data [Taylor
et al., 1975; Young et al., 1981]: \( B^2 / B_0^2 \sim 10^{-4} \) (\( B \) is the magnetic
field of the wave, \( B_0 \) is the ambient field).

Thus, the large amplitude Alfvén waves can generate LH
oscillations in the ring current region. This process may also
limit the growth of Alfvén oscillations here. LHW have
apparently been observed by Dynamics Explorer 1 near the
geomagnetic equator [Olsen et al., 1987]. Evaluations that
could be made on the basis of the data of Olsen indicate a
fairly high level of energy density of the oscillations, \( W/nT \sim
10^{-6} \text{ to } 10^{-7} \) (\( W \) is the energy density of LHW; \( n \) and \( T \) are the
density and temperature of the plasma).

From the above discussion, it follows that in the presence
of the large-amplitude LFW
\[ \frac{E_0^2}{8\pi n T} \geq \frac{\omega_{th}^2}{\omega_{pe}^2} \]
LHW may be generated. Such conditions are fulfilled in some
cases in the auroral zone and in the ring current region \( L<5 \).
The LHW contribute to ion and electron heating. The ion
energy due to this process will approach
This energy is comparable with energization due to the ponderomotive force of the LFW. As may be found from (6), the energy density of the LHW electric field is of order $|E|^2/(\pi\eta Tc^2) - V_s^2/c^2$ ($V_s$ is the Alfvén velocity). The LH turbulence generated by Alfvén waves in the ring current region may lead to saturation of Alfvén oscillations (Gamayunov et al., 1992).

So it may be supposed that LHW excitation may lead to the appearance of an additional channel of energy transfer from LFW to the particles. Such energy transfer may influence the formation of the distribution functions of the plasma species (transverse heating, particle acceleration within the "tails" of the distribution functions).

Analysis of the effects of the pondermotive force of large-amplitude LFW must take into account the possibility of LHW generation and effects connected with this.

It may be concluded from the expressions of (2) and (3) that the relative ion velocity in the electric field of LFW increases with ion mass. The reason is that the relative velocity of the various ions is caused by the different inertia of ions and electrons in the oscillating electric field. The magnetosphere and ionosphere have multicomponent plasmas, and it can be supposed that LHW can be excited by LFW with amplitudes less than that needed for a proton-electron plasma. The minimum energy density of the LFW electric field can be estimated for our case as $\left(\frac{m_i}{m_e}\right)^2$ times less than for a purely hydrogen plasma, where $m_i$ and $m_e$ are the masses of hydrogen and oxygen, respectively.

Let us note, in conclusion, that the present results are of a qualitative nature. To clarify the authenticity of the suggested physical mechanisms, a detailed quantitative description is required as well as a detailed comparison of theoretical results with experimental data.
